CLINICAL DIAGNOSIS OF WHOOPING-COUGH WITHOUT THE WHOOP

BY

P. R. EVANS, B.Sc., M.B., CH.B.

Whooping-cough is a socially important disease, killing more children in this country than scarlet fever and diphtheria together.¹ Its diagnosis, like that of pregnancy, is difficult in the early stages, and obvious to the household in the late. It is made obvious by the onset of whooping. Earlier diagnosis is important, affecting as it does the treatment of the child, the prevention of yet further spread of the infection, and the reputation of the practitioner.

Two laboratory methods may be of great help in early diagnosis: (1) an absolute and relative lymphocytosis is usually present (Kolmer,² Crombie³), and (2) the bacillus of Bordet and Gengou may be isolated in the catarrhal stage of the malady. The former takes too much time in a busy hospital out-patient or general practice; the latter, the efficiency of which has been shown by Madsen in Denmark, and Gardner and Leslie⁴ in this country, should be of considerable value, but facilities for its performance are few and far between. Agglutinins are fugitive and inconstant in the blood; complement fixation develops too late; skin tests are controversial; while the discovery of specific radiological changes is a skilled and expensive procedure.⁵ So one is, in the end, generally driven back to clinical methods.

Of 156 cases in which there was finally no doubt of the diagnosis, personally seen at the Hospital for Sick Children, Great Ormond Street, from May to the middle of October, 1934, fifty-six had not whooped at their first appearance. The account of the symptoms given here results from the study of these latter cases. For the sake of convenience the number of children having any symptom is expressed as a percentage of those in whom the particular feature was investigated, despite the false impression of precision it gives in a small series. The average duration of the cough in the cases considered was just under two and a half weeks; all except one were in the paroxysmal stage.

Symptomatology

Whooping-cough may appear at any season of the year, but is probably commonest in the spring and autumn. It starts like a common cold, with catarrh of the nose and eyes, and slight fever; at this stage it cannot be diagnosed clinically. But a common cold dies away, the catarrh of pertussis persists a while, and a short, dry cough appears. If there has been contact with a case one's suspicions are aroused, as one finds the cough becoming increasingly severe, and, to a more or less extent, paroxysmal.

Age and History of Contact.—The age of the child is significant. In Luttinger's 10,000 cases 80 per cent. were less than 6 years old. The malady may appear at any age, but is definitely uncommon below 3 months or over 7 years. In this series the ages were:

Under 1 year	15 per cent.	5-6 years	18 per cent.
1-2 years	9 "	6-7 "	4 "
2-3 "	17 "	7-8 "	4 "
3-4 "	15 "	8-9 "	4 "
4-5 "	13 "	9-10 "	2 "

The large proportion of cases less than 1 year old is to be expected, for many babies do not whoop throughout the whole of the attack. The slight difference in incidence between the sexes is of no value in any one case. A history of contact with another case is often helpful, for its frequency naturally varies in different groups of cases. In this group it reached the high figure of 74 per cent.

The Cough.—This is paroxysmal, increasing crescendo to the great distress of the child and the mother, who notices that the face is red and puffy (81 per cent.), particularly under the eyes. Before whooping actually occurs the child may be said to "catch its breath" after the paroxysm. The cough is hard, and those who witness the attack say that the child "cannot bring anything up." Nevertheless, careful inquiry usually elicits the fact that some sputum is coughed up and ejected by the child, with or without the aid of the mother's finger (70 per cent.). This is a valuable sign—a young child who coughs and spits has whooping-cough or frank bronchiectasis. It is of more frequent occurrence in older children than younger; the average age of those who produced sputum was 4.3 years, compared with 3.4 years for the whole series. It does, nevertheless, occur in babies as young as 3 months. The sputum is whitish in the early stages; in later cases with bronchitis it may be yellow. A classical feature of pertussis is that the violence of the cough excites vomiting. This is commoner in later cases, but often occurs before whooping (56 per cent.). It occurs at any age, the youngest in this series being 3 months and the oldest 9 years. It is an important cause of the wasting which is obvious in severe cases, but this is not of early diagnostic significance. Typically, the cough is worse at night (77 per cent.), and is a common temporary cause of insomnia in children and their parents. In a few cases (19 per cent.) it is equally bad in the day and in the night; in fewer still (4 per cent.) it is most troublesome in the daytime.

Other Symptoms.—**Appetite.** This is usually (69 per cent.) retained at first (though the onset of most acute illnesses in children is accompanied by anorexia), but it may be lost as the disease progresses. **Haemorrhage.** This is a feature of few cases (under 20 per cent.). Occasionally there may be a visible subconjunctival haemorrhage, but the two common types are epistaxis and haemoptysis. The latter is rather more common. About a third of these cases have frenal ulceration, and the blood probably comes from the ulcer. Others have not, but there seems no reason to assume that the lung is the source; the small necrotic lesion in the larynx is probably responsible. On examination of the child one may be struck at once by the well-marked puffiness of the face (7 per cent.) even between paroxysms. But most cases do not present this till later.

The Frenal Ulcer.—The search for this (18 per cent.) should never be omitted. It is simple, and may clinch a doubtful diagnosis. It occurs in no other acute illness, and is thus practically pathognomonic. It is small, between 1 and 3 mm. long, oval, with its long axis in the line of the frenum; grey-white in colour; painful at first, later painless; it occurs at any age, and not only, as is usually stated, in young children whose incisor teeth are particularly sharp. I have seen it in a baby of 10 weeks and in a girl 9 years old. It is presumably caused by the fretting of the frenum on the lower central incisor teeth when the tongue is protruded in a paroxysm; occasionally there is no ulcer, but a small, oval, grey-white area of raised epithelium.

Throat and Lungs.—Examination of the throat is of itself not helpful. Some faucial congestion is common, and many town children have inflamed tonsils. But it is useful in a doubtful case, for when the history is indefinite one may often elicit an unmistakable paroxysm by touching a tonsil with the spatula (17 per cent.). Absence of pulmonary signs which might explain the cough is a frequent (74 per cent.) and useful finding in these early cases. Signs of bronchitis are usually limited to an occasional rhonchus, but the presence of many rhonchi and rales does not invalidate the diagnosis.

Summary

To recapitulate. The diagnosis may be made on the history, in a child probably less than 7 years old who has not previously had whooping-cough, of a common cold that did not clear up but progressed steadily with the development of a dry cough, becoming paroxysmal; and at least one of the following points: a history of contact with a definite case; absence of any obvious cause of cough in the throat and lungs; a cough worse during the night than the day; sputum coughed up and not all swallowed; cough followed by vomiting; frenal ulceration; an unmistakable paroxysm during examination. Confirmatory points are: a red and puffy face; haemoptysis, epistaxis, or subconjunctival haemorrhage; absence of anorexia.

Skill is not required to elicit these points, and the difficulty lies in correct summing up of the relative importance of their presence or absence. It is hoped that the figures and the rather disjointed remarks in this paper will help in the diagnosis of pertussis before the onset of whooping betrays the condition to all who have ears to hear.

Clinical Memoranda

HEREDITARY SYNDACTYLISM AND POLY-
DACTYLISM DESCRIPTIVE OF RECENT
ADDITIONS TO PEDIGREE

(With Special Plate)

In 1915 I published in the *Journal of Genetics* a pedigree and description of a family showing syndactylism and polydactylism transmitted through five generations. This article, with a description of further additions to the family up to August, 1926, was republished in *Observations on Human Heredity* in 1928.

Altogether sixty-four descendants of the original affected parent, who was born about the beginning of the nineteenth century, were shown on the pedigree chart, and of these twenty-seven were affected, thirty-three unaffected, and four doubtful. During the past eight years—that is, since August, 1926—thirteen additions from five families have been made to the Warrington branch of the original family. Eight of these have come from two families of unaffected parents, five from three families with one affected parent. As the condition does not appear in families with unaffected parents, the eight do not require consideration here; but of the five an only child, a male, is normal—the offspring of affected IV 6 (male), and one female is normal, the offspring of affected IV 8 (female), now dead.

In the pedigree chart published it will be seen that IV 8 had three other unaffected children, so that she had altogether four unaffected offspring, although she herself had both syndactyly and polydactyly in the right hand and both feet. These families of IV 6 and IV 8 are small, and it is likely that had they been more numerous, affected offspring would have appeared. Their mother—affected III 2—had seventeen children, of whom eight were affected.

But the most interesting are the three offspring of IV 16 (female), who are all markedly affected in the hands, and to a slighter degree in the feet. It is remarkable that this should be so, because the mother herself, IV 16, had the slightest abnormality of all the affected members of the family. In her case the abnormality was limited to webbing of the third and fourth digits of the right hand without any bony abnormality whatever. Her husband is free from any abnormality of hands and feet. The children are J. (female),

aged 4½; W. (male), aged 2½; and B. (female), aged 1½. Skiagrams show the following conditions.

J.—Right hand: webbing of third and fourth digits; duplication of terminal phalanx of third digit, which is fused with the terminal phalanx of fourth digit. Left hand: six digits, third, fourth, and fifth webbed; fusion of ends of the proximal phalanges of third and fourth digits. Left foot: fifth digit is broad, with broad nail, and is partially webbed to fourth digit. Right foot: normal.

W.—Right hand: six digits—third, fourth, and fifth webbed; fusion of third and fourth metacarpal bones. Left hand: similar condition to right hand. Left foot: fifth digit is broad, with double nail. Right foot: normal.

B.—Right hand: six digits—third, fourth, and fifth webbed; fusion of proximal phalanges of third and fourth digits. Left hand: six digits—third, fourth, and fifth webbed; fusion of third and fourth metacarpal bones. Feet normal.

DISCUSSION

Apart from the main feature—the persistence of the abnormality through five generations—there is the specially interesting point that, while the mother is but slightly affected, her children have abnormalities of the digits in an augmented form. Evidently somatic manifestation does not indicate the intensity of the hereditary factor present in the germ cells.

As to the nature of the hereditary factor, it might be inferred from the extent and variability of the abnormality that this was related to Spemann's embryonic regulators of organic growth. The hand, and to a lesser degree the foot, are among the most complex anatomical structures in the body, and it would seem that in this family a gene carrying a hyperactive "organizer" was transmitted through the generations, producing a dominant character of either a complete or partial extra digit in the hands and feet, with correlated changes in the skin and soft tissues.

The variable dominance shown in this family waxing and waning through the generations is a feature which is hardly likely to be confined to it, or to abnormalities of the hands and feet, and its presence in other hereditary or supposed hereditary conditions should be borne in mind.

I am greatly indebted to Dr. Edward Fox of Warrington for the x-ray photographs.

RODENT ULCER IN THE YOUNG

Rodent ulcer is generally regarded as a disease of old age. Most textbooks on diseases of the skin so describe it, and rather ignore the possibility of its occurrence in the young. So far as I am aware the only book in which the occurrence in young people is stressed is Sir Norman Walker's *Introduction to Dermatology*, where a table is given showing the occurrence of rodent ulcer at different ages, many being in young people.

The following cases came under my notice at the Royal Infirmary, Edinburgh.

W. S., aged 15, first attended in January, 1933, with a rodent ulcer about the size of a threepenny-piece on the tip of his nose. The condition had been present for more than a year. The appearance of the rodent ulcer was typical, with the rolled edge and depressed centre. A piece was excised for microscopical examination and the diagnosis confirmed.

G. H., aged 25, was first seen in May, 1934, with a rodent ulcer on the left ala nasi. It was about the size of a sixpence, and had been present for several years. The patient was quite definite that he had had the lesion when he was 17, the size then being about half what it was when he first attended the Royal Infirmary. As the condition must have been present for more than a year before that, it brings the age of onset to about 15, and approximates it to that of the preceding case. Biopsy confirmed the diagnosis in this case also.

These cases are of interest as showing how, in young people, rodent ulcers may occur. If slavish attention were paid to the dictum that rodent ulcer is a disease of the middle-aged or elderly, such cases would be overlooked till so much destruction of tissue occurred that disfigurement would be great, even though the malignant process were cured. In the second case there is a definite depressed scar, though the condition is clinically cured. The first patient, having sought advice early, has given a better cosmetic result, it being hardly possible to detect the position of the original disease.

ROBERT AITKEN, M.D., F.R.C.P.ED.,
Physician in Charge, Skin Department,
Royal Infirmary, Edinburgh.

PARALYSIS FOLLOWING MERCUROCHROME INJECTIONS

Intravenous mercurochrome injections may be followed by severe or mild reactions. These latter are for the most part due to the mercury content of the drug; their severity depends on the state of the patient, and the dosage, strength, and brand of mercurochrome used. There is a lack of uniformity in the various makes of commercial mercurochrome. The commoner reactions observed are similar to those seen in acute mercurial poisoning—namely, a metallic taste in the mouth, abdominal pain, vomiting, tenesmus, and copious diarrhoea with pink ejections. If the administration is continued over a longer period the signs of chronic mercurial poisoning appear: salivation, swelling of the mouth and gums, and albuminuria are not uncommon. Puerperal septicaemia is perhaps the disease for which these injections are most commonly used. I record below two cases of this condition treated by mercurochrome injections, and followed by drop-foot and wrist-drop, which were, in my opinion, a direct result of this treatment.

Case 1.—A primipara was admitted to hospital on August 6th, 1933, and confined the following day; it was a low forceps delivery. The patient had a rigor on the 9th, and on the 10th blood taken for culture showed the presence of a haemolytic streptococcus. Twenty c.cm. of 0.4 per cent. mercurochrome was injected intravenously on August 9th, and repeated on the 12th, 14th, and 18th—a total of 80 c.cm. mercurochrome. Other treatment given consisted of the intravenous injection of polyvalent antistreptococcus serum, low vaginal douches, and the administration of stimulants. On August 20th she complained of numbness and pains in the right ankle; two days later the ankle was anaesthetic, the leg showed severe muscle wasting, and the foot was dropped. Stomatitis and diarrhoea were also present. The ankle was massaged, and radiant heat and a splint applied. There was no improvement, and the limb was put at rest by applying a plaster-of-Paris cast to the right leg and ankle on November 16th. The patient was discharged from hospital with the limb in plaster on January 1st, 1934. Two months later the plaster was removed, and electrical treatment and massage given. At the present time the patient is able to move her ankle, and she can walk fairly well.

Case 2.—The patient, aged 30, was admitted on April 10th, 1934. She had had a three months miscarriage at home on March 31st. She was very ill, with a temperature of 105° F. She had a left phlegmasia alba dolens, but blood culture was negative. On April 12th she had a rigor, and the following day was given 20 c.cm. of 0.4 per cent. mercurochrome intravenously; no reaction was observed at the time of injection. Other treatment given consisted of the intramuscular injection of scarlet fever streptococcus antitoxin. On April 14th there was complete left wrist-drop, which never recovered, as the patient died next day.

It is unlikely that the paralysis could be explained by the action of serum, by the septicaemia itself, or, in the first case, by the forceps delivery. Peripheral neuritis,

due to the mercurochrome, would be a more probable explanation. The solutions used were freshly prepared from mercurochrome scales. The action of mercurochrome is cumulative,¹ and repeated injections lead to a concentration of mercury toxic to the nervous system. This would be an explanation in the first case. A similar explanation does not hold in the second case, where only one injection was given before the paralysis developed. It has been shown that mercurochrome has an extremely toxic effect on the nervous system.² The onset of the paralysis so soon after the injection suggests that the paralysis was due to the toxicity of the drug itself: solutions intended for intravenous injection should be made up from mercurochrome which has been shown suitable for intravenous therapy. Several manufacturers now insist that it should be chemically correct in respect of total percentage of mercury, bromine, and dye,³ and that toxicity tests on mice should be done to ensure a product with the minimum variation in toxicity.⁴

CASTOR OIL VAPOUR AS A PURGATIVE

The statement that "castor oil will purge even when rubbed into the skin" occurs in Sir William Hale-White's *Materia Medica*. It is one of those sentences which may well remain impressed on the memory of the student, although he may never see an example of its practical application. Among the methods of administering purgatives described in the various textbooks inhalation is not mentioned, so far as I have seen. Yet that this mode of administering castor oil proves effective is indicated by two examples.

A pilot during the Great War suffered from mild chronic constipation which necessitated periodic laxative treatment. He was flying "pusher" planes, in which the engine was behind the pilot and observer. Later, he changed to aeroplanes with rotary engines. These engines were at the front of the machine, and used pure castor oil as a lubricant. The smell of castor oil was prominent in the fumes which he performed had to inhale. He noticed that during the period when he flew these latter machines he never required to take any laxative medicine, but, when he gave up flying, his old constipation returned. Apart from this case, it was quite generally known among observant flying officers that the fumes from rotary engines kept the bowels open.

A striking case came to my notice recently. A mountaineer treated two pairs of climbing boots with castor oil in the bedroom of his hotel. On retiring for the night he again lavishly spread over the boots a layer of oil, the odour of which filled the room. Next morning the slightly nauseating odour was still noticeable in the room, and the owner of the boots found the purgative effect so marked that his bowels were opened three times in the course of the morning; he noticed, moreover, that there was no gripping effect.

It seems justifiable from these examples to conclude that the prolonged inhalation of the vapour of castor oil produces a purgative effect; although Cushny states that "only volatile drugs can be used thus for their general action," Sollmann writes that "this method is used only for gaseous medicines, such as anaesthetics or oxygen," and other authorities generally concur regarding inhalation.

Reviews

RADIUM AND CANCER

All who are interested in the scientific development of radium therapy in this country owe a debt of gratitude to Mr. H. S. SOUTTAR for his admirably written monograph on *Radium and Cancer*.¹ In one way, certainly, it is a remarkable book, since, though written by one who is professionally a clinician, it devotes no fewer than 143 out of its 340 pages (excluding appendices) to a comprehensive account of the physical principles involved. The neglect of a due appreciation of the paramount importance of physics in this connexion has often been a reproach to radium surgery in England. Mr. Souttar shows in his book what at any rate in his opinion forms the fundamental basis of this very important subject. It is not given to every surgeon to be at once a mathematician and a physicist; but it is incumbent on all who practise or intend to practise radiotherapy that they should have a clear idea of the fundamental principles of the subject. In this book the amount of physical knowledge which its author displays is perhaps a little in excess of that which most can hope to attain; it represents, however, an ideal which has long been recognized in certain Continental and American schools. An account of α rays was necessary, in order to make the physics of radium understandable: its inclusion here, in considerable detail, may serve to emphasize the absolute necessity for the intimate association of α rays and radium in therapy. It is now universally admitted that an up-to-date high-voltage x -ray department is an indispensable part of any department for the practice of efficient radium therapy. Incidentally, a glance at the first chapters of this book will show the importance of having a trained physicist—medically qualified or otherwise—as a colleague upon the staff of a hospital practising these methods of treatment. The physical side is treated in such great detail that it would have been interesting had we been given some account of the most modern theories of the structure of the atomic nucleus, and of the nature of the neutron as well as of some more speculative nuclear elements. But perhaps the author is wise in not venturing upon an attempt to keep pace with these rapidly moving and changing hypotheses.

The section on the biological action of radiations is disappointing, especially when compared with the physical section. A vast amount of work has been done upon the chemical action of the rays, and also upon the various structural elements which go to make up an ordinary animal cell. Not only the cell nucleus, but the cytoplasm, cytoplasmic inclusions, and the cell membranes and nuclear membranes are profoundly influenced by exposure to radiation. In one passage, where reference is made to the work of Cramer upon the subject of the production of immunity in malignant disease, the author seems to have lost sight of the fact that Cramer's work cannot be considered as in any way conclusive upon the therapeutic aspects of the subject, since his experiments were carried out by subjecting tumours to intensive β radiation, whereas in the radiotherapeutic treatment of new growths highly screened γ rays and x rays of short wave-length are employed.

We have dwelt at length upon the more purely scientific aspects of this work, since it is almost, if not quite, alone among books written by clinicians in this country in which scientific principles receive anything like the prominence to which they are indubitably entitled. Of the clinical section there is comparatively little that calls

for remark: to a greater or less extent the methods of radium therapy in different sites are becoming more or less settled along the lines suited to the special requirements of each case or group of cases. One or two points, however, seem to need comment. On page 234 we read, with reference to rodent ulcers: "The best results are obtained with relatively light screenage, the cauterizing action of the beta rays being apparently in this case an advantage." A good many workers will, we think, be inclined not to endorse this view. Light screenage certainly has the advantage of allowing a short time for the application; but it is by no means a matter of agreement that the results are as permanent in the long run as those obtained with prolonged exposures to more highly screened radiation. On page 322 the figures illustrating the Stockholm and Institut Curie (Nos. II and IV) methods of treatment of carcinoma of the cervix surely do not represent accurately the methods specified.

As we have already said, it is an excellent sign that one who is primarily interested in clinical work should stress so emphatically the need for an adequate groundwork of physical knowledge and of scientific collaboration. We cannot all be mathematicians or physicists; but each of us can further the best interests of his or her patients and the cause of truly scientific work by recommending patients only to those institutions where there is an efficient high-voltage x -ray department working in collaboration with the radium department and also the closest collaboration between the purely scientific and the therapeutic departments. Mr. Souttar has rendered invaluable service to the subject of which he is so distinguished and so clear an exponent.

THE NEUROTIC AND HIS FRIENDS

It has been said, "Happy is the home which does not harbour a neurotic." Nowadays—and this is one of the most serious problems of modern life—an increasing number of homes harbour one or more neurotics. For most people everyday life is largely composed of dealing with other people in various states of neurosis. The problem may not be altogether a new one, but it has only lately come to the fore, and there is as yet very little mechanism for helping the ordinary lay person or general practitioner to understand what attitude he should adopt towards a neurotic and how he should behave. Of the making of books on psychotherapy there is no end, but comparatively few of these are at all intelligible to anyone but a specialist. Various attempts have been made in recent years to explain neurosis to the ordinary person, but hardly any of them have been successful. For the layman a book on neurosis must be short, it must be written in plain language, and, most important of all, it must be expressed from the standpoint of the ordinary man and not from that of a psychotherapist, or even of a doctor. It is very difficult for a physician or general practitioner, and still more perhaps for a psychotherapist, to look on a medical subject with the eyes of a layman.

Dr. R. G. GORDON, in attempting this task,² has attained a notable success. He starts by inquiring, "What is a neurotic?" and shows the essence of the breed to be a person whose mental and physical processes do not function in a harmonious way. He takes the optimistic view that, even if the patient is so bad that he cannot possibly be cured, at any rate proper treatment will improve him and make him much less of a pest to his friends and relations. Pointing out that the way to go to work is to understand, and to get the patient to understand, how and when he began to adopt a wrong

¹ *Radium and Cancer*. A Monograph. By H. S. Souttar, D.M., M.Ch., F.R.C.S. London: W. Heinemann Ltd. 1934. (Pp. 387; illustrated 21s net.)

² *The Neurotic and His Friends*. By R. G. Gordon, M.D., D.Sc., F.R.C.P.E. London: Methuen and Co. Ltd. 1934. (Pp. 57; 2s. 6d. net.)

attitude towards life, he examines the various crises of life, from birth to the menopause, and shows how and why the neurotic may fail at each of them. After a study of types of neurotic reaction he deals very acutely and fairly with the misconceptions of the public, most of which are fairly familiar, but few of which have ever been adequately answered. His last chapter, entitled "Help for the Sufferer," distinguishes his book from almost any other of the kind that has appeared.

The chief feature of psychotherapeutic literature, both for the medical profession and for the laity, is its unfortunate absence of constructive suggestion. Dr. Gordon is revolutionary enough to tell his readers what and what not to do. He bids the neurotic's friends remember that gratuitous advice is neither appreciated nor helpful. They should, he says, let the neurotic talk and pour out his troubles and not interfere until he has finished. The next rule—a hard one—is to preserve the strictest confidence in anything learnt from a neurotic. The friend, moreover, must never criticize implicitly or explicitly during the narrative; in all circumstances he must maintain the neurotic's self-respect, and never assume an attitude of superiority, or indeed allow himself to feel superior. He must avoid variations in his own emotional attitude towards the neurotic, and lastly he must never tell the sufferer to pull himself together unless he has some definite idea how this should be done. These valuable suggestions postulate a friend with very exceptional qualities of sympathy and sanity. Perhaps the severest criticism that could be levelled against Dr. Gordon's book is to suggest that the neurotic from his very nature rarely has friends who are capable of following Dr. Gordon's wise advice. If he has, he is lucky.

CLINICAL ELECTROCARDIOGRAPHY

Facility and reliability in the interpretation of electrocardiograms can only be acquired by the regular analysis of records. The *Students' Handbook of Clinical Electrocardiography*¹ has been planned by Dr. WILLIAM EVANS as an aid to those who require a working knowledge without excess of detail. A very brief account of the broad principles of the method and nomenclature is followed by a plan of analysis which is to be applied in the reading of all records. The body of the manual consists of a number of very good reproductions of electrocardiograms, each analysed according to the method advised. Appended are twelve test tracings with a key. Dr. Evans has aimed at providing not only for the needs of general practitioners, but also for those of students working for examinations and house officers in smaller hospitals. This modest claim might appropriately be extended to house officers at any hospital and students at any stage, from the earliest clinical work onward.

Dr. CHAUNCEY MAHER's manual on *Electrocardiography*² has been compiled with an object similar to that of Dr. Evans. It has admirably fulfilled this purpose by the adoption of an explanatory device in which for each arrhythmia the heart is schematically presented with its conducting system and the direction of impulse propagation, together with the corresponding electrocardiogram and an explanatory legend. This is perhaps the clearest system yet devised for the demonstration of the significance of electrocardiograms. While Dr. Maher has achieved his aim, he has somewhat exceeded it. The 250 pages of this volume embrace among the usual

topics a consideration of the theory of the electrocardiogram and axis deviation, the effect of drugs and acute infective disease, and a chapter on the clinical concepts of heart disease and the arrhythmias. This book has been well thought out and carefully compiled; it merits the attention of those to whom it is addressed, and, furthermore, deserves to find a place among the standard books on clinical electrocardiography.

RECENT ADVANCES IN ALLERGY

Only three years have gone by since the first edition of this work by Dr. GEORGE BRAY was published and it is some tribute to the popularity of the subject that a second edition³ has been called for so soon. During the interval it has been necessary to augment it by 700 additional references, and many of the facts set out in the first edition have consequently required condensation to enable the more important of the recent papers to be summarized at some length. The association of allergic with other diseases, nasal catarrh, and other systemic manifestations, such as cardiovascular conditions and dysmenorrhoea, form the subjects of new chapters, while fresh references include work on pyrogenic therapy, erythema nodosum, ulcers, and the Shwartzman phenomenon. Notable events since the publication of the first edition have been the first International Congress on Asthma at Mont Dore, in June, 1932; the third International Paediatric Conference, held in London in July, 1933, in which the role of allergy in children's diseases was one of the two major subjects for discussion; and finally, the death a few weeks later of that outstanding figure in the study of allergic problems, Professor Storm van Leeuwen.

In his preface to the second edition Dr. Bray writes: "The study of allergy is making great strides, and practitioners and patients are anxious to avail themselves of modern methods of treatment, for nowadays most allergic manifestations at all ages are amenable to cure." A tribute is paid to the financial assistance given by the Asthma Research Council to numerous investigators and clinics, and to the Halley Stewart Trustees for further endowments for research into these problems.

PRACTICAL BIOCHEMISTRY

Koch's *Practical Methods in Biochemistry*⁴ is a new publication, but it is intimately associated with one of the best-known textbooks on physiology, being written as a companion volume to A. P. Matthew's treatise. It is admirably arranged in its three sections devoted to cell constituents, digestive juices, and blood and urine respectively. The exercises are set down with great clarity, and a commendable feature is the manner in which the qualitative reactions are treated in terms of the concentrations of the reacting substances, thereby serving to develop in the beginner a true quantitative sense. In general, the student is introduced to selected methods of practical importance, and is not overburdened or confused by being offered too great an assortment of methods. One would like to have seen included a few representative preparatory exercises on the amino-acids, and also some tables recording the normal composition of the body fluids which come under consideration. These omissions, however, do not constitute any serious defect, and the book compares very favourably with other works on the same subject. In subsequent editions the author might

¹ *A Students' Handbook of Clinical Electrocardiography*. By William Evans, M.D., M.R.C.P. London: H. K. Lewis and Co. Ltd. 1934. (Pp. x + 50; 64 figures. 5s. net.)

² *Electrocardiography*. By Chauncey C. Maher, B.S., M.D. London: Baillière, Tindall and Cox; Baltimore: Williams and Wilkins Company. 1934. (Pp. xiv + 250; 85 figures. 15s.)

³ *Recent Advances in Allergy*. By G. W. Bray, M.B., Ch.M. Second edition. London: J. and A. Churchill, Ltd. 1934. (Pp. xv + 503; 106 figures, including 4 coloured plates. 15s.)

⁴ *Practical Methods in Biochemistry*. By Frederick C. Koch. London: Baillière, Tindall and Cox. 1934. (Pp. viii + 280; 17 figures. 10s.)

with advantage assume that the student knows what is meant by a percentage solution, and thereby much reduce a somewhat lengthy appendix.

FOLIN'S *Laboratory Manual of Biological Chemistry*¹ derives its special importance from the fact that the author has for so long occupied a leading position among those who have set themselves the task of devising and improving methods of biochemical analysis. Since the last edition appeared in 1925 many notable advances have been made in the analytical field as well as in other branches of biochemistry, and the new edition (the fifth) describes the very latest developments of the author's technique. New methods appear for blood sugar, non-protein nitrogen, uric acid, and creatinine, and more attention is given to micro-methods. The additions have meant a further increase in the size of the supplement, which now occupies about half the book. This fact, however, is not to be regretted, since it is the supplement rather than the laboratory course proper which holds the greater interest for the majority of biochemists.

Notes on Books

Dr. D. T. HARRIS'S *Practical Histology for Medical Students*,² now in its third edition, is planned on original lines, and cannot fail to be of great use to students of normal histology. Its merit is that it gives the student full directions as to how he is to proceed, at every step in the course. It describes the apparatus required by the student in his private work, the stains he needs, the type and management of his microscope, and under each and every tissue in turn are given directions for fixation, staining, mounting, and study. Brief accounts are also given of special details to be recognized in the preparations, and blank pages are inserted to enable the student to make sketches of the specimens as permanent records. In addition to the descriptions of the mode of making fresh and permanent preparations, many matters are included which will be of clinical value to the student subsequently, such as blood counts, haemolysis, and transfusion tests. The book can be thoroughly recommended to those who are commencing their course.

Professor RICHARD CABOT'S well-known *Physical Diagnosis*,³ now in its twenty-ninth year, shows the same independent expression of experience which has made it so attractive. Thus he considers that the diagnostic value of the state of the pupils has been much overestimated, for except in tabes and general paralysis of the insane they seldom provide much help; the stress laid in textbooks on their condition in coma is regarded as misleading or useless as a diagnostic guide. This edition has been revised and reset throughout, and a number of additions made. The excellent illustrations, more than one to every two pages of the text, form a useful picture gallery for facial diagnosis.

The eighth edition of *The Diabetic Life*⁴ appears rather less than two years after its immediate predecessor. Although it shows no fundamental change, it contains fresh material culled from practical experience, including some additions to the list of recipes. The line-ration scheme has been modified to provide high carbohydrate lower fat diets where they seem indicated, and an important section has been added on the minimal care necessary for insulin cases. Emphasis is laid on the vital importance of always giving a regular fixed amount of carbohydrate

to balance the correct dose of insulin, for without this precaution the patient's condition will always be varying between uncontrolled diabetes with hyperglycaemia and unpleasant hypoglycaemia. The new edition has received careful revision, and its comprehensiveness is very apparent. The author refers in his preface to the foundation of the Diabetic Association, and advises his readers to become members. The book is written for patients as much as for medical practitioners, and serves an undoubtedly useful purpose in that it can be employed by the latter to tighten the necessary control over the lives of diabetic persons, and so ensure the success of treatment.

Injection Treatment in General Practice,⁵ by Dr. M. L. GUJRAL, adds little to what has already been written on this subject. The author has evidently been at some pains to make his compilation as exhaustive as the limit of some 200 pages will allow, but the value of his book is largely discounted by a complete lack of reference to his sources of information. It is impossible to recognize which statements, if any, Dr. Gujral makes on his own responsibility and which are copied from the works of other authors, nor does he indicate the origin of some of his figures. The book contains some curious misprints and spelling errors.

Preparations and Appliances

AN ELECTRICAL MAINS ADAPTOR FOR DIAGNOSTIC SETS

A new mains adaptor for ophthalmic and other diagnostic instruments has lately been placed on the market by Gowllands, Ltd., of Croydon. This firm, whose principal business is the manufacture of optical instruments (which are distributed to the wholesale trade only) makes a speciality of medical diagnostic sets comprising a number of interchangeable observation instruments operated from a common battery handle holding a dry cell. It has now designed a transformer which is fitted into the battery handle so that any suitable instrument, instead of relying on a battery, can be run from the mains. A single wire through a hole in the cap of the handle, which is provided with a special spring to protect the cable against damage and to hold the transformer securely, can be connected up to the nearest wall or light point, and a resistance in the handle can be used to control the intensity of the illumination. Thus the unit may be employed in exactly the same way as a dry battery, but, of course, without exhaustion. The temperature rise of the instrument on continuous use is stated not to exceed a few degrees. It is double wound and tested at 1,800 volts between the windings for insulation, and is guaranteed for one year against breakdown or electrical failure. The transformer is wound for 200 to 250 volts alternating current only, and now that the greater part of the country is fed from the grid system the adaptor can be used almost anywhere—as, for example, by the general practitioner in the homes of most of his patients. The output is 2½ volts, and sufficient power is supplied to operate the small ophthalmoscope or auriscope or other lamp. The unit weighs only a few ounces more than with the dry cell, and is very convenient and portable, offering a means of converting battery-operated instruments into mains-operated ones with the minimum of trouble.

LEMON BARLEY WATER

"L.B.W." is a concentrated extract of pearl barley flavoured with fresh lemons, with the addition of 0.05 per cent. benzoic acid as a preservative. It is a palatable and refreshing beverage for the sick-room, and does away with the need for daily preparation of barley water in a busy household. The manufacturers are L.B.W. Ltd. (Newcastle-on-Tyne), and bottles, price 1s. 9d., may be obtained through the usual retailers.

SURGONS' HAND SOAP

"Allenburys" have brought out a new preparation called "surgeons' hand soap (sample received)" which is described as "a neutral liquid soap, antiseptic and superflatted." It has an antiseptic coefficient equal to 1-20 carbolic. This is recommended as an ideal detergent for doctors, dentists, and nurses, and for general hospital use. It can be used for cleansing hands, instruments, and dressings, etc. In practice it lathers reasonably well, and is not irritant to the skin. The 4-oz. bottle costs 1s. 6d., the 10-oz. size being sold at 2s. 6d.

² *Practical Histology for Medical Students*. By D. T. Harris, M.D., D.Sc. Third edition, revised. London: H. K. Lewis and Co. Ltd. 1934. (Pp. 56; 2 plates, 1 coloured. 7s. 6d. net.)

³ *Physical Diagnosis*. By Richard C. Cabot, M.D. Fifth edition. London: Baillière, Tindall and Cox. 1934. (Pp. xxiv + 540; 569 figures. 25s. 6d.)

⁴ *The Diabetic Life: Its Control*. By Diet and Insulin. By R. D. Lawrence, M.A., M.D., F.R.C.P. Eighth edition. London: J. and A. Churchill, Ltd. 1934. (Pp. 224; 12 figures. 8s. 6d.)

RESEARCH IN MENTAL HOSPITALS

Part II of the Board of Control's Report for the year 1933* (Part I of which was noticed in the *Journal* on October 6th) opens, as usual, with a supplement descriptive of the scientific research work carried out in mental hospitals and mental deficiency colonies during the year. This supplement, indeed, forms the bulk of Part II, occupying 135 of its 176 pages.

The supplement is followed by five appendices: lists of institutions in England and Wales (a) for persons suffering from mental disorder; (b) for voluntary patients only, provided by a local authority; (c) hospitals for voluntary and temporary patients; (d) nursing homes approved for voluntary and temporary patients; and (e) institutions for the mentally defective.

At one time Part II of the report was a bulky tome, but, no doubt in the interests of economy, it has shrunk in recent years to a third of its former size, partly by the deletion of the statistical tables, some of which (for example, tables of forms of mental disorder; tables of assigned causes of insanity, etc.) were of doubtful scientific value, and partly by the cessation of publication of copies of the entries made by the Commissioners at their visits to mental hospitals, some of which contained matter of considerable public interest. Doubtless the introduction of new tables required by the operation of the Mental Treatment Act introduced complications from the statistical point of view which might make the perpetuation of such statistical analyses undesirable: but a certain lack of statistical background to Part I of the report is perceptible.

The seventy-two reports embodied in the supplement certainly afford evidence of the considerable amount of research work now being carried out in the mental hospitals of the country; and also, even though many institutions merely furnish tabulations of pathological and biochemical investigations made during the year in connexion with their great task of clinical treatment, furnish ample proof of activity in this direction on a scale only faintly realized by the public. It may be said without fear that first admissions to mental hospitals are investigated from the physical point of view with a completeness which is not, and need not be, attempted in any other class of hospital. In both of these directions Part II is of value as giving a comprehensive view of the work of the mental hospitals of the country. Of particular interest a few may be mentioned. The Joint Board of Research for Mental Diseases (City and University of Birmingham) continues, *inter alia*, the results of investigations into the prevalence and effects of septic foci in teeth, tonsils, and sinuses, a point also covered by the report of the Cardiff City Mental Hospital, where Dr. J. H. Quastel and others have been for long pursuing researches into narcosis and oxidations of the brain and Professor Cummins into tuberculin tests. The reports from several hospitals summarize their results from malarial therapy, that from Horton (L.C.C.) Mental Hospital containing a very valuable paper by Dr. W. D. Nicol on the relation of syphilis to mental disorder and the treatment of general paralysis by malaria, while Colonel James of the Ministry of Health furnishes a brief account of anti-malarial chemotherapeutic tests carried out at the Devon Mental Hospital, Exminster, with the collaboration of Dr. R. Eager.

From St. Andrew's Hospital a report of much interest by Dr. Ruby Stern gives the results of an investigation into the intestinal flora in physical and mental disease, the case material having been supplied by the Mental Hospital itself on the one hand and from Charing Cross Hospital and Northampton General Hospital on the other.

The scientific work carried out in institutions for the mentally defective is growing steadily in importance, of special interest at the moment being the report of the research department at the Royal Eastern Counties Institution, Colchester, where a five-year plan of research, including a complete clinical, physical, and mental examination of the 1,500 defectives in that institution, is in progress, by Dr. L. S. Penrose and two assistants.

BRITISH HEALTH RESORTS ASSOCIATION

The second annual general meeting of the British Health Resorts Association was held at the Institute of Hygiene, Portland Place, on November 22nd.

Lieut.-Colonel ELLIOT, who was in the chair, said that the report showed a year of good work, but that while the association was now paying its way and was no longer disheartened by a heavy load of debt, it was still handicapped for lack of means. There had been a considerable increase of medical subscribers during the year. He expressed his thanks to those resorts which had supported the association, and particularly to the British Spas Federation, with which there had been happy and effective co-operation. He did not understand why many of the seaside resorts which were usually so energetic in promoting their own interests did not follow the example of those that had supported the association. If the association's propaganda was successful it must mean the extension of the length of the seasons of many health resorts and the creation of new seasons for some of them. During the past year the association had met in conference for the first time on the East Coast at Cromer, and he hoped that in the coming year some enterprising resort on the West Coast would follow suit. The association was endeavouring to interest one or more of the medical educational bodies in the provision of post-graduate education in climatology and hydrology, to be followed by an examination and diploma. It was also hoped to get the Ministry of Health to follow the example of Continental Governments and give, not financial support, but formal recognition to the fact that the health resorts of this country were a national asset in the prevention and cure of disease.

Lord Meston, president of the association, supporting the adoption of the report, said that British people took a long time to absorb a new idea, and the notion that they could get at least as good, if not better, help, attendance, and medical care in their own country was to many a completely new one. He believed that a number of seaside places, which were at present concentrating on the pleasure side of their propaganda, would come to realize their potentialities as health resorts, to the great benefit not only of themselves but of the public.

Lieut.-Colonel W. BYAM, chairman of the Medical Advisory Committee, reviewed the work and the programme of that committee, and emphasized the fact that the association, in endeavouring to interest the public in the value and claims of our health resorts, found its special line of approach through the medical profession. There was much to be done in the way of research before the health resorts could be so differentiated as to put their claims on a proper scientific basis, and he believed that a body like the British Health Resorts Association, with its strong medical advisory committee, could do this if it were properly supported. Dr. C. W. BUCKLEY said that sea-bathing to-day was regarded merely as a form of pleasure, but that its therapeutic advantages—and even disadvantages in certain cases—should be closely studied. Doctors had to treat many cases of severe rheumatism and kindred complaints due to unwise sea-bathing. He announced that Buxton was inviting the association to hold a conference there in the spring. Dr. MATTHEW RAY alluded to the active propaganda which was being carried out in this country on behalf of the muds of a Continental resort which had a deservedly high reputation in the treatment of the rheumatic diseases. Many experiments, he said, had been made in this country by experienced observers which showed it was not the locality from which the mud was derived that mattered, but the latter's capacity for retaining heat, and also the methods used and the after-treatment. He was convinced that there were products in this country, including peats, muds, and china clay, which were quite as effective as any Continental product.

Lord Meston was re-elected president of the association, and Lord Horder and Lord Riddell vice-presidents. The names of Professor W. Langdon Brown, Sir Stanley Woodwork, and Mr. R. C. Vaughan were added to the list of vice-presidents.

ONE HUNDRED AND THIRD ANNUAL MEETING
of the
British Medical Association
MELBOURNE, 1935

THE British Medical Association will hold its 103rd Annual Meeting in Melbourne, Australia, during the week beginning September 9th, 1935, under the presidency of Sir Richard Stawell, K.B.E., M.D., consulting physician to the Melbourne Hospital. The Sectional sessions for scientific and clinical work will be held on Wednesday, Thursday, and Friday, September 11th, 12th, and 13th. The Annual Representative Meeting for the transaction of medico-political business will take place in London at the Association's House on Friday, July 19th, and following days.

Members travelling to Australia through the United States will sail for New York from Southampton on July 27th; if travelling by the Canadian route to San Francisco, they will sail for Montreal from Liverpool on July 26th, or from Glasgow on July 27th. Particulars of the two routes were given in our *Supplement* of March 10th. All arrangements for the journey are in the hands of the Financial Secretary and Business Manager, B.M.A. House, Tavistock Square, London, W.C.1, to whom early application should be made for reservation of places on steamers and trains and at hotels. Members who cannot afford to be away for the whole time of the "round-the-world" tour may leave London on August 8th, travelling overland to Toulon and embarking there on a P. & O. liner which arrives at Fremantle on September 3rd. The journey on to Melbourne takes three days by rail, so that those who follow this route will reach their destination three days before the meeting opens.

The honorary local general secretary for next year's Annual Meeting is Dr. J. P. Major, Medical Society Hall, East Melbourne, Victoria. The names of the officers of the fourteen Scientific Sections are given in the *Supplement* this week; and further information, with provisional programmes, etc., will appear in subsequent issues. We publish below the second of a series of descriptive and historical articles, on the city of Melbourne and its medical institutions; the first appeared on October 20th (p. 730).

THE STORY OF THE MELBOURNE MEDICAL SCHOOL

BY

PROFESSOR W. A. OSBORNE

DEAN OF THE FACULTY OF MEDICINE

The formal inauguration of the University of Melbourne took place on April 13th, 1855, three years and nine months after the Port Phillip district, a portion of New South Wales, had become the State of Victoria. In this

University, Sir Redmond Barry, was just as eager to start a school of law. Brownless, who may be regarded as the real founder of the school, never flagged in his efforts, and at last, by a reduction of his request for

View of Melbourne from across the Yarra River.

same year Dr. (afterwards Sir) Anthony Colling Brownless, a Bart's man, who had come to Australia in the gold rush of 1852, was elected a member of the governing body or council, and immediately started an agitation for the creation of a medical school. He was ably supported by his colleagues in medical practice, but the difficulties at first seemed insuperable: the colony was small, the Treasury exiguous, while the Chancellor of the

£26,000 to a more modest £12,000, and by the generous action of the lecturers in law and engineering in relinquishing part of their salaries, the project was adopted in 1861, and the first lectures in chemistry were given in a private laboratory by Dr. John Macadam, an M.D. of Glasgow.

The curriculum adopted at the start of the school, the first in the Antipodes, showed some remarkable features. Dr. (afterwards Sir James) Paget of London, who had

been consulted, recommended a three years' or, at most, a four years' course of study, but Dr. Brownless realized that in the Old Country there was a belief that all matters, particularly educational, were make-shift and below home standard in the colonies. With great courage the council, on Dr. Brownless's recommendation, insisted that after matriculation—and this involved the passing of a fairly stiff examination—there should be five years of medical study with five exacting examinations. This severity of standard was something new in the Empire, and thirty years had to elapse before the General Medical Council in London could regard it as practical in the United Kingdom. Here may it be stated that from this early date until the present time the university degrees of M.B., B.S. have constituted the one and only local portal to the medical profession. There have never been any back entrances or short cuts, and the status of the profession to-day testifies to the wisdom of the founders.

Department of Pathology, Melbourne University.

Halford : The School's First Professor

It was realized from the start that a professor was wanted who could take on the burden of organization and administration and establish the school on sound lines. Dr. Paget and Professor (afterwards Sir Richard) Owen, acting as a London committee, selected Dr. George Britton Halford, a Sussex man practising in London, as professor of anatomy, physiology, and pathology. He arrived in Melbourne on December 22nd, 1862, and soon was busy with Dr. Brownless drawing up plans of buildings, which with fine optimism were devised much in excess of the needs of the time. Professor Halford gave his inaugural lecture on May 1st, 1863. He had already done brilliant research work on the heart in London, most of which was embodied in the book *The Action and Sounds of the Heart*, published by Churchill in 1860, a volume that might well be reprinted to-day, for the experiments on which it was based took on the exactness of a research on natural philosophy.

Halford demonstrated among other things the fixity of the apex, the action of the pericardium, the valvular contribution to the first sound, and, prettiest of all, the action of eddies in approximating valve flaps so that the valves are really closed before systole begins, and regurgitation or clack is avoided. Halford may also be regarded as a pioneer in comparative physiology, or "Zoological analogies" as the *Lancet* called it (March 17th, 1860): "a mode of inquiry which Dr. Halford appears to have been the first to institute" (*ibid.*). Evidence of his enthusiasm and of his racy style is given in his account of how he listened to the heart sounds of

the apteryx, which bird, Dr. Owen had declared, had "mammalian affinities" in its heart.

"As stealthily as thieves to their business, or as Tarquin to Lucrece, did the keeper and I approach the apteryx by night, he leading the way. Having secured her in his arms she became easily pacified and, unseen by her, I placed my stethoscope to her chest, broad, without a keel, and listened for some time. Never was there a prettier result. The sounds were not like those of the eagle, for the first sound had resumed its mammalian length and lub duc was once more heard."

Halford's somewhat unconventional manner was not pleasing in the eyes of the Chancellor, Sir Redmond Barry, a pompous lawyer. In 1864 Halford argued that a man called Harrison, condemned to death for murder, was probably insane. His pleadings, disregarded by the authorities, aroused the gratitude of the condemned man, who, without legal power of course, bequeathed his body to the professor. Halford got access to the body after execution, severed

the head, and made off with it to his dissecting room. To continue the story in the words of *The Times*:

"The gaol surgeons were in consternation and appealed to the Sheriff. Law and justice were at the moment at fault. At length it was determined that the Sheriff, accompanied by a justice of the peace and by a policeman, should forthwith proceed to the university and demand the brains. On arrival of the formidable Sheriff, six foot four inches in height, at Professor Halford's rooms, the professor was found surrounded by medical men and the brain before him, the dissecting then proceeding. The Sheriff demanded the public property. Professor Halford asserted that the brains were his by bequest of their former owner. The Sheriff contended, with much

force, that the brains were "the Government's brains," and that a convict on the scaffold had no property even in his own brains. Finally, the gaol surgeons being present, it was arranged that the dissection should proceed, and at the end the brain was pronounced perfectly healthy."

Sir Redmond Barry was furious, and addressed a stern rebuke to the over-zealous anatomist. Six years later Halford was anxious to give a public lecture on protoplasm, but the council, led by Barry, forbade it. No doubt they considered the awful word redolent of Huxley, Tyndall, and Herbert Spencer, and yet Halford was an

Wilson Hall, Melbourne University.

anti-Darwinian, and orthodox in his faith.

Growth of the School in the 'Eighties

Halford's first class in 1863 consisted of three second-year students who met for dissection and instruction in a shed; but in May, 1865, a substantial medical school was completed, which now, after some structural alterations, is divided between chemistry and physiology. Steady

growth in numbers necessitated new buildings in 1881. So far one professor with a team of lecturers, most of them in medical practice, was regarded as sufficient for purposes of medical instruction, but in 1882 the chair was divided, Halford retaining physiology and histology, whilst his pupil, Dr. H. B. Allen (afterwards Sir Harry Allen), was given the chair of anatomy and pathology. In 1886 Allen took on the deanship, and from then until his retirement in 1923 dominated the medical school. He was in many respects a remarkable man with exceptional administrative gifts; he was also an enthusiastic morbid anatomist. His reading in English and French medical literature was wide and his memory tenacious. Like most self-trained teachers he was not *au fait* with the methods of research, and did not encourage a research spirit in his pupils. On the other hand, he came to conclusions concerning the syphilitic causation of many post-mortem appearances which later work justified.

In the middle 'eighties the scientific preliminaries for medical study were greatly strengthened by the appointment to the chairs of chemistry and physics of Professor (afterwards Sir David) Orme Masson and Professor (afterwards Sir Thomas) Lyle—both of whom are happily still with us though emeritus—and Professor (afterwards Sir Baldwin) Spencer, great as an anthropologist as well as a biologist. The advent of these distinguished men of science was soon followed by the erection of suitable laboratories.

Reciprocity of Medical Registration with Great Britain

In 1890, through the representations made by Professor Allen, reciprocity with Great Britain in the matter of medical registration, was granted, and Allen himself became the first person to be registered in the United Kingdom in respect of a qualification wholly derived from a British Colony. The curriculum from this time on has conformed to the regulations laid down by the General Medical Council.

The year 1896 marked the retirement of Professor Halford and the arrival of Dr. (now Sir Charles) Martin, who supplied the missing research enthusiasm which was soon to inspire Dr. E. H. Embley, a busy practitioner, to embark on a laborious and important investigation on the causation of death under chloroform. Professor Martin resigned in 1903, and was succeeded by the writer. The opening of the century saw a building reserved for bacteriology. In 1906 a chair of anatomy was founded, the first occupant being Professor R. J. A. Berry, and a department of biochemistry under a lecturer, Dr. A. C. H. Rothera, who was succeeded in 1919 by the present holder, Associate Professor W. J. Young.

Clinical Schools

The Melbourne Hospital was the original general hospital for clinical instruction, but in 1909 the Alfred Hospital and St. Vincent's were recognized as teaching clinical schools. By this time also the Women's Hospital, the Eye and Ear Hospital, the Children's Hospital, and the Asylum were used for instruction in their respective specialties.

The new and spacious anatomy department was formally opened in 1923 by Sir William Macewen. In 1925 Professor Peter McCallum, the present holder, was appointed to the chair of pathology; in 1929 Professor Berry was succeeded by Professor Wood-Jones, whilst in 1930 a new chair of obstetrics was created, and Professor Marshall Allan was appointed. There are at present, therefore, four professorial positions in the medical school: anatomy including histology, obstetrics, pathology, and physiology; a fifth, bacteriology, is likely to be added in the near future. Teaching in medicine and surgery is relegated in each case to a team of experts under the chairmanship of a lecturer; this method has proved valuable for teaching purposes, but it is not conducive to research work. Fortunately the Hall Institute at the Melbourne Hospital and the Baker Institute at the Alfred Hospital are devoted to medical research, and have large and competent staffs.

The student body began, as stated, in 1863 with three members, who were, of course, males, and who displayed their masculinity with abundant whiskers; women were not admitted until 1887. In 1880 a medical students' society was founded, and two of the first members now occupy prominent places in Melbourne life—Sir James Barrett and Dr. Felix Meyer.

The numbers of students have shown fluctuations very similar to those experienced elsewhere. In 1914 there were 402 students and the next year 370. Then came the post-war peak in 1921 of 795, falling to the 1914 level in 1925 and 1928. At present the indications are those of continued growth, the figure for the current year being 581.

ATMOSPHERIC POLLUTION

Thirty-two representatives of local authorities and other organizations co-operating with the Department of Scientific and Industrial Research in the investigation of atmospheric pollution met on November 26th in the half-yearly conference at the offices of the Department. The gathering included representatives from London, Manchester, Glasgow, Liverpool, Southampton, Leicester, Newcastle, Hull, Scarborough, Halifax, Lancaster, Leamington, and Wolverhampton.

The Conference, over which Councillor W. Brownhill-Smith of Glasgow presided, received a report from Dr. G. M. B. Dobson, F.R.S., on the progress of the researches carried out under the Atmospheric Pollution Research Committee. Dr. Dobson stated that the new method which had been developed at the Building Research Station for estimating sulphur in the atmosphere was now being used at twenty-seven stations. It was hoped that it would be adopted still more widely by local authorities, as it gave, with little expense, information of great value concerning one of the most destructive of atmospheric impurities. He also referred to trials which were being made of a photo-electric method for recording daylight. If successful, this method will provide a virtually automatic means for measuring the amount of the sun's ultra-violet light cut off by smoke haze.

Mr. Beaumont of Halifax suggested that there was much more that local authorities could do to provide information about the effects of atmospheric pollution. He instanced that in Halifax, side by side with the deposit gauges recording the highest and lowest deposits, apparatus was employed in order to give information with regard to the sunlight received at those points. A large amount of useful information had been gained in that way, showing that, as compared with the less polluted station, the other lost about 25 per cent. of sunlight during the year, the percentage loss being greater in winter than in summer.

The members of the conference were agreed that the subject of atmospheric pollution needed much greater public attention, and that the scientific investigation of it should receive the support of all local authorities.

A. Patot, Warembourg, and Bédine (*Paris Méd.*, September 29th, 1934, p. 229) state that thoracic cancer is usually secondary to that of the alimentary canal and genital organs, particularly of the uterus; hence females are mostly affected. These neoplasms cause a symptomatic syndrome (Ménérié's) of oedemas, peritoneal and pleural effusions, supraclavicular adenitis, and thrombophlebitis of the jugulo-subclavian confluence. The oedemas commence in the lower extremities and gradually extend to the abdominal wall, in certain cases the left thoracic wall and left arm become infiltrated. The pleural and peritoneal effusions, evidenced by the usual signs of hydrothorax and ascites, may be serous, haemorrhagic, or chyliform, but rarely chylous. Left supraclavicular adenitis is frequently the only sign of thoracic cancerous invasion. Trossier's ganglions are those affected, and the adenitis may be mono-ganglionic or pluri-ganglionic. The diagnosis of thoracic cancer is of merely prognostic value; it is only evidence of a generalization of the cancerous condition, and death usually occurs shortly after its appearance. A typical case is fully described.

VITAMIN A AND NERVE LESIONS

The relation between dietary factors and the nervous system has occupied many workers for a long time, and there is no doubt that the experimental evidence tends more and more to substantiate such a relation. The importance of this work is at once obvious, and gives rise to hope that the problems of the obscure causes of the commoner degenerations in the nervous system will soon receive some measure of solution. The investigations carried out up to the present are of a somewhat drastic nature. The demonstration of distinct nervous lesions in animals fed for long periods on vitamin-deficient diets must be regarded as the necessary link in the chain of knowledge which will lead to the clarification of many problems of human neurology. Parallel with these studies of dietary factors (which are, after all, chemical factors) it is necessary to keep in mind the contributions of the pharmacologists and physiologists to the chemical or humoral theory of nervous transmission. The action of the vagus is no longer a mysterious inhibitory influence of a nerve ending on a special cardiac tissue, but a liberation of a chemical mediator which exerts effects indistinguishable from those of parasympathetic action. Similar conceptions have arisen in the matter of sympathetic action, and the theory of humoral transmission seems to have come to stay, for some time at least. It appears, then, that the proper transmission of nervous impulses requires the presence of chemical mediators between the nerve and the effector organ. The specificity of the chemical mediator is perhaps its most striking character.

In the matter of vitamins and hormones we are already so accustomed to the idea that minute quantities of specific substances are necessary for the normal processes of growth and metabolism, that the essentially remarkable nature of the phenomena is often overlooked. How do vitamins bring about their effects? What is the nature of the interaction of the relevant tissue and the vitamin? Indeed, we are not clear as to where the vitamin molecule acts. In the case of the xerophthalmia which results from vitamin A deficiency, for example, are we to suppose that the cure of the condition by administration of the vitamin is due to a direct action of the latter on the cornea? Some recent work by Professor Edward Mellanby¹ is of interest in this connexion. He starts from the two established sequels of diets deficient in vitamin A and carotene—namely, hyperplasia and metaplasia of epithelium and mucous surfaces with frequent secondary infection and the degeneration of medullated nerves both in the

central and in the peripheral nervous systems. It is interesting to note that as long ago as 1926 Mellanby showed that puppies fed on a diet deficient in fat-soluble vitamins developed severe nervous symptoms with incoordination as the most marked symptom. At that time he attributed the condition to hypothetical "toxamins" present in wheat-germ which he had added to the deficient diet. The effects were annulled by addition of butter or cod-liver oil to the diet; this was, of course, due to the vitamin A thus administered. In the present work Mellanby argued that it should be possible to correlate the epithelial changes with the nerve changes which arise from vitamin A deficiency. He therefore studied the histological changes to be found in the ophthalmic division of the trigeminal nerve and in the Gasserian ganglion when xerophthalmia had been established in rabbits fed on a vitamin A deficient diet. Careful examination revealed that when the corneal changes appeared there were in the corresponding nerve degenerative changes in the myelin sheaths. In early slight xerophthalmia cure could be effected by vitamin therapy in a relatively short time, with removal of the pathological changes in both the cornea and the nerve. The type of degeneration in the nerve in these mild cases was interesting, in that it was mainly a breakdown of the medullary sheath without invasion of the axis cylinder by the myelin droplets, and there was only a slight degree of swelling in the fibres. When, however, the corneal changes were very severe the degeneration of the nerve was of the typical Wallerian type, and cure was not nearly so successful as in the milder cases. In order to prove conclusively that the corneal changes are due to neurotrophic dysfunction it would be necessary to demonstrate that they always followed the degenerative changes in the nerve. This is a rather difficult matter, but it appears that when only one eye is affected by xerophthalmia the nerve of the other cornea rarely contains any degenerating fibres. Further, the author found definite evidence of pathological changes in the cells of the Gasserian ganglion, and he tends, on the whole, to the view that the sequence of events in this syndrome is degeneration of the ganglion cells, consequent demyelination of the afferent nerve fibres and later destruction of the axis cylinders, and, finally, the corneal changes resulting from the removal of neurotrophic supply. Arguing on analogy from these observations Mellanby considers the probability that many of the extensive changes in the respiratory, genito-urinary, and alimentary tracts, and the involvement of the optic, cochlear, and vestibular nerves, as well as of the posterior roots, may all have similar bases—namely, neurotrophic disturbances from afferent nerve degenerations.

The extensive nature of the lesions which may result from vitamin A deficiency is well illustrated in a recent communication by S. B. D. Aberle.² This author found that rats fed on vitamin A deficient diets frequently had foci of infection in the kidneys, cystitis,

¹ *Journ. Path. and Bact.*, May, 1934, p. 391.

² *Journ. of Nutrition*, April, 1934, p. 445.

pulmonary infection, and infection of the glands at the base of the tongue. In addition, lesions were present in the spinal cord, consisting of degeneration of the medullary sheaths of the sensory tracts at the periphery; in some this degeneration was found in posterior columns and in others in the posterior roots. These lesions were associated with a marked weakness or paralysis of the extremities. It is interesting that these symptoms only appeared in those animals which had been on the deficient diet long enough to cease growing or to develop xerophthalmia. Clinical cure could be effected by feeding cod-liver oil, but lesions were still demonstrable in the nervous tissue, which might have been expected to produce marked symptoms. It is suggested that the axis cylinder may function before the demyelination of the nerve is complete, which is supported by the findings of certain workers that stimulation of the motor cortex may elicit motor response before the cortico-spinal tracts are myelinated.

From the purely clinical point of view we have to consider how far these findings may secure application in the treatment or arrest of nervous disease. The necessity of certain minute quantities of specific chemical substances for the proper nutrition of nerve cells, nerve fibres, and the proper maintenance of trophic control, is what has now to be appreciated by the clinician. Hormones, vitamins, chemical mediators: these are the terms in which the future clinician will discuss the problems of neurology.

APPLIED HUMAN BIOLOGY

Professor J. B. S. Haldane is frequently provocative. His utterances always call forth thought, and sometimes dissent. This characteristic is no less evident than usual in his Norman Lockyer Lecture on "Human Biology and Politics," delivered last week under the auspices of the British Science Guild, and published in pamphlet form.¹ The subject itself, quite apart from the manner of its presentation, tends to produce reactions of prejudice and personal feeling not conducive to scientific calm, from which the corresponding applications of physics to industry or of general biology to agriculture and stock-breeding are relatively free. In order that "biology should not be harnessed to the car of any political party," Professor Haldane claims to have suppressed many of his own views and to have "tried rather to stress those opinions which enjoy a sufficiently general support"; but this will certainly not prevent controversy in connexion both with his main theme and with his preliminary observations about the medical profession.

This important parenthesis, which occupies some two pages of the sixteen to which the whole lecture extends, appears to be based upon an insufficiently intimate acquaintance with medical practice; to necessitate certain axioms, or at least postulates, which

cannot be accepted or granted; and to involve inferences which the premisses do not justify. To say that "though we do not go to an individual artisan for our car, we still go to an individual doctor for our healing," is to draw a parallel where none exists, and to give a very imperfect picture of the relation between doctor and patient. To state that "the application of science to other branches of life has led to increase in organization"—with the implication that to this the medical profession is an exception—is to ignore the very extensive organization both of the community and of the profession for purposes of individual and public health which has been so marked a feature of recent years. The assumptions that in the great majority of illnesses an individual patient is better treated by "a team of competent specialists" than by a general practitioner, or that such cases cannot be as well treated in the patient's own home as in a hospital, are entirely unwarranted. The reliance upon "adequate apparatus and laboratory facilities" does not require the removal of the patient from his ordinary surroundings, except in relatively few cases, and is at present being altogether unduly emphasized to the detriment of clinical medicine. The assertions that "the preventive and prophylactic side of medicine is represented by the medical officers of health, the school medical officers, and a few voluntary institutions," and that "under a system of individual medical attendance adequate disease prevention is almost impossible" are not in accordance with actual fact; and the reason given for the latter, that "it is far harder to detect latent disease in an apparently healthy person than to determine the nature of a disease already existing," would surely lead more correctly to an exactly opposite conclusion—namely, that individual medical attendance is essential. In spite of these misconceptions of the purpose and relations of medical practice the profession will, it is to be hoped, agree with Professor Haldane when he goes on to say that when "in the near future there would be an enormous demands for experts," largely for the purpose of killing or mutilating fellow creatures whose existence is deemed to be undesirable, or for "the enforcement of standards of reproduction," these officers should not be required to be members of the medical profession. Certainly such a requirement would revolutionize the relation between doctor and patient.

Professor Haldane's main theme in this lecture is that some form of family allowance offers the best safeguard against an undue diminution in the numbers and quality of the race. This thesis is developed in an extremely interesting way, though the conclusion is not unchallengeably established. The lecturer admits that he has said little that is novel, but the importance of his authoritative emphasis on three major propositions can scarcely be exaggerated at the present moment. These are as follows. In the near future there will be a marked reduction in the population of those countries (except, perhaps, Russia and Japan) which are collectively described as "Western civilization," and unless the present fertility rate greatly alters this

¹ The Norman Lockyer Lecture, 1934 "Human Biology and Politics," by Professor J. B. S. Haldane, M.A., F.R.S. The British Science Guild, 6, John Street, Adelphi, W.C.2. (1s.)

diminution will rapidly become catastrophic. Sterilization of defectives, whether physical or mental, will have only a very small eugenic effect, and would carry with it other consequences which cannot be viewed without alarm. There is no evidence that the children of the poorer classes are innately inferior to those of the richer classes. The facts and illustrations with which the lecturer supports these propositions, though necessarily briefly stated, are of much value, and are in some instances presented in a novel form. Probably most people will accept Professor Haldane's minor conclusion that "our population is ill distributed rather than too large"; though the evidence offered that once when climbing Snowdon he met no one on the way is not, of itself, adequate. As a matter of fact, on a fine day in certain months there are quite considerable numbers who ascend that mountain, and in other circumstances the reward for the exertion does not offer that exhilarating outlook which is associated rather with Mount Pisgah or a peak in Darien.

THE GENERAL MEDICAL COUNCIL

An unusually light session was disposed of by the General Medical Council in four days. Of the thirteen disciplinary cases, seven had been postponed from previous sessions; the facts had been proved, but an opportunity was given to the practitioner to submit testimony of his good conduct in the interval. Sometimes a practitioner upon whom judgement had been postponed appears to suppose that if no further complaints are made against him in the interval his case is automatically discharged. The Council insists, however, upon proper testimonials as to conduct, and one practitioner this session who had neglected to obtain testimonials from medical men with whom he had been in close association had his case referred forward for another six months, when he will have to appear again. In another case, however, a practitioner who at a previous session had been found to have canvassed the patients of other practitioners, now appeared with a sheaf of letters from medical men in his locality testifying not only to his unexceptionable conduct but to his willing co-operation in professional affairs.

As a result of the disciplinary inquiries only two practitioners were struck off the *Register*, one (who did not appear) for adultery with a patient, and the other for repeated convictions for drunkenness. The case which occupied the longest hearing was rather an obscure one from Singapore, where a practitioner had had his name erased from the Register kept by the Medical Council of the Straits Settlements for alleged wrongful certification. There was a sharp conflict of testimony, but all the evidence, except that of the practitioner himself, was by way of depositions and other documents. Eventually the charge was dismissed by the Council, so that the practitioner's name remains on the Colonial List of the *Medical Register*, while presumably it remains expunged from the local Register at Singapore. One case which appeared to raise a fresh point in professional practice so far as the Council is concerned was that of a practitioner who was brought up, on the complaint of a patient, for undue charging

for appliances supplied. It was alleged by the complainant that in the course of professional treatment the practitioner offered to get his spectacles repaired, and also, later, to procure him a new pair, representing that he had an interest in the optical company. The practitioner charged him two guineas for the new glasses, which had actually cost him only 7s. 10d., and half a guinea for the repairs, which had actually cost him not much more than a quarter of that amount. The practitioner claimed that included in the first transaction was the service of testing the lenses, taking the measurement of the frames, sending the prescription to the optical company, and checking the spectacles on delivery. In the course of the hearing it was established that the practitioner had no interest in the optical company. The solicitor defending him made the point that he did not stand alone among the members of his profession in obtaining appliances or material at a wholesale price or discount and retailing them to the patient at a higher price. This was a practice, he said, on which the Council might at some time desire to make a pronouncement, but he protested that in the absence of any warning notice it would be unfair to make an "example" of this practitioner. In the result, having in view the fact that the practitioner had no interest in the optical company, and that the patient in the county court had already secured an abatement of these charges, the Council took no action.

HEREDITY AND TUBERCULOSIS

The conception of the inheritance of tuberculosis, unquestioned from the days of Hippocrates to the middle of the nineteenth century, seemed the logical conclusion from the clinical observation—the sole available then—of the frequency of the disease in children of consumptive parents. Villemin's demonstration that tuberculosis could be transmitted to rabbits and Koch's discovery of the bacillus were responsible, not unreasonably, for a complete swing of the pendulum afterwards. In more recent times, however, increasing support is found for the view that post-natal factors alone will not entirely account for the varied course which tuberculosis takes in the human race, and that the "soil" (or *terrain*), in the form of an inherited predisposition, may play a part. The importance of this consideration is obvious, particularly at present, when eugenics and sterilization are widely discussed topics. A serious contribution to the subject, like that represented by the work of Diehl and v. Verschuer,¹ therefore deserves attention. Their well-produced and beautifully illustrated book gives full details of an intensive study of 127 pairs of twins, in 106 of whom at least one of the pair showed some active or healed tuberculous manifestation. It is of interest to indicate how their material was obtained, as further work on similar lines might profitably be carried out by others. Several hospitals and tuberculosis institutions in Berlin and elsewhere undertook to ask every patient if he was a twin. In addition, the "visitors" of tuberculosis welfare organizations agreed to make constant inquiries for twins on their rounds. A few pairs were obtained through interested laymen or colleagues. In every case

¹ *Zwillings-tuberculose* (Zwillingsforschung und erbliche Tuberkulosedisposition). Von Karl Diehl und Otmar Frhr. v. Verschuer. Jena: Gustav Fischer. (M.30.)

the information was forwarded to the authors, who then tried themselves to examine the patient and his twin—if living—either in hospital or at home. The examination was not only carried out to determine accurately the nature of the tuberculous lesion, but also included full anthropometric investigations. The twins could thus be classified as uni- or bi-vitelline and be grouped into constitutional "types." When information obtained second hand was unreliable or inadequate the twins were excluded from the series. Those finally collected consisted of forty-five univitelline (nineteen male and twenty-six female), fifty-three bivitelline of the same sex (twenty-five male and twenty-eight female), and twenty-nine bivitelline of opposite sex. All ages were represented in each of the three groups, the average being roughly 21 years. Concordance or discordance with regard to tuberculosis was determined by considering whether both twins had a tuberculous lesion; its activity, extent, pathological type, and duration; the organ involved; and the situation if in the lung. Correlation on similar lines was worked out with environment and family history. While identical tuberculosis findings in twins need clearly not have been influenced by a hereditary factor, but may be due entirely to the similar environment in which the pair have lived, especially in early life, this argument applies equally to uni- and bi-vitelline individuals. Diehl and v. Verschuer, after detailed analysis of their material, found, however, that when the environment and conditions of contact of a pair were such that the disease was expected in both twins, and yet only one was tuberculous, by far the largest proportion of the cases were bivitelline. Moreover, they show that, while 70 per cent. of the thirty-seven univitelline twins had "tuberculosis concordance," this was present in only 25 per cent. of the sixty-nine bivitelline. They conclude that heredity plays an important part in the origin and course of tuberculosis, and that this influence becomes more evident with increasing age. Finally, they discuss whether this hereditary predisposition is specific (involving morphological, immunological characters, etc.); non-specific—that is, associated with a constitutional "type"; or a combination of both. Examination of their material leads them to reject the last two hypotheses. A chapter on eugenics closes a most original and stimulating account. In a book² published a little more recently F. Ickert and H. Benze carefully analyse the genealogical trees of eighty-eight families in which cases of tuberculosis had occurred. They reach conclusions similar to those of Diehl and v. Verschuer, and suggest that the specific hereditary disposition is transmitted as a recessive factor. They admit, however, that their work is necessarily subject to greater "experimental" error. Finally, it must be added that Redeker³ has strongly criticized the work on twins, asserting that the identical findings in the univitelline pairs are accounted for by the similar "endogenous basis" (*gleiche endogene Grundlage*); and that both pairs of authors admit the part played by environmental factors (*Modifikationsfaktoren, Hilfsfaktoren*).

FORMATION OF THE CORPUS LUTEUM

The endocrine influences associated with the events of the ovarian cycle are now well known in general outline. The paramount importance of the anterior pituitary cannot be doubted. Implantation of minute fragments of the anterior pituitary in infantile or senile animals produces either premature function in the former or restored function in the latter, with ripening of the Graaffian follicle and the formation of a corpus luteum. The follicle is, from the endocrine point of view, concerned with the production of folliculin (oestrin), and the corpus luteum is said to form a hormone (progesterin) which stimulates the uterine mucosa to undergo the necessary proliferation for satisfactory nidation of the fertilized ovum. Whilst the view of Zondek on the formation of the corpus luteum and progesterin is that the anterior pituitary is the motivating influence, certain other workers have put forward the hypothesis that the maturing ovum produces a hormone specially concerned with this part of the cycle. In some recently published work Zondek has described experiments on the bat which he interprets as showing that the ovum is not concerned with the formation of the corpus luteum. The ovaries of a bat during hibernation are functionally inactive, but one or two of the follicles are enlarged. When, in the spring, these follicles rupture, the liberated ova are at once fertilized, because spermatozoa are present in the uterus and have remained there throughout the period of hibernation, following copulation which took place before the winter sleep. If during this quiescent period anterior pituitary hormone (prolan) is injected pregnancy can be brought about, since the follicle is thus made to rupture. If, however, large doses of prolan are injected many more follicles may reach the luteal stage than ever occur physiologically. Further, with such doses the ovum may not be extruded at all, but be pressed to one side by the proliferating luteal cells; no maturation of the ovum will occur, and it may be destroyed. In spite of this a functional corpus luteum is formed. Although this is suggestive evidence against the hypothesis that the ovum is responsible for corpus luteum formation, it is not conclusive, since it might be argued that the ovum had already produced its hormone before its destruction. Zondek, therefore, in his most recent paper,¹ pursues the matter in a more direct way. It has already been demonstrated by the English workers Fee and Parker that if the pituitary of the rabbit is removed within one hour of copulation there will be no discharge of an ovum and hence no corpus luteum, but if the pituitary is removed more than an hour after copulation then a corpus luteum will follow in the ordinary way. (In the rabbit ovulation occurs only after copulation.) It seems clear, therefore, that copulation leads to a liberation of anterior pituitary hormone which in something over an hour is present in sufficient quantities to lead to ovulation and corpus formation. Zondek, however, goes further. He used mature female rabbits, and, choosing a good mature follicle, aspirated the follicular fluid and ovum out of the cavity and cut away the cupola of the follicle, leaving a readily recognizable field. In such ovum-less follicles luteinization could be produced by intravenous

² *Stammbäume mit Tuberkulosen*. Von Franz Ickert und Hans Benze. Leipzig: Verlag von Johann Ambrosius Barth (Tuberkulose-Bibliothek, No. 55)

³ Quoted by Ickert and Benze.

¹ *Journ. Physiol.*, 1934, **lxvii**, 472.

injection of anterior pituitary hormone from pregnancy urine. Further, in order to exclude any possible influence of neighbouring ova, Zondek chose a mature follicle and resected all the surrounding ovarian tissue, taking care to leave the blood supply intact. The other ovary was extirpated and the isolated follicle was freed from its fluid and ovum by aspiration. Again, a corpus luteum could be produced by injection of anterior pituitary hormone (prolan). It thus appears clear that the anterior pituitary is responsible not only for maturation of the follicle and ovulation, but also for the formation of the corpus luteum and hence the nidation hormone progesterin. But we have still to consider what is responsible for the persistence of the corpus luteum after fertilization, and its continued production of progesterin. Indeed, the life and development of the fertilized ovum depend upon this persistence. It is here that the ovum seems to exert its hormone-like influence, for it appears to make the anterior pituitary increase its prolactin production and hence motivate the persistence of the corpus luteum. This is probably the rationale of the Aschheim-Zondek test for pregnancy.

AETIOLOGY OF ARTERIAL HYPERTENSION

Of those who have investigated the causes and treatment of high blood pressure few will disagree with Dr. S. Weiss¹ that the present state of our knowledge of these problems must cause embarrassment and humility. For although it is true that hypertension has been produced experimentally in animals, and that we know of many lesions in man with which it may be associated, neither throws much light on the vast majority of clinical cases of the symptom. Circulating pressor substances, abnormal nervous impulses, and local mechanical causes are perhaps the chief groups into which suggested causes may be classified. Weiss considers the evidence for the first—in which are included guanidine, cholesterol, pituitrin, adrenaline, thyroid secretion, and lead—as inadequate. The rare paragangliomata of the suprarenal medulla, known to be associated with high blood pressure, would seem to be significant, yet it is held that a direct connexion is still undetermined; and a similar conclusion is reached in regard to the basophil adenoma of the pituitary, while experiments to test the hypothesis that pituitrin is concerned in the high blood pressure of pregnancy toxæmia have given conflicting results. Abnormal secretion by the thyroid is held to play no part in arterial hypertension, yet evidence is accumulating which strongly suggests that it does in fact play such a part. Some German workers claim that pressor substances can be shown to exist in the blood of patients with "pale hypertension"—that is, associated with glomerulonephritis, malignant hypertension, and eclampsia—by the injection of concentrated extracts of such blood into animals; but other workers, including Weiss and his collaborators, have found that pressor substances can be isolated from hypertensive patients and normal subjects alike, and Weiss found that the most potent extract was obtained from the urine of the normals. Alcohol and tobacco, as few would deny, are exonerated from blame in the causation of high pressure. It is admitted, however, that lead is occa-

sionally responsible. Among the hypotheses implicating a disturbance of the nervous regulation of the circulation there is the suggestion that there may be depressed activity of the carotid sinus, as experimental destruction of the nervous connexions of the sinus has led to hypertension in animals. The response to mechanical stimulation of the sinus in hypertensives is found, however, to be exaggerated rather than diminished, while studies of the structural changes in the sinus show no correlation between these and the height of the blood pressure. Patients with hypertension are often stated to have a distinctive type of personality, to be emotional, and to have a highly strung, driving personality. While this may be true, the exceptions are numerous, and there is also the problem as to how far such characteristics may be secondary to the hypertension. Thirdly, there are the views based on primary mechanical changes in vessels increasing circulatory resistance, such as excessive sclerosis as an exaggerated senescent change, occurring in congenitally hypoplastic arterial systems; vascular sclerosis in chronically inflamed kidneys; local vascular changes in the vasomotor centre leading to ischaemia and hyperactivity of the centre; and loss of elasticity in a degenerated aorta. A review of our knowledge—or better, perhaps, of our lack of knowledge—on the subject of hypertension appears to show, at least, that not only are there multiple factors tending to produce this symptom, but that several may be involved in any given case. One of the few positive things known is that it tends to be a familial condition, and the primary constitutional characteristics of the patients probably play a most important part. Given this primary disposition, a number of secondary exciting factors are capable of producing hypertension, and at present the only rational treatment is the prevention or elimination of these factors.

THE GALACTOSE TOLERANCE TEST

The liver occupies a unique position among the major viscera in that its disorders are betrayed by few characteristic signs, and none which in themselves give a trustworthy indication of the degree of damage sustained or of the prognosis. A dependable test of liver function affording such evidence would therefore be of great value, and several procedures based on various metabolic functions of the liver have been proposed for this purpose. The majority of these appear to fail because the functions studied can be carried on adequately by only a fraction of the normal liver tissue; damage has therefore to be very extensive to afford conclusive indications by such means. Of the test substances administered galactose has most to recommend it, since it is metabolized only in the liver, and there with difficulty, while the kidney excretes it irrespective of its concentration in the blood. The work of Shay and others² showed that the normal liver can convert about 40 grams of galactose into glycogen, only traces—and in any case not more than 3 grams—appearing in the urine; whereas in liver disease this amount may be considerably exceeded. These observations are confirmed by K. A. Owen,² who emphasizes the value of the test in distinguishing between

¹ *Ann. Int. Med.*, September, 1934, viii, 286.

² *Arch. Int. Med.*, 1931, xlvii, 650.

³ *Journ. Lab. and Clin. Med.*, 1934, xix, 1311.

obstructive jaundice and jaundice due to hepatitis or hepatic degeneration: the average amounts of galactose excreted by patients in these respective groups after a 40-gram dose were 0.87 gram and 5.22 grams. An analysis of his results also suggests that the test is a useful guide to prognosis. It appears, therefore, that the oldest of liver function tests (for it was first suggested by Bauer in 1906) is still perhaps the most useful. One of its features is puzzling: if the amount of galactose with which the liver can deal is so exactly limited, why does not this amount vary with the body weight? In both Shay's and Owen's somewhat limited series of tests in normal subjects such variation is not discernible.

HEALTH AND THE ARCHITECT

The catalogue of the present international exhibition at the Royal Institute of British Architects reminds us that what some acclaim as the loveliest piece of architecture of the seventeenth century, the colonnade of the Louvre, was designed by a doctor. This was Claude Perrault, who achieved success as a physician and anatomist, and became a martyr to anatomy, contracting a fatal infection at the dissecting table. The writer might have added that his great contemporary, Christopher Wren, was an anatomist before he was an architect. Since those times, however, architecture has become a distinctive profession, and the doctor's part in planning to-day is chiefly in collaboration with the professional architect over hospital drawings and the most workable disposition of equipment and services. The exhibition in Portland Place is designed to show the importance of the architect in an ordered civilization. One section is devoted to planning for health, and includes photographs and models of outstanding hospitals built during the last ten years. In hospital architecture the same note is struck as in modern architecture with other purposes. In American hospitals, such as the new Cornell Medical Centre in New York City, vertical treatment seems to be usually followed, as contrasted with a horizontal treatment in England. But whatever the external impression the prevailing principle in hospital design everywhere is that the ward is taken as the unit, and all other sections are disposed as the wards dictate. This is only to say that in all worthy hospital architecture everything is subordinated to the healing and comfort of the patient. A number of experiments in ward design are exemplified, such as the placing of beds parallel with the walls, which has the advantages that the patients do not face the light, that the radiators are at the foot of the bed, and that greater privacy is possible by means of curtains, as contrasted with the more usual arrangement with the beds at right angles, the chief feature of which is ease of supervision. Careful thought is given to the patient, again, in such an arrangement as that at the Royal Hospital, Wolverhampton, where out-patients, after treatment in any of the rooms, leave the building without re-entering the waiting hall. One interesting exhibit shown in section is a complete unit for the Birmingham Hospital Centre, including two sixteen-bed wards, four four-bed wards, and six two-bed wards. Again, in the views of the Kent and Sussex Hospital at Tunbridge Wells one is struck by the singularly clean and charming effect in the children's wards, or in

those of the Royal Masonic Hospital at Ravenscourt Park by the admirable disposition of the operating theatres and sterilizing rooms so as to afford maximum ease in administration. Schools also, particularly from the point of view of open-air planning, form an interesting section of the exhibition, and it is extraordinary what ingenuity is expended by architects on gymnasiums and swimming baths. The exhibition is open free until January 3rd, and visitors should take the opportunity of seeing something of the new building of the Royal Institute, itself an expression of the best architecture of the present renaissance.

ARTICLES FOR THE GENERAL PRACTITIONER

We publish to-day at page 1059 the first article—on the treatment of influenza, by Lord Horder—of a series on the management of major medical disorders met with in general practice. The writers of these articles are men who devote much of their time to the teaching of clinical medicine, and our object in inviting their co-operation has been to present to readers of the *British Medical Journal* accurate and detailed information on current therapeutics. This information should be of value both to the young medical man setting up in practice for the first time and to the older practitioner who wishes to revise his knowledge. It is plain that the whole field of medicine cannot be covered in such a series, but an attempt has been made to include the common conditions and those which, though less frequent, nevertheless constitute medical emergencies. The best means for meeting a need that is felt by a very large and important section of the members of the British Medical Association has been under consideration during the past year or two. It was recognized that much of what is new in medicine nowadays finds its way into print in the numerous specialist journals that have sprung up during recent years, and that a proportion of what is printed in the *B.M.J.* and the *Lancet* must necessarily make its chief appeal to specialists. The practitioner who reads his journal each week from cover to cover—and we are well aware that some do so—would no doubt be fully acquainted with what is new and keep himself reminded of what is old. But art is long and the life of patients short, and the spare time of the busy doctor shorter still. While, therefore, the scientific standard of the *Journal* must be maintained in fulfilment of one of the primary objects of the British Medical Association, it is proposed in this and later series of articles to adopt a more pragmatic attitude towards medical knowledge, and to try in a practical manner to keep supple the backbone of the medical profession—the G.P.

We are asked to state that the third informal Conference of Cancer Research Workers, organized by the British Empire Cancer Campaign, will take place on Wednesday and Thursday, December 12th and 13th, at the rooms of the Medical Society of London, Chandos Street, W. An informal dinner will be held at the Langham Hotel on the evening of Wednesday, December 12th. Further information may be obtained on application to Mr. Cecil Rowntree or Dr. R. G. Canti, joint honorary secretaries of the organizing committee, at 12, Grosvenor Crescent, S.W.1.

S. COCHRANE SHANKS: THE STOMACH AND DUODENUM AFTER OPERATION

FIG. I.—Male (60), 21/9/33. Normal x-ray appearance after Polya-Lake. Note satisfactory control of efflux.

FIG. II.—Male (21), 17/10/33. Normal x-ray appearance after gastro-jejunostomy for duodenal ulcer in 1929.

FIG. III.—Male (49), 15/12/32. Polya-Lake in September, 1931, for scirrhus carcinoma. Recurrent obstructing the efferent limb of the jejunal loop. Duodeno-jejunal ileus results.

FIG. IV.—Male (47), 12/1/33. Gastro-jejunostomy for duodenal ulcer in 1912. Symptoms recurred in two years. X-ray examination shows large jejunal ulcer.

FIG. V.—Male (45), 18/12/33. Gastro-jejunostomy for gastric ulcer in 1913. Laparotomy in September 1933, for jejunal ulcer. Anastomosis undone. Barium meal shows the stoma to be closed, gross irregularity of the pyloric antrum and duodenal bulb, and a duodenal ileus.

FIG. VI.—Male (40), 13/6/31. Post-operative gastro-jejunostomy complicated by periastric carcinoma. Slight stomal stenosis and well-marked jejunal ileus.

S. E. TANNER AND A. L. McCURRY: UVEO-PAROTID TUBERCULOSIS

FIG. 1.—Case 1. Radiogram showing enlarged lymphatic glands in the mediastinum.

FIG. 2.—Case 1. Radiogram showing appearance one year later.

FIG. 3.—Case 2. Photomicrograph of section of parotid gland showing areas of tuberculous granulation tissue with giant cells and endothelial cells, but no caseation.

FIG. 4.—Case 2. Photomicrograph of section of parotid gland of higher magnification, showing two giant cells and endothelial cells.

STANLEY J. HARTFALL AND LESLIE N. PYRAH: MEDIASTINAL AND APICAL EMPYEMA

FIG. 1.—Radiogram showing subapical and mediastinal empyema, taken on eighth day. FIG. 2.—Six days later, showing satisfactory drainage, apical shadow and reduction in size of mediastinal shadow. FIG. 3.—Thirteen days later, showing apical loculus almost drained and mediastinal shadow shrunk to a narrow strip.

J. S. MANSON: HEREDITARY SYNDACTYLISM AND POLYDACTYLISM

FIG. 1.—Showing digital abnormalities of mother and three children.

FIG. 2.—Radiogram of "W's" hands, showing webbing of third, fourth, and fifth digits, and fusion of third and fourth metacarpal bones.

TREATMENT IN GENERAL PRACTICE

This article is one of a series on the management of some of the major medical disorders met with in general practice

THE TREATMENT OF INFLUENZA

BY

LORD HORDER, K.C.V.O., M.D., F.R.C.P.

Preventive Treatment

Against epidemic waves of incidence of the disease we have as yet no remedy. Nor have we any means of lowering the susceptibility of the individual against being attacked. It is commonly held that to maintain a high standard of general health is a safeguard, but in the epidemic of 1918-19 the incidence of the disease was higher in young adults and adults than in children and the elderly, as also was the mortality; nor did persons of apparently poor physique seem to suffer so much as the apparently robust. The virus of influenza, in other words, unlike tubercle and the more chronic pyogenic infections, does not attack only, or even chiefly, persons of low general resistance.

Specific measures of inoculation, or of passive immunization, are not available as yet. By analogy with other virus infections the serum of convalescent patients may possibly be of protective help, but efforts in this direction lie with future epidemics. The only form of prophylaxis so far available is inoculation against the secondary infections of the disease. These are, however, of great importance, and such inoculation is to be recommended. Of the various formulae used, one which is made up in the proportions 2:1:1:1 for *B. Pfeiffer*, pneumococcus, streptococcus, and *M. catarrhalis* respectively, is perhaps the best; but the composition of a vaccine of this kind should be adapted to the prevailing epidemic. From 25 to 1,000 millions of such a vaccine may be given, in graduated doses, at intervals of three clear days.

Curative Treatment

Immediately the diagnosis is made—or even before this, because the sudden onset of fever, with or without respiratory symptoms, is unlikely to carry diagnostic conviction during the first two or three days, unless an epidemic be prevalent—the patient is confined to bed. The room should be as airy as possible and, by preference, warmed by a coal fire. A free current of air is probably the most important single point in the whole treatment. If both ventilation and warmth cannot be obtained at the same time, then give preference to ventilation. The bed should be placed as near the centre of the room as possible, and all articles of furniture that are not required for nursing, and all bric-à-brac, should be removed from the room.

The bedclothes demand special attention. The amount of them is to be determined by the height of the thermometer, not by the patient's sensations. This is a cardinal point, and nurses scarcely ever understand it unless it is explained to them. Quilts and bed-covers are disallowed. If the pyrexia is persistently high the cradle method of control, formerly so useful in typhoid fever, is excellent. Frequent sponging is also of help in reducing fever; it adds considerably to the patient's comfort and tends to induce sleep. The temperature of the water used is to be adjusted to the height of the fever.

Diet and Drugs

The diet should be restricted to warm liquids, given every two hours by day and every four hours by night if the patient is awake. The total intake of liquid should not be less than four pints in twenty-four hours. The drinking of plain water, cold if preferred, is to be encouraged. "Feeding up" is to be deprecated. In most cases alcohol is unnecessary. The bowels are opened by a double dose of the patient's customary aperient; if there be none, give calomel in 1/4 grain doses hourly for four or six doses, and follow this by a saline draught.

There is no specific drug. Aspirin and Dover's powder, given in doses of 5 grains of each and repeated at intervals of six hours, for four to six doses, help to control the fever and allay the headache and general discomfort. (Alternatives are ammoniated tincture of quinine in half-ounce doses or salicin in 20-grain doses, at the same intervals.) If the headache is severe and is not relieved by these measures give a mixture of phenacetin, caffeine, and antipyrine, 3 grains of each, every three hours for four doses. In the case of all drugs a draught or a powder should be ordered, not tablets. When gastric symptoms are troublesome a mixture of sod. bicarb., sod. sulphocarb., and bismuth oxycarb., 5 grains of each, with glycerin of carboic acid 10 minims, in peppermint water, may be ordered four- or six-hourly. If vomiting is present reduce feeds to a minimum, giving rectal salines with glucose 10 per cent., and order 1 minim of tinct. iodi in a teaspoonful of water hourly for six or eight doses.

In the majority of severe cases respiratory symptoms are present. Treatment is then as for acute bronchitis: temperature of room not below 60° F.; a lightly made "pneumonia jacket"; an evaporating liniment such as lin. camph. et terebinth. equal parts; and a "sedative expectorant," such as ammon. chlor. 5 grains, vin. ipecac. 5 minims, tinct. scillae 5 minims, tinct. camph. co. 10 minims, syr. pruni virg. 20 minims in water, six-hourly. For the cough, if this be persistent and exhausting, as is not seldom the case, order an inhalation of tinct. benzoni co., and spray the upper air passages with 2 per cent. each of chlorotone and menthol in paraffin, adding cocaine 1/2 per cent. if necessary. A linctus, such as syr. cocillanæ co., or syr. codeinae, or tinct. terperoin, may also be tried. Failing these measures—and the cough may be very intractable—order a mixture of ammon. brom. 20 grains with syr. chloral 20 minims and bromoform 1 minim in aq. glycyrrhizae every two hours for four doses.

Sleeplessness calls for a revision of the general measures (v.s.): ventilation, hydrotherapy, diet, etc. Alcohol may now be useful, especially in elderly subjects. Try first a draught of ammon. brom. 20 grains with one drachm of syrup of chloral. If still troublesome, order paraldehyde in one-drachm doses, with tinct. quillaiae and tinct. aurantii 20 minims of each to cover the taste. Or give a hypodermic of 1/4 grain morphine with 1/120 grain atropine. The barbiturates are better avoided.

If heart failure threatens alcohol is indicated, and is best given as brandy, in half-ounce doses every four hours in water. It is better not to mix it with the feeds. Supplement this by strychnine 1/60 grain twice during the day and coramine (synthetic camphor) 1 c.cm. twice during the night. Suprarenal solution (1 in 1,000) 0.5 c.cm.

may be substituted for either of these. If the condition remains serious give an intravenous injection of strophanthin 1/250 grain in 15 minims of sterile saline solution with an ordinary hypodermic syringe, and repeat this in six to eight hours' time.

Convalescence

Convalescence must be watched with care in all cases, even in those which do not give much concern during the active stage of the disease. The patient must not be allowed out of bed until the pyrexia has ceased for at least four days. In cases of longer duration than a week this period of recumbent rest after the fall of the temperature should be extended. The state of the heart and the pulse rate must be carefully noted, and any failure to respond satisfactorily to the initial trial of physical effort must be met by further rest. The diet may be now increased, and mild tonics and haematinics may be ordered, but strong stimulants, whether cardiac or nervous, are usually contraindicated.

A complete overhaul, especially in regard to the heart, lungs, and nervous system, should be undertaken a week after the patient gets up, and again a month later. By these means, and by appropriate measures of treatment if any disturbing feature be brought to light by the examination, many of the tiresome sequelae of the disease may be avoided.

OBSTETRICS IN INDIA

BY

RUFUS C. THOMAS, F.R.C.S.Ed., M.C.O.G.

CHIEF MEDICAL OFFICER TO HIS LATE HIGHNESS MAHARAJAH JAMSAHEB OF NAWANAGAR

Much has already been written on the subject of obstetrics in India. The mortality rate, both among mothers and among newborn children, always finds a place in every census report, and that these rates are very high is well known. Attempts are invariably made to reduce them to percentages, but such statistics are at best only approximate, for several reasons. Stringent rules as to the proper notification of the cause of death are the exception rather than the rule. There is no legal necessity for a medical certificate. Thousands of deaths occur annually without the attendance of a medical practitioner. The supply of doctors is grossly inadequate to the population, medical advice being therefore the exception. Even where such advice has been available, no certificate is asked. Cremation or burial takes place as soon as possible, and no question arises unless there are suspicious circumstances, which might often escape notice. In most instances death is notified by a relative, who makes his own diagnosis, or the cause is inferred from his statement. Such haphazard methods render all statistics unreliable.

Take the case of a woman who dies of puerperal fever ten days after her confinement. Her husband would say she died of fever, and make no reference to the confinement at all: the body will have already been cremated, and the ashes scattered to the four winds or thrown into the river. Post-mortem examinations are extremely rare, and are undertaken chiefly by police request in cases of suspected foul play. I often tried to obtain permission for a post-mortem, but never succeeded once in six years. It was looked upon as a desecration of the dead. The cause of death mattered nothing, and the interests of science still less. During my six years in Jamnagar, the deaths regularly exceeded the births to judge by the notifications, and yet at the census the population was found to have increased by many thousands. Obviously this could not have been entirely due to immigration. Exact figures are therefore an impossibility. Those available must be looked upon as erring on the low side. Comparisons between different parts of India are equally impossible. All one can do is to accept the statement that maternal and infant mortality reach limits which can only be described as colossal.

Hospital Facilities

In this paper I propose to give a short résumé of the conditions as I saw them in a State the population of which was roughly 450,000 and the area 3,500 square miles. During the last four years it had a women's hospital, into which many labour cases were admitted from all parts of the State. During the first twelve months the female hospital was not open, and confinements were only rarely admitted, and then into the male hospital. This fact, together with a complete absence of any nursing staff, is quite sufficient to account for the small number of female admissions. The following year, 1928, I opened and equipped the female hospital, engaged the services of a very able and painstaking lady doctor, a graduate of Bombay University, and began to collect a staff of nurses, the nucleus being four Indian women with Bombay Presidency Nursing Association certificates.

I had, six months before, started a women's clinic, spending three mornings a week there myself. Up to this time I knew it was an almost unheard-of thing for Indian women to permit examination by a male doctor, and I was prepared to encounter great difficulty in this respect. I found, however, that with a little persuasion most of them were quite sensible, and the clinic rapidly became popular. After a while, refusal of an examination became a rarity. The number of women attending was often thirty to forty, which proved the necessity of the clinic. Naturally, when the lady doctor took over, the numbers rose rapidly, so that two years later I had to engage a second lady doctor.

It might be thought that in Jamnagar, with a women's hospital ready to receive labour cases at any hour, and an ambulance service which I had organized about the same time at the disposal of the public at a moment's notice, no woman should be in labour for more than a day or two without receiving assistance. This was actually far from being the case. It was many months before the public would take advantage of the hospital to any extent at all. I often admitted women whose confinements had been in progress for three or four days but whose homes were within a mile or two of the hospital. The first year the women's hospital was open the total confinements amounted to about twenty-five. Most of these were cases of delayed labour brought in by ambulance from neighbouring villages. The number from Jamnagar itself was very small. The next three years saw considerable improvement, and over 150 cases were admitted in 1932-3.

There was obviously some very strong influence at work, preventing the women from taking advantage of the facilities offered. All food, dressings, drugs, and accommodation were free, and there was a full and properly trained staff. And yet there was this great unwillingness to come into hospital. For the first year or so cases came in only as a last resource. I concluded there were three main reasons for this. First came the purdah system, with its ingrained mistrust and dislike of allowing women to leave the shelter of their own homes. It mattered not at all that these homes were often squalid and insanitary in the extreme, and that the hospital was a palace in comparison. The purdah system also precluded the attendance of a male doctor on the unfortunate woman, so that she was from first to last in the hands of that menace to the pregnant woman in India—the "dhai," or native midwife. And the dhai was the second reason why women were so long availing themselves of their opportunities. The third was a fatal apathy on the part of the people themselves, by whom I mean the relatives. Life is cheap in India, and wives, I suppose, rarely come by.

Native Midwives

The part played by the dhais needs more consideration. These women are responsible for most of the evils and suffering borne by the women of India. Members of the lowest class, outcaste and unclean, they are ignorant of all knowledge of midwifery, and dirty in the extreme. A woman in labour is considered in India to be unclean, and so, by a process of perverted reasoning, must only be attended by another unclean woman. For the same reason all clothes used for the confinement are the dirty

remnants of the house which cannot be used for any other purpose. Antiseptics and clean hands are not part of the armamentarium of the dhai. The only qualification necessary, as far as I could gather, was membership of the outcaste community which always did this unclean work. I suppose they were taught their trade by their mothers, who were dhais before them. As no dhai ever had any knowledge of the mechanics or pathology of labour, the true worth of any teaching can readily be assessed. So far from being a help to their clients, they were the greatest danger imaginable. Cases which, if left to themselves, might have had a normal labour, were infected by the interfering dhai, and their chances damned from the outset. She fails almost inevitably to recognize an abnormal presentation, until, perhaps, an arm or a leg presents at the vulva. If no such outward or visible sign affords a warning that all is not well, then only the lapse of time or the obviously critical condition of the woman serves to bestir the relatives. Even if the dhai realizes that something is amiss, I strongly suspect that she will conceal the fact in the vain hope that "time" will right matters and save her prestige.

The presenting of an arm or a foot does not always mean that help is sought at once. The dhai will seize the presenting part and endeavour by main force to deliver the child. It was no rarity to admit cases in which an arm had come down twelve hours before, this interval having been well utilized by the dhai in attempts at forcible traction till the arm was almost denuded of skin. I have known a transverse presentation which the dhai had endeavoured to terminate by passing a hook into the uterus in an attempt to drag the foetus out by whatever part the hook engaged around. No attempt had been made to sterilize the hook. In another case the dhai had attempted to deliver the child by hand, and on admission the woman had a complete perineal rupture extending into the rectum, the vulva being nothing but a mass of bruises and oedema. The child was still undelivered. Several cases came in moribund but undelivered, with their babies already dead and mutilated in this way. Cases of placenta praevia were sometimes allowed to bleed for hours before assistance was sought. When the dhai became "active" and resorted to means of hastening labour, the chances of her patient recovering rapidly receded. One favourite method of increasing labour pains is to place a ball of native medicine in the vagina, as near the cervix as possible. This ball is made up of irritant substances rolled together with bits of string or old cloth, the whole being about the size of a small orange. Other means were employed at the same time, such as kneading and thumping the abdomen with the fists, or even treading it with the bare feet.

Conditions Met With

Under such appalling conditions, how can the mortality be anything but incredibly high? And if the victim survives, what wonder that pelvic infection and uterine displacements are the lot of most of them?

Puerperal fever is the natural outcome of such a state of affairs. It was always of a severe type. Many of the cases were ill nourished, the subjects of chronic malaria, and had little power of resistance. In addition, tetanus was a much-dreaded sequel, even in the so-called normal labour. The mortality was considerable, in spite of the most radical treatment. In this connexion it must be noted that cases were often not brought to hospital for several days after the disease was fully developed. Their chances of recovery were correspondingly small. Those brought in early often did well. Tetanus developed in one or two cases delivered in hospital, and it was impossible to say whether infection was conveyed in their own homes or in hospital.

Of the primary causes of malpresentation, immature development of the mother plays a large part. The custom of early marriages is responsible for this, though Nawanagar State is not so culpable in this respect as other parts of India. I have, however, seen a girl of 15 years delivered of her second child, the first being still at the breast. Luckily for the Indian mother, the average size of a full-time child is in my experience less than that

of the European. The head is decidedly smaller, the trunk slimmer; and these two factors have, I feel sure, saved the lives of countless child-mothers. One does see babies of eight or nine pounds, but they are the exception. If a child of this size falls to the lot of a wife of 14 years, what save trouble can result?

The natives' habit of using the hospital for their confinements in preference to their own homes was very slow to develop. Custom dies hard, and I am sure that the grandmothers and aunts had a great influence in keeping the mothers at home. But I am equally certain that, given time and proper facilities, these customs can be broken down. It was an interesting fact that the class which took greatest and earliest advantage of the hospital were the Borah Mohammedans, who really looked upon it in the proper light, and often made arrangements for accommodation beforehand. I remember a Borah girl with a generally contracted pelvis, whose first baby was delivered in Calcutta by craniotomy, and for whom I did a Caesarean section. Her delight at having a son was unbounded. A year later her husband informed me she was again pregnant, and asked me to do another Caesarean at the appropriate time. This was done in due course, with like success. She became quite a heroine to her community, and deserved all her glory. There is a real dread of surgery in India, and for a woman to brave the ordeal twice was indeed a triumph. Apropos of this fear of operation, I had far less difficulty to persuade the relatives to agree to a Caesarean section than I had in cases of other operations. There is a great anxiety for male children among all classes, and the woman who presents her husband with a male child at the first attempt is fortunate indeed.

From the above it will be seen that midwifery in India is often of the "heroic" type. The difficulty of dealing with neglected abnormal presentations, where labour had been in progress for many days, all the liquor amnii drained away, and the uterus tightly contracted on the child, can be well imagined. The risk of rupture of the uterus in any attempt at turning was ever present, and the condition of many of the patients on admission was grave from the commencement. And yet it was amazing how some, provided they did not develop septicaemia or tetanus, would recover.

It is only to be expected that chronic pelvic infection, injuries to the pelvic floor, and uterine displacements are very common. While managing the women's clinic prior to the advent of the lady doctor, I examined hundreds of women, and found that the bulk of them suffered from one or other of these complaints. Sterility, both absolute and relative, was common, the first due to venereal infection soon after marriage, the second to puerperal sepsis. Such infections were responsible for many abortions and miscarriages also. The ideal of curing husband and wife of a gonorrhoeal infection at the same time is almost an impossibility in India. The husband will not submit to treatment, or even to examination.

The number of quite young girls found to be suffering from some form of uterine displacement was very striking. It was sad to see, as I often did, a girl of 15 or 16 with a retroversion and early prolapse. To persuade the patient to allow operative treatment was, however, a difficult problem, unless there was backache, menorrhagia, or other attendant symptom.

Conclusion

The foregoing notes show a little of the problem of maternal mortality and morbidity in India. In the course of a debate in Parliament on Public Health Administration in India, Miss Rathbone quoted the Indian Census Report of 1931 as stating that "present conditions in India resulted in 200,000 deaths of women in childbirth every year, and in 100 out of 1,000 girl brides dying in childbirth before they finished their period of child-bearing." This paper endeavours to show some of the causes at the bottom of such an appalling state of affairs.

The task of providing a remedy seems almost superhuman. Provision of skilled help and the education of the people to take advantage of that help is, of course, obvious. With regard to the dhai, the scheme of training

the existing dhais has, I know, been tried. In my opinion it cannot attain much success. A woman of this type, slave for years of the dirty customs of her class, cannot be expected to throw aside the habits of a lifetime and imbibe the necessary knowledge of asepsis and midwifery of which she is at present totally ignorant, and to which she is by nature opposed. However earnest and sound the training may be, she will relapse inevitably into her old ways. The better plan would be to take fresh material, from a better class, and train them when they are young; they would then have no fixed notions to get rid of. Such material is to be found among the widows of India, whose number is legion. If a scheme for the training of some of the countless child widows in the principles of nursing could be formulated, it would serve the double purpose of providing the Indian mother with the trained help she now lacks, and at the same time of providing thousands of women with occupation and a means of livelihood who are at present nothing more than unpaid drudges, and whose lot is surely as unenviable as any in India. They cannot remarry, have little prospect of any happiness in life, and are a drag on their families. Why not convert them into useful members of society by making them the medium through whom the lot of their sisters—the mothers of India—can be ameliorated?

At the same time the people will have to be taught that a woman in childbirth is not the "unclean" creature she has hitherto been considered, but is someone worthy of that care and attention in her trials and tribulations which should be her right, and whose need is truly great.

IMPERIAL CANCER RESEARCH FUND

The eleventh Scientific Report of the Imperial Cancer Research Fund, which has just been published, is fully up to the standard of its predecessors, both as a record of experimental work and in respect of its excellent illustrations.

The first three papers, by Mr. Foulds, deal with filterable tumours of the fowl and with autoplasmic transplantation of the thymus in the same bird. The general conclusions drawn from the experimental work support the view that these filterable tumours are distinct pathological entities, with individual characteristics as well marked as those of ordinary mammalian transplantable tumours. Alterations in these tumours have been shown to be of merely a temporary nature, and attempts to propagate adventitious abnormalities in succeeding generations have not been successful. The experiments are of great interest, not only from the point of view of the specific character of the neoplasm-forming filterable virus, but as affording additional evidence of the importance of tissue reactions and consequent modifications of the tumour. In the experiment under consideration, however aberrant any particular growths appeared to be, yet on attempts to propagate them in different birds reversion to the normal type was always the result.

DIETETIC EXPERIMENTS WITH LIVER

The two following papers are by Dr. A. F. Watson, and deal with the effect of adding fresh liver to the diet of mice treated with carcinogenic tar. It had already been shown (1927-32) that "any foodstuff whose inclusion in the basal diet improved the general condition of the animals as shown by their appearance, increased life spans and rates of growth, also produced the same effect on the rates of growth of the benign and malignant tissues. Conversely, any food supplement which adversely affected the general condition of the animals decreased the rates of growth of the tumours." It is, of course, a well-recognized fact that transplanted tumours grow best in young, well-nourished animals, while the rapid growth of human cancer when it attacks young, well-developed subjects is among those unfortunate clinical experiences with which we are all only too familiar. The well-known haemopoietic powers of fresh liver doubtless suggested its selection as an addition to the ordinary basal diet of mice treated with tars known to have carcinogenic prop-

erties. With the addition of fresh ox-liver to the diet it was found that the warts appeared earlier and in a greater number of animals than when they were fed on the standard diet, to which no such addition had been made. The results indicate the possibility of experimentally modifying the susceptibility of tissues to the development of malignancy when they are subjected to the action of a carcinogenic agent. The liver feeding, while it caused an increased number of benign warts to appear earlier than in control animals, had no effect upon the rate of development of malignancy once the benign warts had made their appearance; the number of warts becoming malignant was, however, increased. The author concludes from his experiments "that the development of a benign hyperplasia and the subsequent development of malignancy at the site of this hyperplasia are conditioned, partly at any rate, by different factors."

In the succeeding paper Dr. Watson gives the results of some further experimental work upon the same subject, including the observation that the factor or factors in fresh liver which are responsible for the increased wart and neoplasm formation are comparatively heat-stable. Of considerable interest is the fact that preparations of hog's stomach—stated by the manufacturers to have given good clinical results when administered to patients suffering from pernicious anaemia—caused no increased tumour formation in mice. Unfortunately, in this series of experiments, the mortality among the experimental animals was heavy, gastro-intestinal infections being responsible for a large number of deaths. The author's conclusion was that the results obtained gave "no support to the possibility of identifying the factor responsible for the effect on carcinogenesis with the haemopoietic factor."

It is unnecessary to comment on the great scientific interest of these conclusions if they are corroborated by further work. Little by little the various organs of the body are gradually being made to yield up secrets of their activity, which had not only been unrecognized but entirely unsuspected.

MICRO-INCINERATION STUDIES

The sixth communication in the report is by Dr. E. S. Horning, and deals with "Micro-incineration Studies of the Tar Tumours of Rodents." Although the method of micro-incineration was introduced in 1924, it is probably not very well known to most of our readers. The object of the process is to burn off the organic part of the tissues under examination and to leave the mineral constituents *in situ*, so that their disposition can be examined microscopically. For the purposes of these experiments portions of tumour tissue were fixed and embedded in paraffin. Serial sections were then made, of which some, when stained in the ordinary way, served as controls; while others were incinerated in an electrically heated quartz oven, the final temperature being of the order of from 625° to 650° C. Special optical apparatus was necessary for the examination of these incinerated sections, and their microscopical appearance is well shown in a series of plates, together with their corresponding non-incinerated controls. As shown in these reproductions the appearance of the incinerated sections suggests that even in microscopical sections of fossilized plants, though in these, of course, the carbonaceous elements are still often present.

RADIUM

The next paper, also by Dr. Horning, forms one of a group of six, written by different authors, in which different effects of the action of radium are considered. Dr. Horning's paper deals with the action of radium on the inorganic structure of tumour cells as shown by micro-incineration. The method of irradiation calls for special comment. The radium applicator employed was essentially the same as that used in other experimental work described in this report and its predecessor, its activity being equivalent to 55 mg. of radium element. The thickness of the silver screen used is not specified in the present paper, but a later reference (p. 128) makes it probable that the thickness was 0.18 mm. of silver. If this being the case, it is clear that a large proportion of

β radiation and of the γ rays, which are screened off in most ordinary clinical practices, are allowed to pass and to exert their effect. Since the epoch-making work of Dominici in France, the tendency in the clinical use of radium has been to increase the thickness of the filter, so as to allow only the most penetrating γ rays to reach the tissues. At the present time filters of 0.5 to 1 mm. of platinum (or its equivalent) are those which are commonly employed.

In experimental work, however, the use of β and soft γ radiation has a very important application in many cases; since the intensive local action of these rays often gives an indication of the direction in which the effects of hard γ and penetrating x rays are to be sought. In the piece of work now under consideration it is the effect of both β and the softer γ rays, as well as that of the hard γ rays, which is being studied. The results are very interesting, inasmuch as within eight hours after radiation an increased cytoplasmic ash is recorded, while the maximum increase of mineral salts occurs on the sixth day, a time at which marked degeneration is apparent under the above-mentioned conditions of irradiation. This certainly corroborates the view that one of the actions of radiation is an alteration in the permeability of cell membranes.

DR. CRAMER'S WORK

In the three following papers Mr. Crabtree and Dr. Cramer deal with the effects which changes in environment have with the susceptibility of cancer cells to radium. In the second of these the combined effects of hard β and mixed γ radiation are considered, while in the third γ radiation only was used, an additional filter of 0.7 mm. of lead, together with the glass bottom of the container, being interposed between the experimental tissue and the source of radiation. Broadly, the results indicate that inhibition of the respiratory function produces increased radio-sensitivity. A further communication by Mr. Crabtree deals with the action of bicarbonate- and phosphate-buffered media in producing changes in metabolism and radio-sensitivity. "The Therapeutic Action of Radium on Spontaneous Mammary Carcinomata of the Mouse" is the title of Dr. Cramer's next paper. The use of the word "therapeutic" in this connexion manifestly suggests a comparison with the methods of radium therapy used in human beings, and the first point to be noted occurs in the introduction (p. 127). Here it is said that "the therapeutic action of radium on malignant new growths is a purely local one and restricted to the irradiated area. It has no influence outside that area." The second point is the statement (p. 123), "There is no evidence that malignant cells, as such, are more sensitive to radium than the cells of many normal tissues." Both statements are based upon previous work by Dr. Cramer, and published in the report for the year 1932. As they stand we entirely disagree with them. If they be altered so as to say that "under the experimental conditions of radiation employed whereby there was an intensive local action of β and of the softer γ rays, there was no evidence of any immunity (or other) reaction outside the area irradiated, nor was any difference between the radio-sensitivity of normal and neoplastic cells observed," nobody is likely to dispute the conclusions. The point is that the experimental conditions are entirely different from those used in modern therapy, where the most penetrating x and γ rays alone are utilized. Those who claim the existence of immunity as a sequel to irradiation of tumours insist strongly, not only that the dose must be very accurately given, but that the radiation employed shall only be those of distinctly "hard" (or penetrating) character. They further hold that any factor altering the growth of tumours in any other part of the body is the product not of cells rapidly destroyed by β and soft γ radiation, but of injured, slowly degenerating cells before they die. In short, of such an injury as may be caused by highly penetrating radiations.

Similar remarks apply to the radio-sensitivity of normal and neoplastic tissues. It is expressly held that this is specially manifested by using the most penetrating types of radiation. It is rather curious that in the literature appended to these papers no reference is made to any

of the writings of the French school, where these problems have been receiving unremitting attention for a considerable number of years. The fact is that the conditions employed in therapy and those employed in these experiments are so fundamentally different that it is impossible to establish any comparison between them.

OTHER PAPERS

The two remaining papers are by Dr. Ludford. The first deals with the structure and behaviour of the cells in tissue culture of tumours, while the second concerns the reaction of normal and malignant cells to fat-soluble coloured compounds which are insoluble in water. Both papers are of the high standard of excellence which we have learned to expect from their author, but are perhaps of rather too purely technical a character for those who are not intimately acquainted with this phase of experimental work. Everybody is, however, keenly interested in any specific difference which can be demonstrated or suggested between the normal and the neoplastic cell, and Dr. Ludford's final conclusion may thus appropriately find place here: it is that "these results suggest that, although malignant cells are readily permeable to fat-soluble substances, they are less permeable to water-soluble compounds than normal cells. The tentative explanation is that the plasma membrane of malignant cells is relatively rich in fatty substances."

In addition to the main report there is a supplement written by Mr. Foulds: this is a critical review of the filterable tumours of fowls. The whole subject is carefully examined in a comprehensive essay of little more than thirty pages, while an extensive bibliography covering nearly eight pages forms a fitting conclusion to a survey which is as excellently brief as it is interesting.

Scotland

Edinburgh Royal Infirmary

At the annual meeting of the Royal Infirmary League of Subscribers on November 29th Professor G. Lovell Gulland spoke of the valuable help which was given by the League to the funds of the Infirmary. This institution, he said, was always working at high pressure, and last year had dealt with 18,943 in-patients. The out-patient departments were also as full as they could be, and strenuous attempts had been made to reduce the surgical out-patient clientele by referring patients back to their national health insurance doctors instead of allowing them to return to the Infirmary for all dressings, as in the past. In spite of this the out-patients had numbered 66,000, and there had been over 381,000 attendances. The waiting list for the wards was still nearly 3,000, and consideration had been given to the question of some scheme of co-ordination, whereby more could be done to distribute patients to other hospitals. There were in Edinburgh several municipal hospitals on a somewhat different basis from the Royal Infirmary, but still it ought to be possible to effect co-ordination with these, and so to lessen the waiting list and to keep more up to date. Ways and means were also being considered of getting increased subscriptions from every class of the community, because the Royal Infirmary was obliged to spend more money every year, largely on account of the rise in prices. As an example of this, the bill for milk was going to be £2,000 more this year than last, a matter which the promoters of the Milk Marketing Scheme had not contemplated. The continuous progress of medicine and surgery also made new appliances constantly necessary. With reference to the extension scheme, the managers had in hand about £260,000, but another £100,000 was required. An important piece of work during the past year had been the establishment of a school of dietetics, and there had been as many students in this new department as it could

accommodate. Dr. John Orr said that the public did not realize the vastness of the organization of the Royal Infirmary, which was looked up to everywhere in the medical world. There were many people who enjoyed the advantages of the institution, but who did not contribute anything to its upkeep, and something must be done to secure adequate contributions from this class of the community. The report of the League of Subscribers, which had been closed a month earlier than usual, showed the total subscriptions obtained to have been £18,817 for the eleven months, an apparent, though not an actual, fall of about £2,000. The average yearly contributions for the past ten years had been £21,346, and since the inception of this scheme some sixteen years ago the total sum gathered had amounted to £305,462.

Health of Scotland

The return by the Registrar-General for Scotland for the quarter ending September 30th, 1934, states that the births numbered 21,298, a rate of 17.1 per 1,000 of the population, which was 1.8 below that for the previous quarter, or 1.2 below the average for the same quarter of the previous five years. The rate was highest in the large burghs, ranging from 23.4 in Port Glasgow, 22.8 in Coatbridge, and 22.4 in Stirling, down to 11.9 in the county of Peebles and 11.6 in that of Sutherland, and 10.9 in the burgh of Arbroath. Deaths during the quarter numbered 13,301, or a rate of 10.7 per 1,000 of population. This rate was 2.9 less than that of the previous quarter, and 0.1 below the average for the same quarter of the quinquennial period. Deaths of children under 1 year of age numbered 1,211, equivalent to an infantile mortality rate of 57 per 1,000 live births. This rate was 21 less than in the previous quarter, and 5 less than the average for the preceding five years in this quarter. This was the lowest infantile mortality rate recorded for any quarter in the past twenty years. The rate was 61 for the large burghs and 52 for the rest of Scotland, with a range from 111 in Coatbridge and 102 in Arbroath, down to 29 in Roxburghshire and 0 in Selkirk. With regard to the causes of death, measles accounted for 129 deaths, diphtheria for 115, whooping-cough for 68, influenza for 57, scarlet fever for 55, and cerebro-spinal fever for 30. In each case there was a decrease when compared with the relevant figures for the previous quarter. Tuberculosis accounted for 800 deaths, or 6 per cent. of the total. There were 1,864 deaths from malignant disease, or 14 per cent. of the total; the number, however, was 71 fewer than in the previous quarter. Pneumonia and bronchitis accounted for 603 and 359 deaths respectively, with rates considerably below those of the standard for this quarter. Deaths of mothers from diseases and accidents of pregnancy and childbirth numbered 118; this figure was somewhat below the standard for this quarter.

Treatment of Infectious Diseases

In a recent address upon statutory hospitals for infectious diseases Dr. W. T. Benson, medical superintendent of Edinburgh City Hospital, said that the removal to hospital of infectious cases had proved a great convenience to the public by relieving the householder of irksome precautions and restrictions. There might, however, be disadvantages attached to the aggregation of infectious cases and overcrowding of hospital wards which proved detrimental to patients. This important fact was not fully appreciated by the public during the stress of an epidemic. It was now being realized that the common infectious diseases prevalent in the community would never be controlled or exterminated by this means, and that the real value of the fever hospital was not so much to prevent the spread of disease as to provide treatment.

The present practice of wholesale removal of scarlet fever patients to hospital was being severely criticized, for hospital isolation had no material effect on the epidemic spread. During recent years the majority of cases of scarlet fever had been so mild that they did not require the special medical and nursing care provided by institutional treatment. The modern view was that hospital treatment in scarlet fever should be strictly reserved for severe or complicated cases, or for patients who by their occupation or otherwise constituted a serious menace. Beds at present set aside for scarlet fever might be more advantageously utilized in providing accommodation for cases of measles, whooping-cough, and pneumonia. These infectious diseases in young children were important not only as regarded immediate survival, but from the point of view of permanent residual ill-health. Every child under 3 years suffering from measles, whooping-cough, or pneumonia required not only skilled nursing but also prolonged convalescence in open-air conditions, with an ample supply of suitable food. For the great mass of the population these requirements could be most satisfactorily provided in hospital. The function of the well-equipped fever hospital would be to give expert care and treatment to the infectious sick rather than to provide isolation.

England and Wales

Joint Tuberculosis Council

Twenty-seven members were present at a meeting of the council held on November 24th. It was stated that as a result of an interview at the Ministry of Health it seemed likely that some grant would be forthcoming in aid of the work of the Employment Committee. The committee investigating the results of artificial pneumothorax treatment had collected the results of 4,283 cases, but on actuarial advice it was rejecting series with more than 3 per cent. cases "lost sight of," and this would leave some 3,900. With the control series there were 7,000 cards to be prepared and sorted, so that six months must elapse before a preliminary outline could be placed before the council. The greater part of the meeting was spent in discussing a memorandum, on the examination of the contact, presented by Dr. Ernest Ward, the convener of the committee concerned. An attempt was being made to produce something which would be helpful to those engaged in this work, with the full realization of difficulties involved, in particular as concerns young adult contacts who will not usually stay at home to be examined there or attend a dispensary for the purpose. Professor Jameson had, it was stated, circulated useful information on behalf of the Milk Committee, and recommended the council to support the findings of the committee on cattle diseases of the Economic Advisory Council, but to oppose any suggestion that the Milk Marketing Board's scheme of accredited herds would do anything towards the production and distribution of a safe milk free from infection. After discussion the following resolution, drafted by Dr. Hawthorne, was passed:

"This Joint Council, having received a report on the milk supply from a specially appointed committee, and being aware of the much increased number of school children now receiving a daily ration of milk, reaffirms its resolution of April 20th, 1934, to the effect that protection of the children from the risks of infection can be secured only by adequate pasteurization or by boiling the milk, and notes with every sympathy the corresponding advice given by the Board of Education and adopted by the London County Council and certain other education authorities under the expert direction of the corresponding medical officers of health."

Dr. Brand was planning an attractive series of post-graduate courses for 1935, the chief of which would be at Victoria Park Hospital, being devoted mainly to recent advances in technique in connexion with the diagnosis and treatment of disease of the lungs. The question of Spahlinger treatment and the prevention of the common cold were also discussed, and the secretary was asked to prepare a note on these topics for the next meeting of the council.

Association of Certifying Factory Surgeons

The annual dinner of the Association of Certifying Factory Surgeons was held in the Queen's Hotel, Manchester, on November 24th, with the president, Dr. A. Glen Park, in the chair. The guests included Dr. J. C. Bridge, Chief Medical Inspector of Factories; Professor A. Ramsbottom, Manchester University; Dr. S. A. Henry, of the Home Office Factory Department; Mr. J. A. Parkinson, M.P. for Wigan; and Mr. J. A. K. Ferns, coroner for East Cheshire. Certifying surgeons and district inspectors of factories as far apart as Worcester, Yorkshire, and Scotland attended, as well as medical men interested in some special branch of occupational disease. Dr. Glen Park proposed the toast of "The Factory Department of the Home Office." He traced the history of interest shown, and enactments by the Government of the country from Elizabethan times to the formation of a Factory Act, in the relation of physician and workman. He paid graceful tribute to the help the certifying surgeon received from the medical inspectors in His Majesty's Home Office. Dr. Bridge replied, and Dr. Henry, in proposing the toast of "The Association," emphasized the cordial relations which existed between the Factory Department and certifying surgeons. He suggested that the association should frame its policy always on constructive lines. Dr. H. E. Watkins, Newton-le-Willows, in reply, spoke of the loss felt by everyone in the death, at such short intervals, of Sir Thomas Legge, Dr. Prosser White, and Dr. Dearden, whose contributions to the literature of industrial disease had proved of great value. Dr. D. McKail, Glasgow, proposed "The Visitors." Mr. H. Roston, director of education to the firm Tootal Broadhurst Lee Co. Ltd., in his reply, stressed the need of extending the work of the certifying surgeon beyond certification to regular medical examination and advice to employers regarding the growth under industrial conditions of the adolescent in the factory from 14 to 18 years of age. This, he suggested, could best be operated through the day continuation school. This co-ordination of medical and educational service was actually in operation in his firm, and medical records covering sixteen years had been kept, which proved of real value to the adolescent and the employer. It is proposed to hold the next annual dinner in London.

Portsmouth's Housing Question

Owing to the illness of his successor as M.O.H. for Portsmouth, Dr. Mearns Fraser has brought out yet another annual report on the health of the city. One of the most important steps taken during 1933 was the adoption of a five-year programme of slum clearance. Thirteen clearance areas will be dealt with, comprising 1,277 dwelling houses. In addition, 481 single houses which have been condemned as unfit for human habitation will be demolished. This scheme will involve the displacement of 6,528 persons, to rehouse whom the Portsmouth Council proposes to erect 1,429 houses or flats. It has been arranged that, so far as shall prove to be possible, the displaced persons shall be provided with accommodation in the same district in which they previously lived. In September of last year Dr. Mearns Fraser submitted official representations with reference

to certain areas, which were in due course declared to be clearance areas within the terms of the Housing Act of 1930, and application was made for the confirmation of compulsory orders to enable the council to acquire this land. He believes that these measures will go a long way towards the solution of the housing question in Portsmouth. During the year reviewed 912 dwelling houses were erected in the city. Good progress was made with the council's scheme for 150 working-class houses and flats. Satisfactory features in the health statistics of the past year were the very low maternal mortality (1.9 deaths per 1,000 births), the infantile mortality rate of 52 per 1,000 births, and the lowest death rate from pulmonary tuberculosis ever recorded in Portsmouth—namely, 0.67 deaths per 1,000 population. Dr. Mearns Fraser reports also concerning the unification and co-ordination of the health services of the city. He maintains that, if the health department is to perform effectively the functions which are generally accepted as the minimum responsibilities of a modern health department, two more whole-time medical officers will have to be appointed, one for maternity and child welfare and the other for tuberculosis. St. Mary's Hospital was taken over by the health committee on April 1st, 1933, and closer co-operation is being arranged between it and the other public and voluntary institutions in the city. With the removal elsewhere of about 180 aged and infirm patients, and when the new wards of the Royal Portsmouth Hospital are open, it is hoped to have adequate accommodation for all persons in the city needing in-patient treatment. At the present time there is no laboratory in the city licensed for animal inoculation, so that there is much delay, as well as inconvenience, in obtaining the necessary reports of such investigations as have to be made in London.

Nutritional Problems in North Country Children

Previous references to the nutrition of children have appeared in these columns, and details have been given in the last few weeks about the conditions prevalent in Middleton and Hull. The annual report for 1933 of Dr. J. A. Charles, medical officer of health for the city and county of Newcastle-upon-Tyne, contains an account of an investigation made by Dr. J. C. Spence, assistant physician to the Royal Victoria Infirmary, of the health and nutrition of groups of children between the ages of 1 and 5 years. In the absence of definite standards it was obviously impossible to do more than express the results as opinions, but Dr. Spence concluded that at least 36 per cent. of the examined children coming from poor districts were unhealthy or physically unfit, and consequently appeared malnourished. He believes that the main immediate cause of this malnutrition is the physical damage done by infective diseases occurring in young children at susceptible ages and under conditions impeding satisfactory recovery. The salient causes in this connexion are the housing conditions which permit mass infection of children at susceptible ages, and the improper and inadequate diet which prevents restoration to full health. He regards these two causes as being of equal significance, and urges that a full inquiry should be undertaken by trained observers and on scientific lines. Dr. Charles, commenting on these findings, agrees that they appear to conflict at first sight with the data collected annually by the school medical service, but cites figures to show that this is not really so. Both sources of information point to the same conclusion—namely, that much damage has been done to the health of the children coming from poorer residential parts of the city before they reach school age. In the better-class neighbourhoods, out of every 1,000 cases of measles and rubella reported in 1931 and 1932, 648 occurred in children after the age of 5, whereas in the more densely populated areas 687 occurred in

children below that age. Taking the age of 3 and below as being the most fatal period for measles, it is shown by the city statistics that in the residential neighbourhoods 172 cases out of every 1,000 of measles and rubella were below that age, as compared with no fewer than 391 in the crowded districts. With these facts in mind, Dr. Charles points out, it is not surprising to learn that the case mortality rate for measles per hundred notifications of measles and rubella is three times greater in the overcrowded areas than in the better-class residential districts. The rates for the two groups of wards during the decennium 1923 to 1932 were 2.07 per cent. and 0.68 per cent. respectively. In one area where in 1931 there were 10,944 persons occupying 18,889 rooms, there was only one recorded death from measles during the whole ten years. It is pointed out, further, that the diet recommended by the B.M.A. Committee on Nutrition is beyond the means of many of the poorer section of the Newcastle population, and figures are given showing that the amount spent weekly upon food per man-value was more than one shilling short of the B.M.A. figure. Condensed milk is for many the only form within their financial capacity. Dr. Charles argues that the solution of the present problems is to be found in the extension of services already existing, and in a more liberal conception of the communal responsibilities in other directions. Housing improvement should be directed to mitigating the ills of overcrowding as well as to the replacement of insanitary property. More abundant hospital facilities should be provided for the treatment of severe and complicated cases of measles and whooping-cough, and of patients from overcrowded homes. Arrangements for the institutional after-care of these cases during convalescence would do much to reduce subsequent ill-health and invalidity. An improvement in the quantity and quality of the dietary could be obtained by an extension of the issue of milk through the child welfare centres, so as to benefit more particularly children in those age groups where ill-health and physical unfitness are most prevalent; by an increase in the monetary allowance for the child dependant paid under the various scales of unemployment and transitional benefit and Poor Law relief; and by the education of mothers in the purchasing of foodstuffs, the compilation of diets, and cooking. Dr. Charles considers that it would be of inestimable importance to extend those sections of the Education Act of 1921 which relate to the provision of meals so that they might apply to the pre-school child. Home visiting should take more into consideration the toddler, and there might well be a larger provision of nursery schools.

Ireland

Irish Medical Schools' and Graduates' Association Dinner

The autumn dinner of the Irish Medical Schools' and Graduates' Association, which took place at Claridges Hotel, London, on November 29th, was a delightful function. It was presided over by Colonel G. A. Moore, whose repertoire of amusing Irish stories is inexhaustible. As it was the royal wedding day, after the usual loyal toasts had been honoured, the health of the Duke and Duchess of Kent was drunk, and a telegram of good wishes dispatched to Himley Hall. Mr. R. Lindsay Rea proposed the health of the guests, of whom there were two in chief—namely, Sir Thomas Myles and Sir William Patrick Byrne. He referred to Sir Thomas Myles's distinguished career in surgery, and reminded the company that during that week the jubilee of the first successful operation for the removal of tumour from the brain was

being celebrated. The speaker then remarked on the varied career of Sir Patrick Byrne, who, in the troublous times of 1916-19, when he was Under-Secretary to the Lord Lieutenant, had helped to bring a measure of peace to Ireland. Good feeling was possible even between extremes of Irish opinion, especially when men with such large and open minds as Sir Thomas Myles and Sir William Patrick Byrne had direction of affairs. Sir Thomas Myles, in responding for the guests, said that during the week he had been attending the meetings of the General Medical Council. The popular press was accustomed to assail the General Medical Council, but as an impartial Irishman he felt that none could be more just or fair than his colleagues on that body. Sir William Patrick Byrne, in proposing the toast of "The Association," said that he had met Irishmen in many parts of the world and had found them always delightful. His whole life had been spent in the English and Irish public service, and whether co-operating with Irishmen in ordinary routine work or in more difficult adventure he had never found one who failed his friend and colleague. Colonel Moore, in responding to the toast, gave some details of the Association. He said that the committee sitting in London had facilities for learning about any proposed changes which might affect professional interests, and for ensuring that the voice of the Irish schools and graduates was heard. He was proud to think that at every annual meeting of the British Medical Association the Irish graduates' luncheon was an important event; this year at Bournemouth something like 200 Irishmen were present. They were a proud little society of quite ancient origin, but very much up to date.

Milk Bill in the Dail

Dr. Ward, Parliamentary Secretary to the Minister for Local Government and Public Health, on the second stage of the Milk Bill, 1934, stated that the purpose of the Bill was to safeguard the consumer from infection and contamination in milk. The average yearly consumption in the country was low; Switzerland consumed twice as much, Norway 63 per cent., and the United States of America 43 per cent. more per head of the population. A campaign for increased consumption could not be entered upon under present conditions. Milk was a suitable medium for the production of bacteria, and through uncleanly methods of handling an excellent form of nourishment might become a source of infection and danger. Certain powers were already given to the department to deal with the problem of unclean milk, and the Bill was intended to strengthen its hand. Experience with the scheme by which necessitous children were given free milk had proved that many producers were prepared to adopt progressive methods and to submit their cattle to tuberculin-testing. Dr. R. J. Rowlette stated that the Bill was a good one, but had its defects. A little more courage on the part of the Government would have given it a chance of success. The present time was appropriate for provisions for dealing with clean milk, and the problem of the eradication of tuberculosis in cattle should be tackled vigorously. The absence of the licensing system for milk vendors was a serious omission; the danger of forfeiture of a licence would be a deterrent to abuse. The local authority should have power to go outside its own boundaries to inspect the sources of milk supplied to the areas under its control. Unless the department insisted on the appointment of medical officers of health in the counties which had no such officers at present the Bill would be a dead letter in those counties, since dispensary doctors, who were not in an independent position, could not be expected to discharge the duties efficiently. Dr. Ward, in reply, said the measure was not likely to be very popular, but it dealt with a matter

of the greatest importance. Milk producers would have confidence in a good product, and could expect to enjoy a better market and better prices. The department was greatly interested in the subject, and he was informed that the Minister for Agriculture also proposed to introduce his own legislation. As to pasteurization, there were some methods which were absolutely useless for protecting the public. The process of pasteurization would have to be subjected to regulations, and not every form of it would enable a licence to be obtained. It was true that infected milk could come from a tuberculin-tested herd, but under the Bill the "special designation" would be granted not because the milk came from a T.T. herd, but because it reached a high standard of purity.

Reports of Societies

SOME ASPECTS OF ANAEMIA

Lecture by Professor Minot of Harvard

On his way to receive the Nobel Prize at Stockholm Dr. G. R. Minot, professor of medicine at Harvard, visited London and was prevailed upon to address a special meeting of Fellows of the Royal Society of Medicine on November 29th. Dr. Robert Hutchison, President of the Society, was in the chair.

Professor Minot addressed himself to the question of certain aspects of anaemia. There had been a tendency of recent years, he said, to decide at once on liver or iron treatment and to forget that a proper therapy depended upon an understanding of the mechanisms producing the anaemia. It would be extremely unfortunate in a given case if, both liver and iron treatment having been prescribed, the patient got symptomatically well while yet it was not known whether he should continue on liver for the rest of his life or on iron indefinitely. The economic aspect of such a situation was not unimportant. Therefore, it seemed useful to review some of the problems of the aetiology of anaemia and some aspects of diagnosis.

THE AETIOLOGY OF ANAEMIA

Anaemia in many instances could be attributed to defective nutrition, which might arise in other ways than diet deficiency. Multiple factors might be responsible for the anaemia in any one case. Man in this respect was not like experimental animals. Nutrition might be inhibited by infection or by damage to vital organs of the body, such as the liver or cardiovascular apparatus. The degree of deficiency varied, and each case was an individual problem. The principle of treatment must be to replace the deficient factor on a quantitative basis. That might not always be realized when large amounts of iron were being given at relatively little cost. The patient himself was not to be forgotten for the sake of treating his anaemia *per se*. Pernicious anaemia was a disease affecting more than the blood-forming tissues; it involved the central nervous and the gastro-intestinal systems. In diagnosis the use of the stomach tube or the tuning-fork for bone vibration might be as valuable as a complete blood examination. In dealing with the aetiology of pernicious and related macrocytic anaemias, Professor Minot pointed out that the lack of gastric reaction leading to formation of substances necessary for maturation of red blood cells might be due to deficiency of the gastric (or intrinsic) factor, the food (or extrinsic) factor, or to a deficiency resulting from inability to absorb or utilize substances transformed in the body.

He divided anaemias of specific malnutrition into "liver extract" or macrocytic anaemia, "iron" or hypochromic anaemia, vitamin C anaemia, and copper anaemia, as seen in experiments on rats. In the case of "liver extract" anaemia he catalogued four factors: food, as in sprue; gastric, as in pernicious anaemia; absorption, as in coeliac disease; and internal metabolism, as in cirrhosis. In connexion with "iron" anaemia he

also indicated four factors: intake, absorption (anacidity), utilization, and blood loss, as in pregnancy. He showed a diagrammatic slide in which optimal and usual nutriments were indicated by higher and lower levels, with, below these, a zone of partial deficiency, and, lowest of all, a zone of complete deficiency. In all these anaemias there were two main considerations—namely, what was taken by the mouth and what the gastro-intestinal tract was doing. Given perfect dietary and perfect gastro-intestinal function, there would be perfect nutrition. In a very general way it might be said that these two factors interacted; one might be perfect and the other show some deficiency, but if there were deficiency in both the lowermost zone was reached. But there might also be some difficulty in utilization by reason of certain inhibitory factors such as infection, or some organic abnormality, or the lack of some accessory factor concerned in the mechanism. Again, the absorption stage might be successfully completed when there might occur chronic blood loss, resulting again in a deficiency condition.

RELATIVE FREQUENCY OF PREDOMINANT SYMPTOMS

Professor Minot proceeded to an analysis of 100 cases with a view to discovering the relative frequency of predominant symptoms at the onset of pernicious anaemia; of these cases half were seen in private practice and half in hospital. In thirty-one the predominant symptoms were gastro-intestinal; in twenty-six, nervous; in thirty-three, generalized; and in ten, cardiac. He had also ascertained the time which had elapsed from the onset of noticeable symptoms to the diagnosis of pernicious anaemia. For the four classes just mentioned the average time, in years, was respectively 2.19, 1.28, 0.72, and 0.95, making a total average for the hundred cases of 1.36. In thirty-five cases there had been a long history of "indigestion"; the latter had been noticed occasionally for over twenty years in sixteen cases; in eight others there had been recurrent "bilious" attacks over a period of three to seven years; in seven diarrhoea attacks had been frequent for from seven to fifteen years; and in four indigestion had been more or less constant for from seven to twelve years. In thirty of these cases there was an undoubted gall-bladder symptomatology. If, after treatment with liver or a proper substitute, the gastro-intestinal symptoms, however pronounced, did not clear up, there was a distinct suggestion that gall-stones were also present. A few years ago it was customary to see patients who were jaundiced or distinctly yellow. To-day the amount and frequency of distinct sallowness was not nearly so appreciable. This was explained by the fact that nowadays a patient did not remain long enough to have had a series of relapses and remissions before receiving treatment. In a series of cases analysed in 1918 the spleen was palpable in about 35 per cent., whereas in the present series it was palpable in only about 5 or 7 per cent. This again was explained by the greater promptitude of treatment.

CONCOMITANT DISEASES

Concomitant diseases sometimes upset the diagnosis; Wilkinson had published an excellent paper on that subject.¹ It was interesting to note that an appreciable number of patients had carcinoma of the stomach develop some years after they had had pernicious anaemia. In the lecturer's clinic they had tried to discover whether there was any greater incidence of this condition among the people with pernicious anaemia than among the normal population for a given age. The statistical data had not been completely worked out, but the evidence tended towards the probability that there had not been a greater incidence among the people with pernicious anaemia than among a normal group, yet reasons why cancer of the stomach might develop could readily be imagined. A considerable number of papers had appeared during recent years showing the coincidence of diabetes and pernicious anaemia, and the diabetes had almost invariably, with a few exceptions, occurred first, and the pernicious anaemia

¹ *Quart. Journ. Med.*, 1933, ii, 281.

some years later. That opened up some interesting speculations, but he knew of no clear explanation at present. Of course, it must not be forgotten that pernicious anaemia, like other diseases, might have not so much complications as concomitant conditions. In his series of 100 cases, for example, some thirty patients had certain evidence of chronic arthritis of one type or another, and sometimes the symptoms of arthritis were so apparent that the state of the blood had been considered as secondary to the arthritis, so that there had been failure to recognize the case as one of pernicious anaemia. Pernicious anaemia also brought about an aggravation of conditions which had arisen earlier and independently. For example, women who had been subject all their lives to easy bruising, with defects in the blood-coagulation factors or platelets, might show concurrently with pernicious anaemia a great increase in that bruising sufficient for a diagnosis of purpura to be made. The differential diagnosis of other blood disorders he would not discuss. If there was failure of treatment with liver it meant that there was incorrect diagnosis, or that the treatment had been inadequate in quantity, or that the patient suffered from a condition such as an infection severe enough in itself to lead to a fatal issue. There were very rare cases of macrocytic anaemia with no distinctive features and a normal gastric analysis, which showed no response to liver or other therapy.

As with all deficiency diseases, it should always be borne in mind that the disease might be precipitated by infection. In some 11 per cent. of his cases the symptoms appeared concurrently with an outspoken infection; in 15 per cent. they appeared in association with some change of dietary; it was probable that in these cases the intrinsic and extrinsic factors worked together according to the law of mass action. In treatment it was necessary not only to get the patient better, but to get him as well as possible. The reservoirs of the body must be filled up. The treatment must be optimum. There could be no standardization of treatment, no prescription of arbitrary amounts. Enough material must be given to meet all the demands of the individual patient. Probably it took more to prevent the progress of neural lesions than to permit the blood elements to be maintained. A study of what could be done for the neural lesions should not be based on the degree of amelioration, but on the evidence of arrested progress. Of course, if the blood could be improved it meant a return of strength, an exercise of muscles, and improvement of the circulation, and reacted on the general progress in that way. Unfavourable reports on liver therapy were often due to a failure to appreciate the fact that there was no standard dose, and that it was the individual patient who must be treated.

NEURAL LESIONS

In his own clinic during three years there had been twenty-six cases of pernicious anaemia with advanced subacute combined degeneration. An observation of these cases lasting over many months was made by a number of independent neurologists, and in no instance while the patients were under treatment with liver did a single objective neurological sign become more marked; there was objective arrest in many cases and subjective improvement in all. He showed a chart of these twenty-six cases, and indicated that in 17 per cent. signs which had been abnormal became normal, and in no instance was there evidence of progress in the lesion. It was considered, therefore, that the progress of a spinal cord lesion could be arrested with enough material. The sooner the treatment was begun the better. In these patients it was very important to pay attention to training exercises and to improvement in the circulation, if this was not normal. If these patients had to take to bed for some other cause their disorder would be more noticeable on resuming activity, and this should not be ascribed to a progressive lesion. Such patients also complained that their symptoms got worse with the onset of cold weather. This was simply that a person with a damaged spinal cord felt the cold more than others. If severe infection were present it would inhibit the effect of therapy on the

cord lesion quite as much as on the blood. Individualism throughout was the keynote.

In a word on liver preparations Professor Minot stressed the need for a knowledge of the material which was being used. Many extracts in all countries were labelled as "Derived from . . ."; the important information was not what they were derived from but what they were equivalent to. He emphasized the value of the parenteral use of extract. To administer the material intramuscularly had various advantages. It was probably as economical as the oral method, and absorption was assured. It was useful in cases of increased resistance to therapy because it enabled as large an amount to be given as desired, with the assurance that the patient was definitely obtaining the material. Administration must be regular and frequent; arbitrary methods led to unnecessary illness. Each case, however, was an individual problem; there was no one rule for all cases, and if it was more convenient to give by the mouth this might be done. More liver was required when the patient was over 50; when there was arteriosclerosis, cardiovascular or kidney disease, or disease of other vital organs; when there was infection; perhaps when there was chronic fatigue; during pregnancy; and in the presence of neural lesions.

IRON AND ITS UTILIZATION

The use of iron in hypochromic anaemia had been dealt with in a most scholarly way by L. J. Witts.¹ In passing, it might be well to mention that there were other substances in liver besides the liver extract which were effective in anaemia, these including iron itself. In the use of iron the exact proportion was unimportant so long as enough was given for the individual case. There was probably almost no use for iron administered intramuscularly; it must be an exceedingly rare case in which that was strictly needed, and to give enough iron intramuscularly would create uncomfortable symptoms. A certain number of patients might have a double deficiency in the sense that they needed liver extract and also needed iron. The combination of liver and iron was worthy of study. An occasional case might do better with both than with either alone, but it was usually one or the other that was needed, and the combination was seldom of importance.

In his clinic the question had lately been raised whether the pigments of the body could in any way be used in the manufacture of haemoglobin. Some of the bile pigments had been studied from this point of view. Concentrated bile pigments were obtained, and a group of cases studied by means of the double reticulocyte reactions. If material was given to a certain amount and there was a reticulocyte reaction, and then more material was given, and there was a second reaction, it implied that the second lot of material was more potent than the first. With that in mind, the effect of bile pigments introduced at a certain point was studied. Professor Minot exhibited graphs which went to show that the addition of bile pigments accelerated the utilization of iron, and was probably not dependent on absorption phenomena. Chlorophyll also had been studied in many directions. Pure chlorophyll preparations had only been available for a short time. Chlorophyll accordingly was tried, and thirty observations had been made on fifteen cases of idiopathic hypochromic anaemia. When the chlorophyll preparation was added to the iron there was an increase in the haemoglobin and a definite reticulocyte rise. With iron and crude chlorophyll employed in disproportionate amounts the result was negative, but it became positive when iron and crude chlorophyll were used in the relation of 1 to 6 up to 1 to 12. Positive results were obtained with iron and crude chlorophyll and with iron and sodium chlorophyllide given orally or intramuscularly, as well as with other preparations. In other words, it might be said that chlorophyll as a pigment in the body did something which accelerated the utilization of iron. Professor Minot added that he did not regard this for a moment as being of any great practical importance, though it was of physiological interest, and there might occasionally be

¹ *Proc. Roy. Soc. Med.*, 1933, xxvi, 67.

cases in which it had a practical bearing. So far he had had two cases in which a preparation of bile pigment brought up the haemoglobin quite promptly, in two weeks, 14 or 15 per cent. It was then stopped and the chlorophyll preparation was used, and a fall when it was withheld. He thought this had a bearing on the way in which iron might be used in the body, but he did not want anyone to race off with the idea that chlorophyll must be given in all cases. At the same time, it might offer some further approach to an understanding of the mechanism whereby iron was utilized. The observations had left him wondering whether the value of spinach might not be in its goodly amount of chlorophyll as well as in its content of iron. Possibly some natural foodstuffs enabled a better use to be made of iron in the body, and of these accelerating factors probably chlorophyll was one. He concluded with the remark that in spite of recent advances in the knowledge of anaemia there remained much that was still unknown. The continual study of patients at the bedside was essential, as well as a recognition that the science was unstable, that the art was uncertain, and that the sick individual must remain in the centre of the picture.

A vote of thanks to the lecturer and of congratulation to him on the Nobel award was accorded on the motion of Dr. MORLEY FLETCHER.

AETIOLOGY AND TREATMENT OF ASTHMA

At a meeting of the Section of Medicine of the Royal Society of Medicine on November 27th, with the vice-president, Dr. MORLEY FLETCHER, in the chair, Sir HUMPHRY ROLLESTON opened a discussion on "The Aetiology and Treatment of Asthma."

Sir Humphry Rolleston suggested the elimination of renal and cardiac asthma, but said that even with this limitation the subject was enormous. Asthma was a symptom, and only one, of a large and as yet incomplete group of diseases known as allergic—the toxic idiopathies. The name "allergy" had been introduced by von Pirquet to describe all forms of altered reaction of the organism, but it was now used only for hypersensitiveness, the word "anergy" or "negative idiosyncrasy" being used for diminished sensitiveness. The cause was the underlying constitutional state, usually inherited or latent, transmitted on Mendelian lines. It was tempting to invoke an endocrine origin, particularly in the adrenal or thyroid, but the suggestion was met with clinical inconsistencies, as allergic symptoms were rarely seen in Addison's or Graves's disease. Strong evidence had been adduced to show that failure of adrenal secretion was the cause. The integrity of the internal environment depended on the autonomic nervous system, and vagotonia had been described as the primary cause. Should eosinophilia, he asked, be regarded as a defence mechanism or a concomitant reaction? If adrenaline injection drove the eosinophils from the peripheral circulation they must be at best an inconstant protection. Secondly, there was the localizing cause which determined the particular manifestation. In addition to trauma an inherent want of vitality might exert an influence. The many methods of treatment included physical exercises, wide-field x-ray exposures, specific and non-specific desensitization, and urinary proteose.

Dr. JOHN FREEMAN said that the modern minute doses of toxin-antitoxin offered a danger of sensitizing people, so that the next protective inoculation might cause necrosis at the site of injection. The definition of allergy given by Sir Humphry Rolleston must include anaphylaxis and immunity phenomena; von Pirquet had included cancer and old age. All the symptoms of an infectious disease must be in a way allergic. Whenever the irritant poison came in contact with the tissues there were symptoms likely to arise; this accounted for localization. There was also a tendency for one particular variety to run in the family. Damage was undoubtedly a precipitating cause of great importance, and irritation was likely to limit the manifestation to a special spot. Psychological

factors undoubtedly played a part; they were present in all cases. Psychologists described the toxic idiopathies as anxiety neuroses, the mind "choosing" the type of reaction that best symbolized the patient's trouble. Amelioration, and at times real cure, might be produced by desensitization.

Dr. J. LIVINGSTONE said that specific sensitization could be cured or helped by inoculation, but that some patients were sensitive to a very large group of causes, and some 40 per cent. of patients would get better whatever the treatment, if it were given with sufficient authority. Expiratory breathing exercises had proved successful in many patients. The principles were to expire and get rid of the functional emphysema, to get the diaphragm working habitually, and to mobilize the chest muscles. Extraordinary control and mobility could be attained. Of seventy-seven cases 66 per cent. were very much improved, and only 18 per cent. showed no benefit. A good deal of time and patience were required to keep the patients practising regularly and to arouse enthusiasm. Also, much depended on giving them the feeling they were going to improve. Patients learned to prevent attacks by doing the exercises. The treatment was simple, and the results compared well with other methods.

Dr. GEORGE BRAY said that an ordinary case of asthma was mostly sensitive to inhalants, food playing but a small part. The groups were: animal hairs, feathers, dust, and orris root. The obvious treatment was to inject with these singly or together. An ordinary case could be desensitized by relatively large intramuscular doses of a solution of these four, as concentrated as possible and combined with adrenaline. Patients who ascribed their attacks to food usually had gastro-intestinal disturbances, and treatment of these was needed—not desensitization to food. Attacks might become conditioned reflexes in allergic persons, but the changes disappeared after desensitization, and operative interference was seldom necessary. Bacteria did not play an aetiological part in the attacks, but lowered resistance and so increased sensitiveness. Specific desensitization was therefore the most practical method of treatment.

Mr. C. GILL-CAREY reported on 181 nasal cases seen in the last ten years. Allergic rhinitis accounted for a large proportion, and could be recognized by the typical colour changes in the mucosa. Bacterial infection had been superadded in about 10 per cent. Treatment was difficult. Temporary improvement followed practically any surgical operation. Interference should, however, be confined to removal of polypi in purely allergic cases. Non-allergic abnormalities accounted for about 10 per cent., and satisfactory results were obtained by treating sinusitis. The temptation to attack hypertrophic masses of allergic tissue must be withstood, but rhinological treatment gave tissue factory—at times brilliant—results in asthma.

Professor ERNEST M. FRAENKEL showed his film on allergy and protective apparatus. There were, he said, two independent variables to be considered: the constitution, and specific allergens. The film showed skin tests, portable filtering apparatus, an allergen-free room, a zip-fastened sleeping-bag, and a high-pressure tube for several out-patients to use at once. A patient sensitive to dog hairs was shown breathing contentedly through the filter, although dog hairs were shaken into the air in front of her; without her knowledge the filter was removed from the apparatus, and at once she suffered a typical attack. The apparatus had therefore diagnostic as well as therapeutic value. In some cases the psychological effect of confinement in the mask or room was bad at first, and had to be overcome. Use of the apparatus for part of the day sometimes protected the patient for the whole day. Asthma in Germany and in England was very similar. Sir JAMES DUNDAS-GRANT emphasized the importance of examining and treating the nose in asthma. In some of his cases specific sensitiveness had disappeared after nasal treatment. Hypersensitiveness was an explosive, but it required a detonator, and this part might be played by the nose. Dr. E. PARKES WEBER mentioned adrenaline treatment, which, he said, diminished or prevented the reaction in some cases of asthma. Acute generalized

some years later. That opened up some interesting speculations, but he knew of no clear explanation at present. Of course, it must not be forgotten that pernicious anaemia, like other diseases, might have not so much complications as concomitant conditions. In his series of 100 cases, for example, some thirty patients had certain evidence of chronic arthritis of one type or another, and sometimes the symptoms of arthritis were so apparent that the state of the blood had been considered as secondary to the arthritis, so that there had been failure to recognize the case as one of pernicious anaemia. Pernicious anaemia also brought about an aggravation of conditions which had arisen earlier and independently. For example, women who had been subject all their lives to easy bruising, with defects in the blood-coagulation factors or platelets, might show concurrently with pernicious anaemia a great increase in that bruising sufficient for a diagnosis of purpura to be made. The differential diagnosis of other blood disorders he would not discuss. If there was failure of treatment with liver it meant that there was incorrect diagnosis, or that the treatment had been inadequate in quantity, or that the patient suffered from a condition such as an infection severe enough in itself to lead to a fatal issue. There were very rare cases of macrocytic anaemia with no distinctive features and a normal gastric analysis, which showed no response to liver or other therapy.

As with all deficiency diseases, it should always be borne in mind that the disease might be precipitated by infection. In some 11 per cent. of his cases the symptoms appeared concurrently with an outspoken infection; in 15 per cent. they appeared in association with some change of dietary; it was probable that in these cases the intrinsic and extrinsic factors worked together according to the law of mass action. In treatment it was necessary not only to get the patient better, but to get him as well as possible. The reservoirs of the body must be filled up. The treatment must be optimum. There could be no standardization of treatment, no prescription of arbitrary amounts. Enough material must be given to meet all the demands of the individual patient. Probably it took more to prevent the progress of neural lesions than to permit the blood elements to be maintained. A study of what could be done for the neural lesions should not be based on the degree of amelioration, but on the evidence of arrested progress. Of course, if the blood could be improved it meant a return of strength, an exercise of muscles, and improvement of the circulation, and reacted on the general progress in that way. Unfavourable reports on liver therapy were often due to a failure to appreciate the fact that there was no standard dose, and that it was the individual patient who must be treated.

NEURAL LESIONS

In his own clinic during three years there had been twenty-six cases of pernicious anaemia with advanced subacute combined degeneration. An observation of these cases lasting over many months was made by a number of independent neurologists, and in no instance while the patients were under treatment with liver did a single objective neurological sign become more marked; there was objective arrest in many cases and subjective improvement in all. He showed a chart of these twenty-six cases, and indicated that in 17 per cent. signs which had been abnormal became normal, and in no instance was there evidence of progress in the lesion. It was considered, therefore, that the progress of a spinal cord lesion could be arrested with enough material. The sooner the treatment was begun the better. In these patients it was very important to pay attention to training exercises and to improvement in the circulation, if this was not normal. If these patients had to take to bed for some other cause their disorder would be more noticeable on resuming activity, and this should not be ascribed to a progressive lesion. Such patients also complained that their symptoms got worse with the onset of cold weather. This was simply that a person with a damaged spinal cord felt the cold more than others. If severe infection were present it would inhibit the effect of therapy on the

cord lesion quite as much as on the blood. Individualism throughout was the keynote.

In a word on liver preparations Professor Minot stressed the need for a knowledge of the material which was being used. Many extracts in all countries were labelled as "Derived from . . ."; the important information was not what they were derived from but what they were equivalent to. He emphasized the value of the parenteral use of extract. To administer the material intramuscularly had various advantages. It was probably as economical as the oral method, and absorption was assured. It was useful in cases of increased resistance to therapy because it enabled as large an amount to be given as desired, with the assurance that the patient was definitely obtaining the material. Administration must be regular and frequent; arbitrary methods led to unnecessary illness. Each case, however, was an individual problem; there was no one rule for all cases, and if it was more convenient to give by the mouth this might be done. More liver was required when the patient was over 50; when there was arteriosclerosis, cardiovascular or kidney disease, or disease of other vital organs; when there was infection; perhaps when there was chronic fatigue; during pregnancy; and in the presence of neural lesions.

IRON AND ITS UTILIZATION

The use of iron in hypochromic anaemia had been dealt with in a most scholarly way by L. J. Witts.¹ In passing, it might be well to mention that there were other substances in liver besides the liver extract which were effective in anaemia, these including iron itself. In the use of iron the exact proportion was unimportant so long as enough was given for the individual case. There was probably almost no use for iron administered intramuscularly; it must be an exceedingly rare case in which that was strictly needed, and to give enough iron intramuscularly would create uncomfortable symptoms. A certain number of patients might have a double deficiency in the sense that they needed liver extract and also needed iron. The combination of liver and iron was worthy of study. An occasional case might do better with both than with either alone, but it was usually one or the other that was needed, and the combination was seldom of importance.

In his clinic the question had lately been raised whether the pigments of the body could in any way be used in the manufacture of haemoglobin. Some of the bile pigments had been studied from this point of view. Concentrated bile pigments were obtained, and a group of cases studied by means of the double reticulocyte reactions. If material was given to a certain amount and there was a reticulocyte reaction, and then more material was given, and there was a second reaction, it implied that the second lot of material was more potent than the first. With that in mind, the effect of bile pigments introduced at a certain point was studied. Professor Minot exhibited graphs which went to show that the addition of bile pigments accelerated the utilization of iron, and was probably not dependent on absorption phenomena. Positive results were obtained with iron and crude chlorophyll and with iron and sodium chlorophyllide given orally or intramuscularly, as well as with other preparations. In other words, it might be said that chlorophyll as a pigment in the body did something which accelerated the utilization of iron. Professor Minot added that he did not regard this for a moment as being of any great practical importance, though it was of physiological interest, and there might occasionally be

¹ *Proc. Roy. Soc. Med.*, 1933, xxvi, 67.

cases in which it had a practical bearing. So far he had had two cases in which a preparation of bile pigment brought up the haemoglobin quite promptly, in two weeks, 14 or 15 per cent. It was then stopped and the haemoglobin fell back. A similar rise was noted when a chlorophyll preparation was used, and a fall when it was withheld. He thought this had a bearing on the way in which iron might be used in the body, but he did not want anyone to race off with the idea that chlorophyll must be given in all cases. At the same time, it might offer some further approach to an understanding of the mechanism whereby iron was utilized. The observations had left him wondering whether the value of spinach might not be in its goodly amount of chlorophyll as well as in its content of iron. Possibly some natural foodstuffs enabled a better use to be made of iron in the body, and of these accelerating factors probably chlorophyll was one.

He concluded with the remark that in spite of recent advances in the knowledge of anaemia there remained much that was still unknown. The continual study of patients at the bedside was essential, as well as a recognition that the science was unstable, that the art was uncertain, and that the sick individual must remain in the centre of the picture.

A vote of thanks to the lecturer and of congratulation to him on the Nobel award was accorded on the motion of Dr. MORLEY FLETCHER.

AETIOLOGY AND TREATMENT OF ASTHMA

At a meeting of the Section of Medicine of the Royal Society of Medicine on November 27th, with the vice-president, Dr. MORLEY FLETCHER, in the chair, Sir HUMPHRY ROLLESTON opened a discussion on "The Aetiology and Treatment of Asthma."

Sir Humphry Rolleston suggested the elimination of renal and cardiac asthma, but said that even with this limitation the subject was enormous. Asthma was a symptom, and only one, of a large and as yet incomplete group of diseases known as allergic—the toxic idiopathies. The name "allergy" had been introduced by von Pirquet to describe all forms of altered reaction of the organism, but it was now used only for hypersensitiveness, the word "anergy" or "negative idiosyncrasy" being used for diminished sensitiveness. The cause was the underlying constitutional state, usually inherited or latent, transmitted on Mendelian lines. It was tempting to invoke an endocrine origin, particularly in the adrenal or thyroid, but the suggestion was met with clinical inconsistencies, as allergic symptoms were rarely seen in Addison's or Graves's disease. Strong evidence had been adduced to show that failure of adrenal secretion was the cause. The integrity of the internal environment depended on the autonomic nervous system, and vagotonia had been described as the primary cause. Should eosinophilia, he asked, be regarded as a defence mechanism or a concomitant reaction? If adrenaline injection drove the eosinophils from the peripheral circulation they must be at best an inconstant protection. Secondly, there was the localizing cause which determined the particular manifestation. In addition to trauma an inherent want of vitality might exert an influence. The many methods of treatment included physical exercises, wide-field x-ray exposures, specific and non-specific desensitization, and urinary proteose.

Dr. JOHN FREEMAN said that the modern minute doses of toxin-antitoxin offered a danger of sensitizing people, so that the next protective inoculation might cause necrosis at the site of injection. The definition of allergy given by Sir Humphry Rolleston must include anaphylaxis and immunity phenomena; von Pirquet had included cancer and old age. All the symptoms of an infectious disease must be in a way allergic. Whenever the irritant poison came in contact with the tissues there were symptoms likely to arise; this accounted for localization. There was also a tendency for one particular variety to run in the family. Damage was undoubtedly a precipitating cause of great importance, and irritation was likely to limit the manifestation to a special spot. Psychological

factors undoubtedly played a part; they were present in all cases. Psychologists described the toxic idiopathies as anxiety neuroses, the mind "choosing" the type of reaction that best symbolized the patient's trouble. Amelioration, and at times real cure, might be produced by desensitization.

Dr. J. LIVINGSTONE said that specific sensitization could be cured or helped by inoculation, but that some patients were sensitive to a very large group of causes, and some 40 per cent. of patients would get better whatever the treatment, if it were given with sufficient authority. Expiratory breathing exercises had proved successful in many patients. The principles were to expire and get rid of the functional emphysema, to get the diaphragm working habitually, and to mobilize the chest muscles. Extraordinary control and mobility could be attained. Of seventy-seven cases 66 per cent. were very much improved, and only 18 per cent. showed no benefit. A good deal of time and patience were required to keep the patients practising regularly and to arouse enthusiasm. Also, much depended on giving them the feeling they were going to improve. Patients learned to prevent attacks by doing the exercises. The treatment was simple, and the results compared well with other methods.

Dr. GEORGE BRAY said that an ordinary case of asthma was mostly sensitive to inhalants, food playing but a small part. The groups were: animal hairs, feathers, dust, and orris root. The obvious treatment was to inject with these singly or together. An ordinary case could be desensitized by relatively large intramuscular doses of a solution of these four, as concentrated as possible and combined with adrenaline. Patients who ascribed their attacks to food usually had gastro-intestinal disturbances, and treatment of these was needed—not desensitization to food. Attacks might become conditioned reflexes in allergic persons. The nose became very unhealthy after repeated attacks, but the changes disappeared after desensitization, and operative interference was seldom necessary. Bacteria did not play an aetiological part in the attacks, but lowered resistance and so increased sensitiveness. Specific desensitization was therefore the most practical method of treatment.

Mr. C. GILL-CAREY reported on 181 nasal cases seen in the last ten years. Allergic rhinitis accounted for a large proportion, and could be recognized by the typical colour changes in the mucosa. Bacterial infection had been superadded in about 10 per cent. Treatment was difficult. Temporary improvement followed practically any surgical operation. Interference should, however, be confined to removal of polypi in purely allergic cases. Non-allergic abnormalities accounted for about 10 per cent., and satisfactory results were obtained by treating sinusitis. The temptation to attack hypertrophic masses of allergic tissue must be withstood, but rhinological treatment gave satisfactory—at times brilliant—results in asthma.

Professor ERNEST M. FRAENKEL showed his film on allergy and protective apparatus. There were, he said, two independent variables to be considered: the constitution, and specific allergens. The film showed skin tests, portable filtering apparatus, an allergen-free room, a zip-fastened sleeping-bag, and a high-pressure tube for several out-patients to use at once. A patient sensitive to dog hairs was shown breathing contentedly through the filter, although dog hairs were shaken into the air in front of her; without her knowledge the filter was removed from the apparatus, and at once she suffered a typical attack. The apparatus had therefore diagnostic as well as therapeutic value. In some cases the psychological effect of confinement in the mask or room was bad at first, and had to be overcome. Use of the apparatus for part of the day sometimes protected the patient for the whole day. Asthma in Germany and in England was very similar.

Sir JAMES DUNDAS-GRANT emphasized the importance of examining and treating the nose in asthma. In some of his cases specific sensitiveness had disappeared after nasal treatment. Hypersensitiveness was an explosive, but it required a detonator, and this part might be played by the nose. Dr. E. PARKES WEBER mentioned adrenaline treatment, which, he said, diminished or prevented the reaction in some cases of asthma. Acute generalized

dermatitis of unspecified allergic origin gradually disappeared in time, but if treated by rest in bed and semi-starvation it cleared away much more rapidly. The reason might be removal of an allergen from the food, or that relative starvation lowered the allergic reaction just as adrenaline did: probably both factors played a part. Bleeding might be a correlated factor; it had afforded relief, in olden days, in "sthenic attacks of pneumonia"—probably allergic phenomena. Dr. JAMES ADAM spoke of the nutritional factor, ending in toxicosis. Asthma in canaries, dogs, and other pets could be cured by regulated feeding, plenty of open-air exercise, and blue pill. Nasal, nervous, endocrine, and psychic factors did not enter in animals. "Only" children were in the same position as pets: they were coddled, overfed, and their sympathetic systems were not stimulated. The struggle of the body to maintain the alkalinity of the blood was the chief problem. A dose of urea sent up the eosinophil count, and might precipitate an attack. A cold douche after a warm bath kept adrenaline flowing and reduced eosinophilia. Golf was most useful in treatment. Mr. C. FRANCIS thought that removal of polyp benefited asthma only if the blood pressure was normal and the patient was not aspirin-sensitive. Light cauterization of the septum reduced high blood pressure and improved asthma. Anything that improved the circulation improved asthma.

DIAGNOSIS OF INTRACRANIAL TUMOURS

At a meeting of the Medical Society of London on November 26th, with Lord HORDER in the chair, a discussion took place on the value of accessory methods in the diagnosis of intracranial tumours and allied conditions.

VENTRICULOGRAPHY AS AN AID TO LOCALIZATION

Mr. HUGH CAIRNS said that it was just fifty years since Godlee's operation for the removal of tumour of the brain. The greatest significance of that event of 1884 was that Hughes Bennett, Ferrier, and Hughlings Jackson felt sufficient confidence in their growing knowledge of cerebral function to predict the presence and precise situation of the tumour and advise its removal. Looking back, it seemed that brain surgery was set in motion by the advance in diagnosis. Accessory methods had helped greatly to increase its scope. They could not be employed with discrimination in any one case, however, until careful clinical studies had been made; the value of these accessory methods was enhanced or belittled according as clinical studies were positive or negative. A preliminary question was whether lumbar puncture was dangerous in intracranial tumour. It seemed to him that lumbar puncture was often rather loosely used, also that too much fluid was taken. The dangers were minimized if the fluid was only in small quantity. After showing some cases which illustrated the value of x rays alone, he came to the methods of air injection, introduced in 1918. The method was at first called ventriculography, but when it was found that a lot of air went into the subarachnoid space as well it became "encephalography," and as such was adopted widely in Germany, where, in spite of initial claims that it was without danger, it had been shown that the injection of such a large quantity of air resulted in severe headache, lasting for some days. It had been found recently, however, that by putting in 10 or 15 c.cm. of air by lumbar puncture, with the patient sitting and the head slightly flexed, a good outline of the ventricles in the antero-posterior view was obtained, and without too great an ordeal for the patient. It was this method of ventriculography which he had used, and by means of lantern slides he discussed the significance of the appearances in the various deformities of the ventricular system produced by tumours, and it was remarkable what a large deformity a small tumour would produce. He showed how the position could be inferred from the difference in level of the two ventricles, also how guidance could be obtained as to third ventricle tumours, the localizing diagnosis of which, from the clinical point of view, was extremely difficult.

The limitations of ventriculography were that it would not show gliomatosis or sarcomatosis or any of the diffuse

tumours, that non-surgical lesions would sometimes produce deformity of the ventricles, and that the method would not give the pathological diagnosis. Its advantages were that it saved operative exploration in a number of cases suspected of tumour, it was a better form of exploration than operation, because it enabled more to be seen of what was going on inside the cranial cavity than an opening in the skull, and it was not without use in the post-operative period. He had never experienced any trouble with it in a patient who had normal ventricles and no intracranial tumour though one had been suspected, but in cases in which there were actually tumours the method had its dangers, the most important of which appertained to general reactions in the patient. Sometimes after air injection there ensued progressive stupor. To avoid danger the first thing was to let out the air and operate immediately. It was customary to make the x-ray examination early in the morning, and proceed with the operation as soon as the plates had been read. To avoid the dangers attending ventriculography the method of ventricular estimation had been introduced. The estimation was done by aspirating fluid instead of injecting air. If one lateral ventricle was small or collapsed and the other reasonably large, the tumour must be on the side of the collapsed ventricle; if both lateral ventricles were dilated, the tumour must be in the third or fourth ventricle. Ventricular estimation was done as a routine in every case of cerebellar exploration, and saved many mistakes. Mr. Cairns had particulars of 129 cases, in forty-two of which air injection had been done, and in twenty-seven ventricular estimation. Of the 129 cases the tumour was wholly or partly removed at operation in ninety-four; in eleven other cases the lesion was identified, but did not give histological material; in four cases there were mistakes in diagnosis. In 105 of the cases the tumour could be localized correctly by clinical methods alone; in twenty of these the clinical methods did not give a certain localizing diagnosis, and in four the clinical examination gave a wrong localizing diagnosis. X-ray examinations provided crucial diagnostic evidence in three cases and false localizing signs in three. Ventricular estimation was the main factor in five cases. The future lay in much more careful clinical examination and further experience of tumours.

EXAMINATION OF CEREBRO-SPINAL FLUID

Dr. J. G. GREENFIELD said that in going through his records he had been struck with the great variations from the typical cerebro-spinal fluid syndrome which were seen in cerebral tumours. The syndrome typical of cerebral tumour had raised pressure and increase of protein, with no increase of cells. Once the pressure passed 200 mm. it might rise rapidly to pressures dangerous to life. Pressures of 200 mm. were often found before there was any evidence of headache or vomiting. The rate of reduction of pressure was probably much more important than the situation from which the fluid was withdrawn. Normal pressures might be found with cerebral tumours and even with cerebral abscess; they were not uncommon with subdural haematoma. With regard to the dangers of lumbar puncture, probably tumours in the middle line and low down in the posterior cranial fossa were much more liable to cause dangerous symptoms after lumbar puncture than those above the tentorium. The exceptions to the rule that cerebral tumour produced no increase of cells were few and well defined. One of the exceptions was gliomas when these occurred in the walls of the lateral ventricles. Another was cancers of the posterior fossa. There were forms in cerebral tumours in which excess in protein was the rule, and others in which it was the exception. In eighth nerve tumours a considerable excess was always found. Cancers of the posterior fossa also usually raised the protein above 100 mg., but slow-growing gliomas and gliomatous cysts apparently did not. Nor was any great excess found in angiomatous cysts of the cerebellum. With tumours above the tentorium yellow fluids with only a slight excess of protein were indicative of haemorrhage only. It was uncommon to find excess of protein (over 100 mg.) in cases of meningeal endotheliomas or meningiomas, but his records included a few

cases of endotheliomas with proteins of between 100 and 200 mg. The more malignant gliomas were more apt to cause oedema of the surrounding brain tissue, usually reflected in a rise of protein in the fluid. In some cases it might be possible to distinguish between cerebral tumour, cerebral abscess, and subdural haematoma by the cerebro-spinal fluid, but one was never very safe.

Dr. M. H. JURE said that results and conclusions could only be reached by a combination of methods. At times the radiograph would lead to the diagnosis of a case when other methods failed, but that was seldom. He showed examples of routine radiography, pointing out the signs indicating general increase of intracranial pressure. It was in meningiomas that the surgeon was most likely to turn to the radiologist for help. Meningiomas were extremely complex; they calcified, ossified, caused hyperostosis, and destruction.

BILATERAL VENTRICULAR EXAMINATION

Dr. OLJENICK of Amsterdam, who has worked out a special modification of ventricular estimation, said that the mortality figures for ventriculography were not very high, though he knew surgical departments where they were up to 8 per cent. He did not regard ventriculography as purely diagnostic, since by using it a long surgical intervention might be avoided, therefore perhaps some small mortality was not without excuse. Nevertheless, to reduce even this small mortality was worth while. In his clinic a method of bilateral ventricular estimation or examination had been adopted, puncturing the ventricles, examining the fluid from the two aspects (chemical and microscopical), and measuring the pressure. If symmetrical conditions were found in the right and left laterals it must mean that the obstruction, if any, was in the middle part of the ventricular system, in either the third or the fourth ventricle. He strongly agreed with the late Mr. Donald Armour that the pressure should always be measured on a manometer; it was not safe to count drops. Bilateral puncture and examination made it possible for the fluid to be taken out first on one side and then on the other. In a case of cystic glioma he had found a reciprocating action between the pressures, as though the fluids were in communicating vessels, which was not the case, and he came to the conclusion that it was due to the fact that the glioma was adjoining the ventricle on one side, and so the fluid might go one way or the other, according to the change in pressure of the ventricular system. Another advantage in having a double puncture opening was that in cases where it was not possible to reduce the intracranial pressure before opening the dura mater, the complementary opening allowed the pressure to be reduced without introducing intravenous salines. In 1933 he had carried out sixty-one bilateral ventricular examinations. When the results did not coincide with the clinical localization the examination was repeated—which was easy to carry out, as the openings were already present—and when again the results did not coincide, ventriculography was done; this happened in four of the cases. So far in 1934 he had done 110 ventricular examinations, and the number of ventriculographies had increased to twenty-seven. The danger of ventriculography was mostly in temporal lobe tumours, probably because in such tumours there was no *fals cerebri* to act as a buffer, and if there was a shift with any such tumour it reacted directly on the neighbouring tissue and the brain stem. If a ventriculography was done he followed it immediately by operation, but it was perhaps not correct to say that this reduced the mortality rate, because in such cases it was difficult to say whether the patient died from the ventriculography or from the operation, or both.

Dr. C. P. SYMONDS said that neurologists owed a great deal to the surgeon for the advance which had taken place in knowledge of the localization of cerebral tumours. The work of Mr. Cairns and his colleagues and of Dr. Oljenick in Holland had opened up a very real advance. Mr. JULIAN TAYLOR drew attention to curious annular shadows sometimes seen in the x-ray picture right in the substance of the hemisphere. One such case proved to be an aneurysm. He was unable to say why the aneurysm

should show such a clear shadow, but that it did so there was no doubt.

Mr. HUGH CAIRNS, in reply, expressed his agreement with Dr. Oljenick's remark that with a diagnostic method proper there should be no mortality, but in practice every diagnostic method had a mortality. If all the methods available were discriminatingly used, however, the ultimate outcome should be a lessened mortality for brain tumours, provided, of course, that surgeons did their work properly. People had asked whether it was worth while to diagnose intracranial tumours. The results in the past had not been such as to answer that question promptly in the affirmative. The brain had seemed rather a hopeless field for radical surgery. But he recalled a remark by Gowers in 1893 to the effect that it was not likely that the removal of a tumour from the mid-cerebellum could be survived. The people who were going about their ordinary activities to-day after having had tumours taken out of the cerebellum were numbered by hundreds, and he believed that in future the results of brain surgery would be still further improved, especially if, beforehand, the cases worth operating could be distinguished from those not worth operating. The future lay in the hands of the physician and in closer clinical examination of cases.

BILATERAL RENAL CALCULUS

At a meeting of the Cork Clinical Society, held on November 16th, Dr. D. F. HEGARTY presented clinical notes and treatment of a case of bilateral renal calculus in a married woman.

The history was that some years ago this patient was operated on for chronic appendicitis, and two months afterwards she had an attack of right renal colic, and passed a small stone two days later. She suffered no further disability for the next six years and had four full-term pregnancies. She became pregnant twelve months ago, and when seven months advanced she had another attack of right renal colic, and again passed a small stone. A month before confinement she had an attack of left renal colic, the pain remaining for four days. Radiography and pyelography after her confinement showed four calculi in her right kidney and a small one blocking her left ureter, and free excretion of the dye by the right kidney. Owing to the risk of calculus anuria and to the patient's condition, it was decided to remove only the calculi on the right side and not to interfere with the left side for the present. The patient made an excellent recovery.

Professor J. M. O'DONOVAN read a communication on "Pernicious Anaemia: Results in a Series of Cases." He subdivided his cases treated since the advent of liver therapy according to the response to treatment, and in each group suggested the reasons for rapid or slow response. One case of particular interest was that of a patient who developed pernicious anaemia after a partial gastrectomy. A prolonged discussion followed.

J. Rousset (*Presse Méd.*, September 29th, 1934, p. 1518) records a case of acute gastric dilatation with perforation after hysterectomy. Many causative factors of post-operative gastric dilatation have been suggested: infection from a perigastric peritonitis; mechanical obstructions; aerophagia and sialophagia; anaesthetics (especially chloroform); the state of the nervous system; and shock. Perforation is an exceptional complication; it has been noted during the course of certain nervous conditions, and ulcerous lesions may be a possible factor. Rousset believes that the dilatation is the most probable cause, and advances the following hypothesis. Subacute gastric dilatation supervenes after the operation, followed by haemorrhage, due to vaso-dilatation or distension of the mucosa; the mucosal lesion gives rise to an ulceration with subsequent necrosis and perforation. Simple gastric lavage, repeated as long as necessary, should be instituted on the first appearance of symptoms. Operative measures, owing to their poor results, are not advised.

CORRESPONDENCE

London University and its Medical Schools

SIR,—The awful prospect of being thought foolish and unwise by Mr. Eric Pearce Gould (December 1st, p. 1018) will not, I hope, deter your readers from expressing their opinions upon the question of principle raised by Sir Ernest Graham-Little. The additional information sought by Mr. Pearce Gould happens to be irrelevant to the question raised, which is not why so many undergraduates fail to graduate in medicine, but whether those who have completed the second M.B. should be allowed to become at once graduate members of the University.

There seem to me to be two reasons strongly in favour of Sir Ernest's contention. The first is that to enter a son or daughter for the London M.B. course is not an absolute guarantee against death or misfortune. A youth who, owing to family misfortune, is unable to complete his medical course at all is at a disadvantage in London as compared with Oxford or Cambridge. He is not a university graduate, and, whether we like it or not, the right to append academic letters to one's name is an economic advantage in many careers.

The second and, in my opinion, more important reason is that one of our academic weaknesses in London is the faintness of the emotional appeal made by the University. Oxford and Cambridge men take a legitimate pride in membership of illustrious corporations. Too often London men seem only to take pride in having passed rigorous examinations. Affection for or pride in the University as something nobler than an examining body is still rare. But an examination is a means, not an end; it is used as a test—one test—whether a person is worthy to become a member of a great corporation devoted to the service of liberal education. If it be true that the young men and women who have completed their pre-clinical education are worthy to be admitted to full membership, or that a relatively slight modification of their intellectual training would make them worthy, we should rejoice. It would mean that a number of young people who, in the ordinary course of events, will continue their education in London for some years, would be able to participate as graduates in the life of the University. I do not believe the University of London can fulfil our aspirations unless we have an increasing number of young graduates who take pride in the University as such. It is very difficult to catch these young people without running the risk of lowering intellectual standards. If, in this particular case, we can make graduation easier without providing a "soft option," we ought to do so.

The late Professor M. S. Pembrey, no believer in "soft options," was an enthusiastic advocate of this reform. He it was, I think, who moved for a return to the Beard of the Faculty of Medicine of the statistics upon which Sir Ernest has based his argument.—I am, etc.,

MAJOR GREENWOOD.

Loughton, Dec. 2nd

Fractures of the Neck of the Femur

SIR,—I note with some surprise, in your issue of December 1st (p. 1012), remarks which I cannot pass without some commentary.

Gunshot fractures of the neck of the femur in 1915 were the first to suggest to me that the blood supply of the proximal fragment was very often inadequate, and this, combined with sepsis, caused a large percentage of heads to necrose, which, in turn, were duly removed at operation. These observations were carefully noted, with x-ray pictures (Figs. 24, 25, and 26), in my book *Fractures*, which illustrates these points and hints at the very long prognosis. The correct and almost universal application

of the Thomas splint—first, in the trenches; secondly, as a bed splint; and finally, as an ambulatory splint—reduced (1) the appalling death rate from shock and sepsis from 80 per cent. in 1916 to 15.6 per cent. in 1917, and (2) saved innumerable limbs which would certainly have been amputated if treated otherwise.

After retiring from the Service, and since 1926, I have been working at the L.C.C. hospitals, where some 200 cases of fractures are constantly under my care. A very great number of intracapsular fractures have during this time passed through my hands; the majority of these have been satisfactorily treated in Thomas splints and extended, as I was wont to do during the war. When union is solid enough—see *Fractures*, Fig. 138, showing marked displacement, and Fig. 139, showing complete replacement with union—the result will, I hope, even please the hypercritics.

The age of these patients has varied between 13 and 94 years, and large numbers of them have left the four hospitals walking, some united and others not, in calliper splints—even a spontaneous fracture in a malignant case returned, after being treated and sent out of hospital, with some union, in her calliper splint, to die a year later of the primary cause. At Dulwich Hospital, S.E.22, where there have been for years casualties in these high fractures occurring at the rate of two deaths per month, there has not been a single death in this variety of case since the fractures were taken over by me some eighteen months ago. Surely this is sufficient proof as to the efficiency of the Thomas splint. All these statements of mine can be readily verified.

These are some of the facts and figures I advance for denying the remarks made by Mr. Watson Jones, who is reported to have said "that the Thomas splint or calliper was dangerous in such high fractures, and was not to be recommended at any stage of treatment."—I am, etc.,

London, W.1, Dec. 3rd.

MEURICE SINCLAIR.

Short-wave Diathermy

SIR,—As one who took part in the discussion on this subject at the Royal Society of Medicine on November 16th (see *Journal*, November 24th, p. 956), and who had on that date given 1,792 ultra-short-wave treatments, I would like to comment on Dr. C. B. Heald's letter.

Papers on ultra-short-wave therapy have been published since 1926. Schliephake, in the second edition of his book *Kurzwellentherapie*, which has just become available, gives 236 references to books and articles dealing with this subject. This method, therefore, can hardly be described as a new one, though its use in this country is comparatively recent. In regard to the differences between treatment given by diathermy and by ultra-short waves, it should be remembered that some of the greatest successes which have followed the use of ultra-short waves have been in cases where there has been enclosed pus—namely, pulmonary abscesses, pleural empyema, sinusitis, dental abscesses, etc.—conditions in which diathermy is contra-indicated; also in cases such as carbuncles, boils, whitlows, etc., where it would not be possible, for technical reasons, to give diathermy treatment. At the Royal Society of Medicine discussion it was noticeable that those speakers who had had an opportunity of using apparatus of sufficient power appeared to have had the greatest success in treatment. As in every other form of therapy, efficient apparatus is essential, and in ultra-short-wave treatment particularly improvised home-made accessories have not proved satisfactory. Adequate care and skill in the technique is, of course, just as necessary. Exaggerated claims are equally to be deplored as uncritical condemnation without personal experience or trial.—I am, etc.,

London, W.1, Nov. 26th.

W. KERR RUSSELL.

Treatment of Epilepsy by Snake Venom

SIR,—I shall be pleased, as Colonel Elliot says, to offer any help in my power to medical men wishing to treat epilepsy by snake venom, but I would like to make my attitude clear.

There is, I think, sufficient evidence of the successful treatment of epilepsy in this way to warrant further investigation, but I have no evidence to make me more optimistic than this. The treatment would, of course, be quite empirical, though reports of cases seem to show that it depends on something in the nature of protein shock.—I am, etc.,

BURGESS BARNETT, M.R.C.S.
Curator of Reptiles, Zoological
Society of London.

December 3rd.

SIR,—I have recently received communications from sources which cannot be considered either unimportant or negligible, to the effect that the medical profession in this country has been very slow to take up the treatment of epilepsy by the injection of snake poison. It is suggested that we have been prejudiced because a leading part in this movement has been taken by laymen and not by those of our own profession.

In favour of the treatment of epilepsy by venom there are two sources of evidence. (1) Very striking cases have been published, both in America and in Africa, of the complete cure of epilepsy following the bites of poisonous snakes in which, though the patients were made very ill, the amount of venom injected was not sufficient to cause death. (2) There are a number of records of patients treated by the injection of snake venom in which it is claimed that long-standing epilepsy has been cured. These come both from America and from Africa, and, unfortunately, many of them are open to some criticism. In both the above countries it has been comparatively easy for medical men to obtain a supply of snake venom, whereas in this country it is very difficult for them to get it. Moreover, snake venom, as usually obtained, is full of dangerous septic organisms.

The fact that the curator of reptiles at the Zoological Society's Gardens is now a medical man who has in the past been in active medical practice, has an important bearing on snake problems at the present and I hope for a long future. Dr. Burgess Barnett, the curator of the reptile house, is very keen to help in work of this kind. He is prepared to advise medical men as to the most suitable form of snake venom for use in any particular type of case, and as to the method of obtaining an aseptic product by appropriate treatment of the venom.

If low doses are given to begin with, the risk of any unfortunate happening is practicably negligible. Through the kind introduction of Mr. Ditmars of the New York Zoological Park, I was put in touch with Colonel M. L. Crimmins, a retired Army medical officer of the United States of America. Colonel Crimmins, taking advantage of an accident to begin with, has immunized himself against rattlesnake poison, and has shown conclusively that it is possible to do this in the same way as we have long known that immunity against snake venom could be established in animals. Colonel Crimmins's blood has been used successfully in the case of a child bitten by a venomous snake. Needless to say, the method has been well established in animals, so that it can no longer be described as an unjustifiable experiment, or, indeed, as an experiment at all. Even were it an experiment, which it is not, I have abundant evidence in writing from epileptics and others that they would be only too willing to take the risk involved if it offered any reasonable prospect of cure.

May I venture to hope that some enterprising medical men, preferably those with hospital opportunities and

practising in London, will get in touch with Dr. Burgess Barnett, who has most kindly promised to give any such all the help in his power. He has authorized me to make this offer on his behalf, and he can be addressed at the Zoological Gardens, Regent's Park, N.W.8.—I am, etc.,

R. H. ELLIOT, M.D.,
Lieutenant-Colonel,
Late of the I.M.S.

London, W.1, Nov. 26th.

Ingrowing Toe-nail

SIR,—From articles that have appeared in the *Journal* it seems that rather severe surgical procedures are still in use for the relief of the above. The following will be found a method of treating the condition which is simple, painless, and entirely successful. The relief is immediate, the cure is complete in a few days, and if ordinary after-care is used there is no recurrence. I was shown this treatment forty-five years ago by a farmer's wife in Australia, who operated on me, and I have used it ever since.

The procedure is simple, but it is important that the technique should be followed exactly. Two points must be borne in mind. First, the downward curve of the nail from side to side must be replaced by an upward curve, or its nearest approach; and secondly, on no account must anything be removed or pared from the edge of the nail where the so-called ingrowing is taking place.

The toe must first be thoroughly soaked in hot soap and water. Then a groove, or rather a "flat," is made down the centre of the nail by paring. The instrument to do this with

Illustration showing spur on left and area to be shaved thin to form hinge in centre.

is a piece of broken bottle glass. It is quite useless to try to do it with a file or scissors. It will be found that the sharp edge of the broken glass "spokeshaves" down the softened nail with the greatest ease and accuracy. The shaving must be continued until the centre line is quite thin, and the pink nail bed shines clearly through. This line now forms a hinge on which the two sides of the nail can be bent up. Of course, this is done chiefly on the affected side. As the edge of the nail is lifted pledgets of wool are packed under it. In a few hours, for convenience at the next visit, the edge of the nail can be lifted clear of the bed and packed again.

Now comes a very important point. If the case is of any standing it will invariably be found that on the edge of the nail at the most painful point is a spur or spike. This seems, and probably is, the cause of the pain, and it seems the obvious thing to do to remove it. On no account must this temptation be yielded to. If it is removed recurrence is certain to take place. The proper course is to raise it tenderly, by bending the nail still further on the central hinge, and letting it grow out, up, and over the irritable ulcer under it. This preserves the full width of the nail. As soon as it is raised the relief is immediate, and in a few hours the patient can walk without any pain.

The spur is, I believe, caused by the sufferer cutting round the nail, and leaving a small piece at the corner at each cutting; hence the importance of cutting the toe-nails straight across and always leaving projecting corners. If this is done ingrowing toe-nail will not occur. Those who have a tendency to suffer should always keep their nails on the long side. There is one difficulty which may be

met with. In some of these cases the nail is very short and sunken. This makes shaving a proper groove and raising the edge difficult, but it can generally be managed to some extent, which will give relief, and further treatment can be carried out on the same lines as the nail grows. Many of the cases treated by this method show a good deal of suppuration, and a boric compress is a useful addition to the treatment in such circumstances.

I would be interested to hear from anyone who may try the above treatment.—I am, etc.,

P. F. CHAPMAN, M.B., C.M.Ed.

Taynult, Argyllshire, Nov. 26th.

Obstetric Methods at St. Mary Abbots

SIR,—I have carefully read the report of the work at the Louise Margaret Hospital, published by Colonel E. L. Moss in 1924 (*British Medical Journal*, 1924, ii, 272), and it is clear that his "challenge," published in your issue of November 24th (p. 964), is due to the fact that he has confounded morbidity with mortality. His paper contained no figures relating to morbidity as measured by any known standard. It is quite impossible to compare the mortality rate of a sheltered hospital, where all except four of the patients were soldiers' wives, and regularly attended an ante-natal clinic, with that of a unit like the one at St. Mary Abbots. During the last fortnight three of the puerperal patients in the suspect ward suffered from tuberculosis, two were sent in from outside after being many hours in the second stage of labour, and one was sent in because of severe varicose veins. There are in the ante-natal ward three patients sent in with morbus cordis, one being admitted with serious circulatory failure, one with asthma, one with pyelitis, and one with a blood sugar of just under 400 mg. per 100 c.cm. All of these patients save one were sent in because of the "complication," and they are typical of the material dealt with in the unit. I still assert that, so far as I am aware, the morbidity rate at St. Mary Abbots Hospital was the lowest ever recorded in this country.

I must apologize for the error pointed out by Colonel Moss. The enema is given towards the end of the first, not the second, stage of labour. I regard a temperature of 98.4° F. during the puerperium as pathological because, so far as I am aware, a healthy individual confined to bed rarely, if ever, records a so-called normal temperature. All the patients are kept on an exceedingly generous diet, and I can assure Colonel Moss that they have plenty to get rid of, and are not suffering either from acute diarrhoea or burned "seats." It does seem to me that he tends to assume that a thing is good because it is new. Are his present results superior to those published in 1924, at which time he could not have used dettol, and probably did not wear a mask? Still, I agree so heartily with much of his letter that I hope he will allow me to congratulate him on his excellent results.

Dr. James Cook has succeeded in astonishing me. I am delighted to have his categorical assurance that for the last quarter of a century general practitioners have always worn gloves, shaved the pubic hair, used more than a gallon of antiseptic solution, and a corresponding number of swabs for each confinement; have dispensed with vaginal examinations in normal cases; have not touched the perineum during delivery; have dispensed with induction of labour and Caesarean section, and kept the forceps rate below 4 per cent.; have used adequate amounts of anti-streptococcal serum in possibly infected cases; have insisted on adequate drainage and purgation; and have kept the urine alkaline during the puerperium.—I am, etc.

G. W. THEOBALD.

London, W.1, Dec. 3rd.

SIR,—May I, a humble practitioner who practises midwifery without having "resided for at least three years in a maternity hospital," offer some comments upon various points mentioned by Dr. G. W. Theobald (*Journal*, November 10th, p. 850).

1. Two ounces of castor oil plus two enemata during labour might be considered by some to be unnecessarily enthusiastic treatment.

2. "The nurses . . . do not wear masks." As every surgeon now wears a mask while operating, is there any reason why a nurse, "when conducting a confinement," should not do the same?

3. "It may be assumed that organisms responsible for puerperal infection gain access through this narrow portal"—that is, the vulva. Why may this assumption be made? Is there no such thing as autogenous infection?

4. "If the vulva is kept antiseptic . . . infection cannot and does not occur." I make bold enough to say that even if the vulva is kept antiseptic infection *can* and *does* occur. We all know the case in which the confinement has been normal, with every aseptic and antiseptic precaution, with no vaginal examination at all, and in which death has resulted from puerperal septicaemia.

5. "Two drachms of liquid extract of ergot are given as soon after the placenta is delivered as possible." Assuming this to be a prophylactic against post-partum haemorrhage, is not an intramuscular injection of pituitrin or lemergin more efficacious? And is it not a little difficult to administer drugs by mouth when the patient is, presumably, anaesthetized?

6. "Each patient is given 3ij of castor oil on the morning after delivery and a purgative on each subsequent night that she spends in hospital." (My italics.) Is this necessary? It is certainly unnecessary in general practice. I am sure that most doctors would find themselves very unpopular if they ordered this drastic procedure for their private patients.

7. "I have long been convinced that infection of the urinary tract usually precedes or is causally connected with puerperal infection." What pathological or bacteriological evidence is there for this statement?

8. "Each mother . . . soaks her hands in biniodide before feeding the infant." Might not biniodide get from the mother's hands to her nipples, and thence to the child's stomach?

9. "I maintain that a temperature of 98.4° during the puerperium is pathological." I am going to be charitable, and suggest that this is a misprint!

10. "Forceps were applied on twenty-nine occasions." Without making the slightest suggestion that forceps were applied unnecessarily, one would like to know the specific reason in each case, as one has been taught that there are only two absolute indications for forceps: (a) maternal distress, (b) foetal distress.

11. There has been no mention of anaesthetics whatsoever—apart from an injection of morphine and scopolamine at the beginning of labour—whether they are given at all, what they are, or the technique of their administration.

May I say that it is with the greatest diffidence that I submit these points to one whose ability and experience in obstetrics is so many times greater than my own.—I am, etc.,

Sydenham, S.E.26, Nov. 19th.

W. A. BELLAMY.

Puerperal Morbidity

SIR,—Much alarm has been caused generally throughout the country by reason of the rising death roll of maternity. Many suggestions have been offered to lessen this rate, both in medical journals and in the lay press, and money has been promised by the Government for methods for its solution. Emphasis has been laid on the creation of more ante-natal clinics and for their increased use, for the creation of hospital beds, and for the linking of home and clinic by the creation of more district visitors.

I do not deprecate any of these suggestions—rather are they all in their way very useful—but I do stress the fact that in my opinion the chief factor in reducing maternal

him only three days before. (Incidentally, I had seen him in private with Dr. B some time ago.) Yet, without a word to anyone, he is sent off to hospital because the school inspecting medical officer cannot take the trouble to discover what is being done, and finds it simpler to send direct to hospital than to advise the parents to consult their own medical adviser.—I am, etc.,

Bristol, Nov. 26th.

F.R.C.S.

Pott's Paraplegia: Pathological Material Wanted

SIR.—During the last two and a half years we have been engaged in a study of Pott's paraplegia, and our findings were reported in papers read at the annual meeting of the British Orthopaedic Association on November 2nd (see *Journal*, December 1st, p. 1011).

Although the pathology and the clinical features of this condition are by no means obscure, there are still many points meriting further investigation. Pott's paraplegia is no longer a particularly lethal condition, and when a fatal case does occur a necropsy is rarely performed. Consequently, there is a dearth of fresh pathological material.

As we are anxious to continue this work, may we take this opportunity of seeking the aid of those who see the occasional fatal case? Specimens may be sent to either of us, and we shall be pleased to send photographs and microscopical preparations made from the material to the donors, and, whenever possible, return half the specimen if desired. We should also welcome opportunities to see cases clinically.—We are, etc.,

R. W. BUTLER,
Grove Lodge, Cambridge.

H. J. SEDDON,
Royal National Orthopaedic Hospital,
Stanmore, Middlesex.

November 29th.

Harvey Memorial Tower

SIR.—The response so far to the appeal, which was circulated at the beginning of November to every member of the profession with reference to the above memorial has not been sufficient to warrant the committee taking any steps at present to complete the building of the Harvey Memorial Tower.

As it was our earnest hope to do so early in the New Year, may I ask those who have not yet contributed to kindly send a donation made payable to the Harvey Memorial Fund, and addressed to me at the Royal College of Physicians, Pall Mall East, S.W.1.—I am, etc.,

G. DE BEC TURTLE,
Honorary Secretary.

* An article commending this appeal to our readers, and showing the progress so far made with the tower, appeared on November 3rd (p. 820).—ED., *B.M.J.*

Medical Benevolence

SIR.—“Fair Play's” apologia (November 24th, p. 968) in defence of the medical non-subscriber to our own charities is beside the point. In his original letter Dr. Hawes laid down the principle, with which most of us will agree, that it was the duty of the profession to look after its own poor. This duty is not being adequately carried out, for lack of sufficient funds. Moreover, the admirable relief work that is being done is financed by a minority of practitioners which includes many who are not in “rosy” circumstances.

No one wishes to rob the harassed doctor—country or town—of his hard-earned savings for the sake of this or any other charity. All that is asked for is that in

assessing his charity budget for each year a practitioner will remember the distressed brethren of his own Hippocratic family.—I am, etc.,

HONORARY LOCAL SECRETARY, ROYAL
MEDICAL BENEVOLENT FUND.

Scotland, Nov. 24th.

R.M.B.F. Christmas Gifts

SIR.—In October, by your courteous permission, I was able to make an appeal to your readers for contributions towards our Christmas Gift Fund. I do not wish to labour the distress which, unfortunately, exists, for it is well known to all. The response to my appeal to date is £126 4s., a sum far short of what we need. I am confident that it will be the desire of the profession that we should distribute gifts to each of the 650 beneficiaries on our books. May I ask once more for a generous response, and as soon as possible, so that when we sit down to our comfortable dinners we may know that some comfort and pleasure has been given to our own poor people.—I am, etc.,

THOMAS BARLOW,

President, Royal Medical Benevolent Fund.
11, Chandos Street, Cavendish
Square, W.1, Nov. 26th.

Obituary

The death took place at his residence, The Cedars, Corstorphine, Edinburgh, on November 27th, of Dr. JAMES GRIEVE CORMACK, who for many years was a medical missionary in China, and who, since his retirement in 1927, had been in practice at Corstorphine, Edinburgh. Originally a missionary under the China Inland Mission, to which he had been attached in 1890, Mr. Cormack returned to this country on furlough in 1898. He was then so greatly impressed with the special need for doctors in China that he decided to study medicine, and took the triple qualification at Edinburgh in 1904. Returning to China under the London Missionary Society's auspices, he did medical work in Shanghai, Hankow, and Hwangpei, and in 1910 was transferred to the Peking Medical College, of which he became Principal in 1913. While on furlough in 1912 he took the higher qualification of F.R.C.S.Ed., with midwifery and gynaecology as his special subject. In 1917 he began private practice in Peking, being appointed specialist in gynaecology and obstetrics at the Central Hospital, Peking, and professor of surgery at the Army Medical College. He was also surgeon to the Peking-Mukden Railway, and medical officer to the British Legation in that city. He rendered a special service to Chinese medicine in the translation into Chinese of several medical textbooks, of which the chief were Rose and Carless's *Manual of Surgery*, and Hutchinson and Rainy's *Clinical Methods*. Dr. Cormack is survived by a widow and two sons and two daughters.

The death of Dr. CHARLES JOHN JACOMB-HOOD took place with great suddenness on November 28th, at Hove. He was attending a dinner party at a friend's house, when he suddenly collapsed and died immediately. Dr. Jacomb-Hood took the M.R.C.S. and L.S.A. in 1884. At the time of his death he was in his seventy-third year, and had been a member of the B.M.A. for thirty-five years. He retired from the chairmanship of the Brighton Insurance Committee, of which he had long been a member, in September last. His services to this committee were invaluable, and were much appreciated by his colleagues. He held the office of vice-president of the Navy, Army, and Ambulance Section of the Association at the Annual Meeting at Brighton in 1913. During the war he held the rank of lieutenant-colonel in the R.A.M.C.(T.), and did good service from 1914 till 1918. He was a bachelor, and had retired from practice some few years owing to indifferent health. He was popular

among his patients, to whose interests he was devoted. It was said that he never sent in accounts, but left it to his patients to do as they liked as regards fees. The funeral took place on December 1st at the Brighton Crematorium, and was attended by many of his old friends, colleagues, and patients, including members of the Brighton Insurance Committee, and of the Women's Hospital, on the staff of which Dr. Jacomb-Hood served for a long period.

The death occurred, at 3, Minto Street, Edinburgh, on November 24th, of Dr. WILLIAM MORRISON MILNE, a well-known practitioner on the South Side of Edinburgh. Dr. Milne was born at Gortich, Morayshire, and after a distinguished course at the University of Aberdeen graduated M.A. in 1885, with the intention of taking up the teaching profession. Determining to study medicine, however, he graduated M.B., C.M. at Edinburgh in 1896, and took the F.R.C.S.Ed. in 1901. After a period as house-surgeon at Leith Hospital, he entered private practice in Edinburgh. In a period of thirty years he had gained a large general practice, and was regarded with great affection by his numerous patients. Dr. Milne had a serious illness while on holiday last August, and since that time he had been in failing health. He is survived by a widow and two sons.

Universities and Colleges

UNIVERSITY OF OXFORD

Congregations will be held, for the purpose of granting Graces and conferring Degrees, on the following days at 2.30 p.m. Michaelmas Term, 1934—Saturday, December 15th. Hilary Term, 1935—Thursday, January 24th, and Saturday, March 2nd.

UNIVERSITY OF CAMBRIDGE

Dr. F. Goldby has been appointed University Lecturer and Dr. H. W. Hall University Demonstrator in the Department of Anatomy for three years from October 1st, 1934. The Faculty Board of Medicine has appointed Dr. G. S. Graham-Smith, Dr. T. S. Hele, Dr. G. H. Orton, Dr. E. P. Cumberbatch, Professor S. Russ, and Dr. R. J. Reynolds to be members of the Committee for Medical Radiology and Electrology for the year 1935.

Gwynneth Pretty Studentship

Applications for this studentship, the holder of which shall devote himself to original research in the aetiology, pathology, and treatment of disease, with particular but not exclusive reference to those diseases which cripple or disable in childhood or early life, are invited, and should be sent, accompanied by copies of papers containing published work, and by testimonials and references, before February 1st, 1935. The studentship is of the annual value of £200 and is tenable for three years. The place and nature of the studies of the student are subject to the approval of the Professor of Pathology, provided that the student shall be bound to pursue his studies within the University unless the Managers dispense with this requirement for special reasons. At a congregation held on December 1st the following medical degrees were conferred:

M.D.—T. G. Reah.
B.Chir.—C. E. P. Markby, W. F. Richards.

UNIVERSITY OF LONDON

The Paul Philip Reitlinger Prize, offered this year for the best essay embodying the result of some research work on a medical subject carried out by the candidate, has been awarded to Edward Graham Murphy, M.Sc., a student of University College, for his essay on "The Behaviour of Liver Glycogen in Experimental Animals." The prize, of the value of £30, was founded with funds given to the University by Mr. Albert Reitlinger in memory of his son, a student of Middlesex Hospital Medical School. Next year the prize will be awarded for the best essay on "A Critical Study of Post-war Historical Biography."

The following candidates have been approved at the examination indicated:

POST-GRADUATE DIPLOMA IN PSYCHOLOGICAL MEDICINE.—(With Special Knowledge of Psychiatry): W. E. Mellroy, J. H. Malloy, R. W. Maxwell. (With Special Knowledge of Mental Deficiency): R. M. Norman.

Medico-Legal

BUSINESS RELATIONS BETWEEN DOCTORS

TRANSFER OF PRACTICES

The British Medical Association and the defence societies issue from time to time detailed advice to medical men who contemplate buying a practice, and many useful facts are also set out in Barnard and Stocker's book. The purpose of this article is not to duplicate such work, but to point out one or two of the legal implications of an agreement to buy a practice. The value is generally calculated on the average gross yearly receipts for the last three years—that is, the actual cash receipts. The average of three years is usually taken in order to obviate the effects of ordinary fluctuation. The buyer should also, however, take into account such factors as the expenses of carrying on the practice and the amount of work required to earn the income, which differ widely in different practices; and also the prospects of the practice increasing or diminishing. If the gross figures are not available, an annual figure has to be estimated from the books.

NEED FOR AN ACCOUNTANT

It is most important that the prospective purchaser should have the figures audited or prepared by a qualified accountant with special experience of medical work. A doctor's training does not necessarily make him an expert in accounts, and a vendor may in perfect good faith and with the best intentions produce an entirely incorrect estimate. A medical man who neglects this precaution practice is not worth nearly as much as he thought it would be. This is an unfortunate beginning to a very important stage in a man's life, and if he is to work in partnership with the vendor it may well be disastrous to their mutual confidence. Moreover, if a doctor, after purchasing a practice, finds that the income it actually produces is substantially less than the income the seller said it produced before it was sold, he can only bring a successful action if he can prove that the seller made material misrepresentations to him, or withheld material information from him about the practice.

In addition to securing an expert investigation of accounts, the purchaser should make all possible inquiries of the agents acting for the seller. If, also, he knows a medical man who practises in the immediate neighbourhood, he might do well to ask him for confidential information about local conditions, with special reference to any personal quarrels which may adversely affect the practice. If the purchaser can afford the somewhat heavy cost, it might pay him to employ a good inquiry agent to supplement this information.

INTRODUCTION TO PATIENTS

The introduction to the patients is one of the most important parts of the purchase, and when an introduction cannot be given, as when the vacancy is due to death or serious illness, the practice is worth less by a quarter or a third. The written agreement to buy and sell a practice therefore usually contains a clause under which the seller binds himself to stay in the neighbourhood for a specified time (often three months), actively assist the purchaser in the conduct of the practice, and do all he can consistent with medical ethics to introduce his successor and secure for him the custom of all the patients and the transfer of all the appointments. As the seller is being well paid for the introduction, he should consult the purchaser's views on the best way to effect it, and should make sure from time to time that he is satisfied. The introduction is a

* The first of these articles, by a legal correspondent, appeared on June 9th, 1934 (p. 1053), the second on June 23rd (p. 1145), the third on July 7th (p. 42), the fourth on July 21st (p. 141), the fifth on September 22nd (p. 574), the sixth on October 6th (p. 660), the seventh on October 20th (p. 750), and the eighth on November 3rd (p. 841).

London and Counties Medical Protection Society, Annual Report, 1928, p. 33.

fairly frequent source of complaint, and the seller should spare no reasonable effort to fulfil it.

When complaints of incomplete introduction have been made to the courts, the legal question has usually been either how far it is consistent with morality to recommend another to a position of trust, or how far the court can compel a doctor actually to carry out a promise to do so. In 1803 (*Bunn v. Guy*) the King's Bench—apparently with some misgivings—held valid a contract binding an attorney to introduce his clients to two others who were succeeding him in practice. This decision has not been overruled, and the courts will probably regard such a transaction as legal. To compel a doctor or solicitor to perform specifically a promise to introduce is, however, quite another matter. If the seller does not do what the purchaser has bargained for, the court can fairly easily make him return part or all of the purchaser's money, or can release the buyer from paying it. If the buyer has suffered damage it may make the seller recompense him. But the whole essence of introduction is that it has to be done willingly, and the court never commits itself to an order which it may not be able to enforce. When one medical man agrees to transfer his practice to another, and afterwards refuses to carry out his contract, the court has no means by which it can put the newcomer in possession of the practice. To get over this difficulty Barnard and Stocker recommend that the agreement should contain a condition that if the introduction is not actually carried out, or does not last as long as the agreement specifies that it should, the purchaser shall pay less. If this is not done the court may hold that the promise of the owner to introduce the newcomer, and the promise of the newcomer to pay the purchase money, are independent of one another, and that the introduction is not a condition which must be fulfilled before the purchase money is handed over. Moreover, if the owner dies before he has handed over the practice, and there is no provision for such an accident in the agreement, the purchaser cannot claim any relief, for "death is a contingency which all persons must be supposed to have in their contemplation."

The agreement should contain provision for the period during which the newcomer is being introduced and before he actually takes over. One of the defence societies suggests that if the successor is giving his professional services free during this period he might reasonably expect to be at least entertained free of charge, but that if he is being adequately paid he should bear the cost of his own board and lodging. If, on the other hand, the retiring practitioner stays on for the benefit of the successor after the transfer has taken place, he likewise can expect to be properly remunerated. The terms will depend on what is reasonable in the particular circumstances.

The same society points out that when a new partner is entering the firm, or the practice is being transferred, the present members or the owner may send a circular letter to all the *bona fide* patients of the practice informing them of the change and of any alterations that are to be made in the hours of attendance or the address, but the letter should not contain any laudatory observations on the in-coming practitioner. In order to protect the firm or doctor who sends the letter from an accusation of advertising if a circular should by mistake fall into the hands of a person who is not a patient of the practice, each circular should be sent in a closed envelope, and each envelope should bear the name of the patient for whom it is intended.

SUCCESSION TO APPOINTMENTS

In many cases the purchaser buys, besides the goodwill of the practice, the prospect of succeeding to the appointments of the seller. The retiring practitioner cannot of course sell the appointments themselves or guarantee that the newcomer will be appointed in his place, but he can bind himself to use all legitimate means, by recommendation and otherwise, to secure that the purchaser succeeds him. One of the defence societies warns the purchaser not to commit himself in paying for a mere possibility, but to insist on a clause in the agreement that the seller shall return a certain part of the purchase price if the appointments are not transferred. Barnard and Stocker

suggest that the agreement should lay down that if any appointment is not in fact transferred the purchase money shall be reduced by an amount appropriate to the annual value of the lost appointment. If, for instance, the buyer is paying one and a half years' purchase for the practice, the deduction would be the income from that appointment for one and a half years. The buyer may be well advised to insist that the seller should not resign until the introduction has been completed. The agreement should therefore provide for a time limit of three to six months for the transfer of the appointments. It is not usual to stipulate that the price shall be altered if the appointment is transferred at a lower or higher salary, or to make the sale itself depend on the transfer of the appointments. If, however, any particular appointment brings in an exceptionally large proportion of the income, it is reasonable to make an exceptionally large allowance for its loss.

The following case¹ shows the necessity for insisting on security against the loss of appointments, and also of instituting local inquiries before buying a practice.

Dr. A bought a practice of Dr. B, who held two appointments to which Dr. A hoped to succeed. Dr. A was then unlucky enough to enter into partnership with a Dr. C, with whom the family of Dr. B had for many years carried on a bitter feud. The family thereupon induced another doctor to open a branch practice in competition with Drs. A and C, and to apply for the two appointments. Dr. A complained to his defence society, but it replied that Dr. B could not be held responsible for the opposition unless it could be proved that he had encouraged it, and that it would be difficult to prove that he was able to exercise any control over his friends and others.

Apart from the matter of the appointments, this situation could not have been avoided by the strictest legal safeguards, but only by careful preliminary inquiries in the neighbourhood. It is not clear from the report of the society concerned whether Dr. A, in taking Dr. C into partnership, acted with his eyes open or in ignorance of the quarrel.

If the purchaser is also proposing to succeed to the owner's house, it is better transferred by a separate agreement. The agreement for the transfer of the practice should also contain a clause providing for arbitration in the event of a dispute arising between the parties. If it came to the knowledge of patients that the parties were engaging in a lawsuit, it would be bound to decrease the value of the practice.

A HOSPITAL EXONERATED

An unfortunate fatality recently occurred at the Crumpsall Hospital, one of the hospitals administered by the Manchester Corporation.

A young married woman arrived at St. Mary's Hospitals, a voluntary hospital in Manchester, at about 6 p.m. on May 11th. She was expecting to be received as a maternity patient, and arrangements had been previously made for her to enter that hospital. Within twenty minutes of her arrival, and while she was still waiting in the out-patient department, her child was born. No bed was available for her, and the medical officer on duty gave orders that she and her child should be transferred by ambulance to the Crumpsall Hospital, which is some miles away. She and the child were admitted to Crumpsall at 7.40 p.m., and she was put to bed in a maternity ward. She died at the hospital at about 1.25 a.m. next day. The Board of Management of St. Mary's Hospitals, with the approval of the Health Committee of the corporation, held a private inquiry in June. The City Council considered the report presented, and made a request to the Minister of Health for a public inquiry, which was held by Dr. Isabella D. Cameron and Mr. Henry J. Comyns on September 20th. It took place in public and was attended by about 200 persons each day. These were chiefly women, and many of them were either critics or supporters of the hospitals. The hearing lasted five and a half days, and the commissioners have just

¹ London and Counties Medical Protection Society, Annual Report, 1932, p. 37.

issued their report, which consists of twenty-six foolscap sheets of typescript, together with the report of the private inquiry and various appendices.

REPORT BY THE MINISTRY OF HEALTH

The inspectors, in the absence of any report of a post-mortem examination, found that the patient's death was due to delayed obstetric shock, and that her death was neither caused nor materially affected by her transfer from St. Mary's Hospitals to Crumpsall Hospital. They recommended that the City Council should review the staffing position at Crumpsall Hospital and satisfy itself that the arrangements for medical and nursing attendance are adequate for the number of beds now provided for maternity patients. It should also take steps to ensure that the services of the obstetric consultant are utilized fully. With regard to St. Mary's Hospitals they recommended, among other things, that every effort should be made to reduce the number of patients transferred to other hospitals by a reorganization of the system of booking cases; that an administrative medical officer, senior in status to the resident medical staff, should be responsible for the medical administration of the hospital; that the printed notice supplied when a bed is booked should show more clearly that a bed is not guaranteed, and that each patient's attention should be drawn to this statement; that when transferring a patient after delivery ample time should be allowed and suitable nourishment should be supplied to her, and an experienced midwife should accompany her, and a telephone message be sent to the other hospital. While the inspectors did not consider that the arrangements at Crumpsall prejudiced Mrs. Taylor's condition, they found them highly unsatisfactory. They also made a number of suggestions concerning the allotment of beds at St. Mary's. In conclusion, they expressed sincere sympathy with the relatives and friends of Mrs. Taylor, and acknowledged that the public interest and anxiety aroused by her death was an expression of the desire for efficiency and humanity in the administration of hospital services. This public interest is, they say, an invaluable support to the responsible authorities, but it carries with it a corresponding responsibility to consider the problems presented in an informed and balanced attitude of mind. The public inquiry thus confirms the result of the private inquiry, which exonerated both hospitals.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

Resolutions authorizing the grant of money to the new Commissioners for the Depressed Areas and for British shipping subsidies were discussed by the House of Commons this week.

The text of an international convention for mutual protection against dengue fever was laid and issued. This convention has not been ratified by the United Kingdom.

On December 4th the Parliamentary Medical Committee was addressed by Sir George Newman on nutrition and malnutrition. He compared present figures and reports issued by the Ministry of Health and Board of Education, and also the investigations now made through school attendance officers and the national insurance, Poor Law, and Ministry of Health medical services in different areas and under different conditions, with those of 1908, when the school medical service was instituted, and back to the year 1892, when Sir George first started research into nutrition at Dr. Barnardo's Homes. During the discussion which followed, Dr. Salter commented that during the period medical men's standard of normal nutrition had altered, and that comparisons were made more difficult by other factors, such as the greater and earlier use made of the medical attention available under national health insurance.

An address to the Conservative M.P.s Health and Housing Committee, by Dr. Orr of the Rowett Institute, Aberdeen, was arranged for December 5th. The subject

was nutrition in relation to the present economic conditions, with special respect to the depressed areas.

The House of Lords had no business during the week.

The Educational Endowments (Scotland) Bill, to continue for two years the existence of the present Educational Endowments Commission in Scotland, was read a second time by the House of Commons on November 30th after a critical debate.

Detection of Disease Carriers.—Sir HILTON YOUNG told Mr. T. Morris on November 28th that there was no evidence that the number of disease-carrying persons was increasing. Improvements in bacteriological and serological technique and their wider application in public health practice had enabled the presence of such persons to be more readily discovered. No national statistics were available, but the results of many special inquiries, both at home and abroad, had been published. Present knowledge suggested that most infectious diseases might be carried in this way.

Small-pox and Vaccination in Nigeria.—Replying to Mr. Groves on November 28th, Sir PHILIP CUNLIFFE-LISTER stated that he had seen the statement in a report recently issued by the Health Section of the League of Nations that in Nigeria small-pox was considered to be endemic, and frequently gave rise to epidemics, especially in the Northern Provinces. In Nigeria vaccination was compulsory in the Colony and in the Southern Provinces of the Protectorate. In the Northern Provinces it could be made compulsory in any area by order of the Governor in Council, and so far it had been made compulsory in the townships of Minna and Idah. Cases of small-pox in the larger centres of the Colony and the Southern Provinces were isolated, and immediate steps were taken to vaccinate all contacts. Isolation was not at present generally practicable in the Northern Provinces, and preventive measures had been mainly confined to vaccination, to which the people, by careful propaganda and education, were being gradually persuaded to submit.

Carriers of Foot-and-Mouth Disease Infection.—During questions to Dr. Elliot, on November 29th, about foot-and-mouth disease, Sir FRANCIS FREMANTLE asked if the Ministry had evidence that this disease was carried by starlings. Dr. ELLIOT said the Ministry had no special knowledge of its dissemination by starlings, but the possibility of the disease being spread by the contamination of birds, foxes, or other animals was obvious.

The Next Census.—Mr. SHAKESPEARE, replying on December 3rd to Sir Arnold Wilson, who asked if it was proposed to make an Order in Council, under the Act of 1920, for a census in 1936, said the Minister of Health hoped to make a statement on the subject in the near future.

Maternal Mortality Investigations.—Mr. H. WILLIAMS asked the Minister of Health, on December 3rd, to explain the differences in the maternal mortality rates per 1,000 births in the following urban districts of not dissimilar characteristics: Rochdale, where the rate was 2.71; Huddersfield, 8.81; Cardigan, 9.6; and Merioneth, 4.8. Mr. SHAKESPEARE replied that the Minister was not yet in a position to explain the differences, but special investigations were directed into the circumstances of the areas where there was a persistently high maternal mortality rate.

Drunkenness from Methylated Spirit.—Sir JOHN GILMOUR, replying to Sir Arnold Wilson on December 3rd, said the figures of convictions for drunkenness due to methylated spirit had increased in recent years, but in 1933 they amounted to less than 2 per cent. of the total convictions for drunkenness. No special action in the matter, so far as England and Wales were concerned, was at present contemplated by the Government. No information was as yet available to indicate the effect of the new denaturant.

Casual Wards Closed.—On December 4th Mr. SHAKESPEARE, replying to Sir Arnold Wilson, said that for the three years ending December 4th the Minister of Health had sanctioned the closing of 115 casual wards. The average number of persons relieved in casual wards from April 1st, 1934, to date

was 12,616. For the corresponding period in 1931-2 the figure was 12,462. The policy adopted in this matter was based on the report of the Departmental Committee on Vagrancy, which made a full inquiry into the subject. The wards closed were redundant ones, and the Minister was satisfied that there had been no overcrowding as a result of the policy, which had been coupled with extensions and improvements in many of the wards which remained open.

Health Insurance on Leaving School.—On December 4th Mr. LLEWELLYN-JONES asked if the Minister of Health had considered representations from organizations connected with the administration of national health insurance which advocated that the National Health Insurance Act of 1924 should be amended to bring within its scope all children as soon as they left school and entered insurable employment. Mr. SHAKESPEARE said that the matter was not being overlooked.

Milk-in-Schools Scheme.—Mr. RAMSBOTHAM told Sir R. Aske on November 29th that as the existing law made it possible to provide free milk for all necessitous children, there was no need to introduce legislation which would enable free milk to be given to all children of parents who had been unemployed more than six months, irrespective of the physical condition of the children. The Board had made it clear in its Circular 1437 that the children should be selected for the provision of free meals or milk who showed any symptoms, however slight, of subnormal nutrition.

Mr. SKELTON told Mr. Storey on November 28th that the Lancashire Education Authority had decided to adopt the scheme for milk in schools. They were making the necessary arrangements with distributors, and it was expected that the scheme would be brought into operation when the schools reopened after Christmas. On December 3rd Mr. RAMSBOTHAM informed Mr. West that as the milk scheme had only been in operation since October 1st it was too early to express any opinion regarding its effect on the health of school children. He did not think it would be possible to show the effect of the scheme for at least six months or so.

During the debate on the second reading of the Depressed Areas Bill, on December 3rd, Mr. OLIVER STANLEY stated that he had provided that the scheme for cheap milk, which was now current in the schools, should be extended to the junior instruction centres. He had also made arrangements that in any case where a medical certificate was obtained of evidence of malnutrition two-thirds of a pint of milk should be supplied free daily.

The committee stage of the Bill was put down for December 6th.

Notes in Brief

A committee appointed by the late High Commissioner of Palestine to examine the labour legislation has recently reported, and the report covers the question of health insurance. The Colonial Secretary awaits the High Commissioner's recommendations on the report.

During 1933 880 persons were killed by accidents at mines and quarries in Great Britain and Northern Ireland.

The Services

DEATHS IN THE SERVICES

Major Thomas Joseph Lencham, R.A.M.C. (ret.), died on September 29th, aged 68. He was born at Rathgar, Dublin, on September 13th, 1866, and was educated at the Carmichael School and at Trinity College, Dublin. He graduated B.A., M.B., B.Ch., and B.A.O. at the Royal University of Ireland in 1890. Entering the R.A.M.C. as surgeon captain on July 28th, 1891, he became major after twelve years' service, and retired on July 28th, 1911. In August, 1914, he was recalled to duty from the Reserve of Officers. He served on the North-West Frontier of India in the Chitral campaign of 1895 with the relief force, receiving the frontier medal with a clasp; and in the South African War in 1899 to 1902, when he took part in the defence of Ladysmith; and in the operations in the Transvaal, Orange River Colony, and Cape Colony, receiving the Queen's medal with four clasps, and the King's medal with two clasps.

Medical News

The Duke and Duchess of York have promised to attend a *matinée* at the New Victoria Cinema, S.W., on December 13th, in aid of the work of the Grenfell Association on the coast of Newfoundland and Labrador. Since Sir Wilfred Grenfell started his medical and social work in Newfoundland and Labrador forty-two years ago, five hospitals, seven nursing stations, four orphanage boarding schools, together with hospital steamers and a supply schooner, have been provided.

H.R.H. Princess Alice, Countess of Athlone, and the Earl of Athlone will visit the Harrow and Wealdstone Hospital on the afternoon of December 14th to open the new extensions, comprising a children's sun balcony, the linen guild room, and a consultation block to be called the Exeter Rooms.

An address will be given by Professor H. Levy, entitled "Science and Philosophy in Nature," at University College, Gower Street, W.C.1, on Tuesday, December 11th, at 8.15 p.m., with Professor E. A. Milne in the chair. Application for cards of admission should be made to the Director of Studies at University Hall, 14, Gordon Square, W.C.1.

The Royal Sanitary Institute and the South-Eastern Centre of the Sanitary Inspectors' Association will jointly discuss "The Moyné Report on Housing" on Tuesday, December 11th, at 6 p.m., at 90, Buckingham Palace Road, S.W., with Dr. James Fenton in the chair.

A meeting of the Pharmaceutical Society of Great Britain will be held at 17, Bloomsbury Square, W.C., on Tuesday, December 11th, at 8.30 p.m., when a lecture on "Dosage above the Pharmacopoeial Maximum" will be given by Dr. A. F. Hurst.

At a meeting of the Food Group of the Society of Chemical Industry, on December 12th, at 8 p.m., in the London School of Hygiene and Tropical Medicine, Professor E. Waldschmidt-Leitz of Prague will lecture on "Recent Developments in Enzyme Chemistry."

The Jewish Health Organization of Great Britain (Woburn House, Upper Woburn Place, W.C.1) has arranged a series of health lectures to be given at the Synagogue Hall, Harley Street, Bow, E.3, on Monday evenings, and another series at Bayswater House, 111, Blenheim Crescent, W.11, on Thursday evenings. Particulars may be had from the secretary.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that lecture-demonstrations will be given at 11, Chandos Street, W., on December 11th and 18th, at 2.30 p.m.; also the last of the lectures on diet and dietetics, on December 12th, at 8.30 p.m. A special M.R.C.P. course in chest diseases will take place at the Brompton Hospital on Wednesdays and Fridays at 5 p.m. from December 12th to January 11th (excluding Christmas week). Courses in the New Year include: cardiology, at the National Hospital for Diseases of the Heart, January 14th to 26th; urology, at St. Peter's Hospital, January 21st to February 2nd; diseases of the heart and lungs, at the Royal Chest Hospital (all day), January 19th and 20th; manipulative surgery, January 29th to February 1st, at 5.15 p.m.; surgical tutorial classes, on Tuesdays and Thursdays, at 8 p.m., at the National Temperance Hospital, January 15th to March 7th; a series of demonstrations at the Wellcome Museum of Medical Science, on Thursdays, at 3 p.m., beginning January 17th; lecture-demonstrations on general medicine, on Fridays, at 4.30 p.m., at 11, Chandos Street, W. Full details of all courses, which, with the exception of the cardiology course, are open only to members and associates of the Fellowship, will be issued shortly.

The third Pan-American Congress of Tuberculosis, organized by the Latin-American Union of Societies of Phthisiology, will be held at Montevideo from December 16th to 19th.

The Deutsche Gesellschaft für Wissenschaftliche Filme of Berlin is giving a private demonstration of German medical and surgical films in the Academy Cinema, 156, Oxford Street, London, W., on Sunday, December 16th, at 11 a.m. Members of the medical profession are invited to attend. Admission is free on presentation of a visiting card. The following films will be shown: fertilization and first segmentation of the rabbit ovum; version and extraction in transverse lie; normal and malignant cells *in vitro*; tumours of the brain, technique of operation after Olivecrona; action of the heart; and cholecystectomy in empyema of the gall-bladder.

At a meeting of the Académie de Médecine on November 6th the president, Dr. Siredey, congratulated Dr. Guéniot on his one hundred and second birthday.

The issue of *La Riforma Medica* for October 6th is devoted to the proceedings of the recent Italian congresses of internal medicine, surgery, urology, and orthopaedics.

A committee, under the direction of Dr. Larguet of the Tunis Pasteur Institute, has gone to French East Africa to study methods of inoculating against yellow fever.

A new university institute for balneology and dietetics has been founded at Bad Homburg under the direction of Dr. Lampert of Frankfurt.

The Société de Neurologie of Paris has awarded the Déjerine prize for 1933 to Dr. Laruelle of Brussels.

As we go to press we regret to announce the death of Lord Riddell, an honorary member of the British Medical Association, and an honorary Fellow of the British College of Obstetricians and Gynaecologists.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to the EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Antiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kidare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Delayed Birth of Second Twin

Dr. J. M. POSTLETHWAITE (Whalley, Lancs) writes: There has been a good deal of discussion in the daily press about maternity cases. I can recall a case of twins, or dual conception, that occurred in my own practice that is of both medical and, I think, legal interest. The mother, a multipara, was delivered of a male on February 24th, and, though another child was in the uterus, things were left alone to take their own course, and she brought forth a female on April 4th (1913). After this length of time I am not able to give the infants' weights, but they were healthy children and grew up quite normally.

I should be glad to know whether there has been any other case of such an interval between the births. The occurrence caused quite a stir at the time, and the parents had several attractive music-hall offers, which were, however, rejected.

Priapism after Circumcision

"M.D." writes in reply to "D. R." (November 24th, p. 975): Erection of the penis when the bladder is full, particularly on waking, is a common and healthy phenomenon in young and adolescent males, whether circumcised or not. It is probably due to stimuli originating in the neighbourhood of the sphincter vesicae and passing, via the hypogastric nerves, to the cells of origin of the nervi erigentes in S2 and S3 segments of the spinal cord, as it is through the nervi erigentes that the bladder is voluntarily emptied. One can readily imagine that when voluntary stimulation to the bladder is forcibly withheld the brunt of the reflex stimulus falls on the erectile mechanism, which is less under the control of the will. The condition has nothing to do with sexual erection, so I suggest that the boy's father be reassured and his mother and medical attendant exonerated.

Dr. R. MACDONALD LADELL (Birmingham) writes: The parents of "D. R.'s" patient appear to be unnecessarily worried over their boy's tendency to erection, and probably their anxiety communicates itself to the youngster, and thus tends to promote the condition. The mother should be told that she need not fear masturbation, which is a habit common to all young people and not in itself detrimental. Such a habit is not likely to become excessive or to stand in the way of normal development if it is mildly discouraged instead of being actively reprobated.

Chronic Enlargement of the Lip

Dr. D. H. SHEAHAN (Portsmouth) writes: Regarding Dr. H. L. Pearson's query concerning the treatment of macrocheilia (*Journal*, December 1st, p. 1024), I have treated the condition in three cases with intravenous injection of 0.3 gram N.A.B. at weekly intervals. Case I was markedly improved after a course of seven injections; in Case II there was a marked temporary improvement; Case III was not affected in any way by the treatment. A consultant who saw this latter case suggested that the infection had taken place through a fissure in the nose. The enlargement in all three cases was of the upper lip. The Wassermann reaction in each was negative at the commencement of treatment.

Income Tax

Payment for Guaranteeing a Loan

"W. G. R." writes with reference to a case in which a bank loan was obtained for the purpose of purchasing a practice. Charges have been paid annually to the brokers who guaranteed the loan. The inspector of taxes proposes to disallow such payments in calculating the practitioner's income tax liability.

** The statement of facts in the leading case of *Ryall v. Hoare* makes it clear that while claiming that such payments were assessable on the recipients the Revenue did not refuse to allow them as expenses incurred by the company making the payments. While there are presumably various differences in detail between that case and the present one, the same general principle would seem to apply—that is, the payments in each case are made annually for the purpose of providing capital necessary for the taxpayer to carry on the income-earning activity.

Car Allowance to M.O.H.

"J. C. M." receives a payment of 6d. per mile when using his car in connexion with his duties. Can he claim any allowance for costs exceeding that rate—for example, half his total car expenses less the amount received?

** The rules of Schedule E restrict the deduction to sums expended wholly, exclusively, and necessarily in the performance of the duties of the office. Presumably the council which granted the allowance of 6d. per mile thought it adequate, and "J. C. M." would probably have difficulty in persuading an income tax appeal tribunal to the contrary. It should be borne in mind, for instance, that if a small and low-powered car would serve the purpose any additional expense caused by the use of a better car would not be allowable. The inspector of taxes was apparently within his rights in obtaining the information from the council. Unless there is something quite unusually harmful in the use to which the car is put professionally we would not advise an appeal.

LETTERS, NOTES, ETC.

Salyrgan in Cardiac Oedema

Dr. J. M. GREENWOOD (West Didsbury, Manchester) writes: A patient, aged 23 years, was admitted to the Withington Hospital on November 14th, 1934, suffering from cardiac failure, following mitral valvular disease. She was extremely ill, with dyspnoea and a massive oedema, and was passing very little urine. Digitalis was given by mouth until the 24th of the month, when, although the general condition was rather improved, she still had marked oedema, and was passing approximately 25 ounces of urine in the twenty-four hours. Salyrgan 2 c.cm. was administered intramuscularly without previous medication with ammonium chloride, and 305 ounces of urine were passed during the following twenty-four hours. The patient appeared rather weary after this effort, but generally much improved, with only a slight degree of oedema remaining. Is this a record?

Maternal Morbidity and the G.P.

Dr. MICHAEL H. DOBBYN (Southwick, Brighton) writes: Some ten years ago I, together with many others, passed my final examination, having learned my midwifery at the Rotunda. On buying a practice I also purchased an expensive bag and set of midwifery instruments, ready to take on all the "midder" I could get, and very keen I was. The years have gone and I am disillusioned; the cases which I hoped to get have been taken from me by organized and subsidized nurses, clinics, and hospitals, which I am expected to help to pay for. Having done about 250 cases in ten years with no maternal deaths, I hardly think my lack of cases is due to bad midwifery or bad luck. How can a G.P. become expert at maternity work when he only gets a few cases a year to do? Just picture a surgeon remaining skilled and keen with about ten to twenty operations a year! He would soon become out of date, and give it up as far as possible; and that is what the G.P. is doing with midwifery at present. The nurses, backed up by public health officials, have failed to reduce the death rate. Give midwifery back to the G.P., to whose province it rightly belongs, and relieve him of all the futile clerking work which is rained upon him from all sides, and I believe you will see a reduction in the maternal death rate.

Labelling Patients

Dr. CHARLES J. HILL AITKEN (Kilnhurst, nr. Rotherham) writes: I was called urgently to a man, not a patient of mine. From the history given to me, and as the result of my examination, I felt justified in saying there was nothing serious the matter. Some days later I heard that this man, a few hours after I saw him, had been operated on for perforated gastric ulcer. Presumably I had seen the patient in the "quiet" stage of perforation. To prevent such a catastrophe happening to any of my own patients I now, if they are diagnosed as "ulcer," hand them a card on which I have written: "I am supposed to have an ulcer of the stomach." An intelligent patient said: "I see. If I collapse among strangers they will know what's amiss with me." The "stranger" I had seen had a history of indigestion, but made no mention of it to me, although I gave him the chance of taking me into his confidence.

Allergy

Dr. H. S. RUSSELL (Bradford) writes: Dr. C. Paget Lapage's article (*British Medical Journal*, December 1st, p. 985) is interesting both for his review of allergy and for his new word "autophil." As regards the question of diet, I am pleased to find some support for Adam's condemnation of milk. As food for asthmatics it would be hard to find anything worse. Exercise, however, which he tends to "damn with faint praise," rarely does anything but good in asthma. Admittedly violent exercise carried to the point of producing breathlessness may occasionally precipitate an attack, in the same way as coughing, sneezing, or even laughing, though this effect depends not on "overloading of metabolism" but on forced expiration. An "autophil" who gives up motoring and takes to walking instead will find his tendency to asthma considerably reduced.

Cancer Research: A Suggestion

Dr. RICHARD KERRY (Montreal) writes: There is one method of attacking the cancer problem which does not seem to have been sufficiently explored. If the technique of the Canti film, or even high magnification, be used, and if,

instead of radium, which kills growth, the effect of modifying the electrical potential or pH of the fluid which surrounds the growing malignant tissue by other electrolytes be studied, such direct observation on the process of growth should yield valuable results. As mouse cancer develops in an acid medium one would use divalent alkalis to begin with, such as lime-water or a weak suspension of magnesium hydroxide, and then other compounds as indications may suggest. If positive results be obtained, repeated infiltration of the tissues surrounding any tumour presents no insuperable difficulty, and the method can easily be applied to practical treatment.

Chemically Bleached Flour

Dr. JAMES OLIVER (London) writes: Because flour—that is, white flour—as obtained by grinding and bolting wheat, enters so largely into the dietary of every one of us, and more especially of the children, as bread and other forms of food-stuffs, it should be as wholesome as possible, and it should in every sense of the word be in conformity with Section 2 of our 1928 Food Act, wherein it is decreed that "no person shall sell, to the prejudice of the purchaser, any article of food which is not of the nature and not of the substance and not of the quality demanded by the purchaser." Flour bleached by any one of the following four powerful chemical reagents—namely, benzoyl peroxide, nitrogen trichloride, chlorine, and nitrogen peroxide—when ingested and assimilated, is prejudicial to health, and should be prohibited by the Government. No commercial interest should be allowed to stand in the way where health is concerned.

Queen Alexandra Sanatorium Fund

Lord BALFOUR OF BURLEIGH desires to bring the above fund to the notice of the professional and middle classes, for whose benefit it was originally founded. The fund is primarily intended to enable those of small means who are threatened with consumption, or who may be suffering from consumption in its earlier stages, to obtain the benefits of mountain air in Switzerland. The fund is not intended for those who are suffering from chronic or advancing disease, or for patients who require surgical treatment. To selected cases grants are made at the rate of 50 Swiss francs a week during the late autumn, winter, and early spring, on condition that the recipient stays at an approved institution in Davos. Grants will also be made to parents or guardians of children of the professional and middle classes who may be suffering from consumption or other diseases of the chest, to enable them to stay in an approved home for children at Davos. In general, patients require about 100 francs a week in order to live in comfort at Davos, which means that they require a private income of £3 a week in addition to the grant provided by the fund. Forms of application may be obtained from the honorary secretary, Mr. A. Stanley Herbert, 25, Birch Lane, London, E.C.3. Applications will be considered by the Selection Committee, and, if necessary, an appointment will be made for the applicant to see one of the honorary examining physicians in London. If after this interview applicants are for any reason not considered suitable, a third-class railway fare will be paid to those residing over fifty miles from London.

"Ciba" Jubilee

The Society of Chemical Industry in Basle (Ciba) is celebrating the jubilee of its foundation, and has produced a handsome volume describing the history and present activities of the company. In 1859 the production of coal tar dyes was instituted in Basle by Clavel, who was a native of Lyons. This and other works were combined in 1884 to form the present organization. The chief activities of the company are the production of coal tar dyes and of pharmaceutical products, and to-day they have branch factories in many parts of the world.

The medical meeting of the Charterhouse Rheumatism Clinic, on December 13th, at 5 p.m., will be held at 15, Portland Place, and not at the premises of the Clinic (94, Hulam Street).

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 68, 69, 70, 71, and 74 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 72 and 73.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 292.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, DECEMBER 15th, 1934

PAIN AND THE MECHANISM OF ITS PRODUCTION*

BY

DAVID WATERSTON, M.A., M.D., F.R.C.S.ED.

HONORARY CONSULTANT, JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH; BUTE PROFESSOR OF ANATOMY,
ST. ANDREWS UNIVERSITY

You might anticipate that my task as an anatomist in opening this discussion would be to describe the structures concerned in pain production, the distribution and the connexions of the nerve apparatus, and to present to you a more or less finished picture of the anatomy of the appropriate parts of the nervous system, leaving you to discuss the bearing of what I might say on the clinical manifestations with which you are all so familiar. That method of approach to the subject would be a stereotyped one, but in the present instance it is inapplicable. Let us try another method, first seeing where we stand and what exactly we want to know about pain; then we can approach the problems from the experimental side, discuss the results of these experiments, and see where they lead and what the next step is to be.

Pain is the most important of complaints, and the commonest and most clamant symptom with which the physician and surgeon have to deal. It drives the patient to his doctor, whose most urgent task is often its relief, while the search for its cause provides some of the most difficult problems he has to face. On the clinical side volumes have been written about it; I need only mention the classical work of John Hilton, and the monumental works of Behan and Pottinger. The current literature dealing with it is enormous; there is hardly a single number of the recent issues of the *Journal of the American Medical Association* in which there is not a reference to, or abstract of a paper dealing with, some aspect of the subject or recording observations upon it. Interest in pain is not confined to the medical world; philosophers and ecclesiastics have pondered over it, and the problem of pain has raised issues of deep significance in philosophy and theology.

Much of the discussion about pain has dealt with its "protective" aspect, but I do not think that any good purpose is served by philosophizing about this aspect of the question. Pain in some instances serves a useful purpose by warning against agencies to be avoided, or by deterring the sufferer from attempting physical exertion which would be harmful to the condition underlying his pain; but this principle is not a universal one. Pain is not always "protective," nor does it invariably arise when harmful agencies are at work, and pathological changes are going on. A burnt child may dread the fire, but the sufferer from renal colic is warned by his pain neither what to avoid nor what to do to ease it; and pathological changes may take place in the body, such

as those which convert a pliable artery into a rigid pipe-stem, without a hint of pain being given.

The definition of pain is also an unprofitable subject of discussion. Like other forms of sensation it can be defined only in terms of itself. Visual phenomena can be described only in terms of sight, and are unappreciable by one who has never seen. We have all experienced pain and know what it is like; we can say of it only that it is painful and immediately recognizable whenever it occurs. It is different from a mere unpleasantness of sensation, which is a "tone" that may accompany other sensations, just as may its opposite, pleasantness or agreeableness.

Our first task must be to discover the mechanism of its production if we are to solve any of the later questions which arise. We cannot, for example, understand the action of anaesthetics or of any means employed to relieve pain unless we know it. Pain is so varied in its forms, and arises apparently from so many different causes, that at first sight it might appear almost hopeless to discover the underlying mechanism and the processes that are at work, and still more difficult and improbable that any common cause operating in all cases will be discovered. The search will be a prolonged and difficult one.

Mechanism of Pain Production

The study of the mechanism of pain production is a problem in which anatomy and physiology can take a part, leaving clinicians to determine the diagnostic value and the prognostic significance of its occurrence. At this age of physiological research, when so many secrets of the action of the nervous system have been discovered, it may seem strange that we still have to discover the mechanism of pain production, but this is indeed the case. We do not know what are its nerves, or, indeed, whether it has its own nerves or not, nor whether the "centre" is in the thalamus, if there is a "centre"; nor do we precisely know the pathways for its impulses within the central nervous system. The reason for this ignorance is doubtless due largely to the impossibility of carrying out such physiological experiments as can be employed for other forms of nerve activity. The existence of pain can be recognized only in a sentient animal, and man himself must undergo experiment.

Another reason why pain is not better understood is found in the failure to recognize in it a definite form of sensation, with its own nerve apparatus. In many people's minds there is present the idea that pain is peculiar and unlike other sensations: that it is merely a manifestation of some sort of increased or disordered activity of any sensory nerves, and that, for example, it may arise from "over-stimulation" of these nerves. There is also the idea that this form of sensation can arise

* The opening paper of the discussion on "Pain," held in the Section of Neurology, Psychological Medicine, and Mental Diseases at the Annual Meeting of the British Medical Association, Bournemouth, 1934. [By inadvertence a contribution to this discussion appeared in the *British Medical Journal* of November 17th before the opening paper had been published.]

in consciousness independently of the afferent impulses which are its ordinary cause; that there is what is termed, as I understand it, "psychogenic pain."

All recent work on sensory physiology is opposed to the former of these ideas. It has been shown that variations in the stimulus applied to afferent nerves alter the number of impulses which are transmitted by them, and increase or diminish the intensity of the sensation, but there is no alteration in its quality. Division of the optic nerve may excite some visual sensation, but it does not cause pain, and the cutaneous nerves of the epidermis, the nerves, as I believe, of tactile sense, can also be divided without the production of pain. With these examples before us it is difficult to imagine that pain is ever due to impulses along nerves of other forms of sensation.

Pain is often, but not invariably, accompanied by other symptoms such as pallor, fainting, and sweating, and these are sometimes ascribed to the pain. They are not, however, invariable concomitants of pain, and hence we must conclude that they are produced in a different way, by other afferent impulses than those which cause pain, travelling by a different path and producing their effects often by exciting the sympathetic system. These concomitants fall into Mackenzie's group of "associated phenomena."

Different Pain Response from Different Tissues

The mechanism of pain production may be studied in two successive steps: the first is to determine the tissues and organs that can give rise to pain, and the second, the effective stimulus in each of them for its production.

It is a well-recognized fact that different parts of the body are entirely different in their pain responses. I remember well a case of enormous prolapsus of the rectum which came under my care during the war, and the difference in the sensory responses which could be elicited from its surface. The prick of a pin near the margin of the anal orifice was painful, but whenever one passed beyond a definite line and stuck the pin into the mucous membrane higher up no pain whatsoever was elicited. This afforded a simple but dramatic illustration of "visceral insensibility," or, in other words, that stimuli which are effective or adequate for pain in some tissues, which we may call the "somatic," produce no sensation from the "viscera." We know that the alimentary canal is so insensitive to such stimuli that the intestine may be cut or pierced or even burned without any pain resulting.

We have not as yet equally precise and well-established information about other viscera, but there is evidence to show that the lungs, the heart, and the brain itself show the same sort of "insensitivity," in that pain is not produced from them by mechanical stimulation such as that described, though it may originate from other causes. This is a field of study in which clinical observation on the sensitivity of exposed organs will in time provide the necessary data. The problem of visceral pain presents special features, and my own view is that its mechanism will not be understood until we know more about "somatic" pain—namely, the mechanism of its production from the tissues and organs of the body wall and limbs.

Experimental Mechanical Stimulation of Different Tissues

The experiments which I have carried out in work on the first of these problems have been published, and I need only summarize the results. They were devised to test whether pain could be produced by direct mechanical stimulation of different tissues. The stimulus used was a sharp needle, the point of which was passed through

the skin and onwards into different tissues, muscle, fibrous tissue, periosteum, and also into the walls of veins and arteries. These experiments showed that among "somatic" tissues there are great differences in the responses elicited by stimulation in this way.

Epidermis has its own nerves, but pain does not arise from them, even when they are divided. The dermis gives an immediate and acute response, as everyone knows, to a wide variety of mechanical stimuli. The subcutaneous tissue is less responsive. For the greater part it does not give a pain response to mechanical stimulation. We all know that the introduction of a hypodermic needle is painless once the skin has been penetrated. The subsequent injection may, however, cause acute pain, and evidently in subcutaneous tissue there is a pain mechanism. Fibrous tissues are responsive to direct mechanical stimulation. Acute pain is caused by the passage of a needle through the fibrous aponeurosis of muscles.

The walls of veins are almost entirely insensitive or give but slight response. This is my experience, but some who have observed the results in a similar experiment have found that considerable pain was produced. One observer told me that in himself he found pain produced almost as severe as that which I have described from arteries. Arteries give a very acute response: the pain is immediate, severe, and sickening, and tends to radiate along the course of the vessel. In my own observation, the wall of my brachial artery was penetrated, and I have received confirmation of my observations from those who, in their clinical work, have had occasion to open an artery.

Ordinary striated tissue gave practically no pain response to mechanical stimulation; the sensation elicited was dull, felt like pressure, and was unpleasant, but not as a rule definitely painful. Periosteum may give a pain response, but often does not, and bone is definitely insensitive to this kind of mechanical stimulation. To strip periosteum from bone, however, is definitely painful.

The value of these observations lies in the demonstration they afford that the somatic tissues do not all give a pain response to mechanical stimulation, while we know also that severe pain can be produced even from those insensitive to mechanical stimulation, by the operation of other causes. The case of muscle is specially instructive. Severe pain can be produced from muscles which contract if they have not a proper blood supply, and Sir T. Lewis has provided the important discovery that the pain is due to the production locally of a chemical stimulus, which he terms the "p substance." There are reasons which lead one to suspect that a chemical agent may be the stimulus for pain in certain other tissues and perhaps in all of them. Pain, for example, is seldom momentary; it persists for a shorter or longer time after the exciting stimulus has ceased to act, and this can be due only to the continued operation of a local cause.

Pain and Hyperalgesia

The condition of hyperalgesia throws some light upon the mechanism of pain production. Hyperalgesia shows itself by the occurrence of a pain response to a mild form of "stimulation," such as usually, and in the normal condition, fails to cause any pain. Illustrations of this are numerous, and among those with which we are familiar are the tender scalp which is present in neuralgia, and the subcutaneous and the muscular hyperalgesia found in visceral abdominal disease and in angina pectoris, when pressure on a fold of skin or on muscle produces an acute pain.

The same sort of hyperalgesia may be produced by local causes. If, for example, the skin be reddened by the application of a mustard leaf, the affected area is hyper-

aesthetic to warmth, or hyperalgesic, for exposure of the surface to even a mild degree of warmth causes severe pain. Lewis has recently shown that if the skin be injured in a variety of ways a local condition which he terms "susceptibility" follows, in which stimuli usually painless cause pain from the affected area. He has ascribed this to the local production of a chemical substance, which raises the excitability of the terminals of the pain nerves. These facts throw a very important light upon the mechanism of the production of pain, showing as they do again that a chemical factor may be the agent.

"Referred" or "Heterotopic" Pain

While pain is often localized to an area at or near the site of its cause, there is also the large group of instances in which pain is, as it is termed, "referred," as in many forms of visceral disease. Examples of this are innumerable, but one may mention particularly the pain of angina referred to the arm, shoulder pain in liver and diaphragmatic disease, and the headaches which arise from defective ocular accommodation. In this group we should, I suppose, include the labour pains of childbirth, which are referred to regions remote from the uterus. The term "referred pain" for these forms of pain is not to my mind a good one, and its use has led to misconceptions. All pain is "referred" by the sufferer to some place; the point of distinction between the two kinds of pain is that in some forms the pain is referred or localized by the sufferer to the place where the disordered process is at work, while in the others it is referred to some distant region. The distinction between the two types is of importance, and for the former I would suggest that the word "homotopic" be used, while for the latter in contrast we might apply the term "heterotopic." An advantage found in these terms is that they provide a contrast, whereas to "referred" pain there is no suitable contrasting term.

The means of the production of "heterotopic" pain is yet uncertain. Mackenzie's provisional theory of its production, his "viscero-sensory reflex," postulated that an "irritable focus" was produced in the spinal cord by afferent impulses from the viscera, and that this focus was in some way responsible for the transformation of the ordinary impulses of touch and pressure in cerebro-spinal nerves of that segment into impulses which gave rise to pain. The facts at least are clear—namely, that the hollow viscera do not give rise to a sensation of pain from ordinary stimulation, while afferent impulses from them induced by a special local condition—spasm of unstriated muscle—do cause severe pain, localized to some portion of the distribution of the cerebro-spinal nerves.

There are many difficulties in accepting Mackenzie's theory in its details, and another theory based upon what we have come to learn about pain production may now be put forward. Areas of heterotopic visceral pain and tenderness are very puzzling; there are present in them severe pain and acute tenderness, but there is usually no other feature to distinguish them from their surroundings. The colour is the same, there is no added warmth, there is no pilomotor excitement, and the activity of the sweat glands is unaltered. Some observers have claimed that they have been able to detect slight alterations and especially a difference in the local response to the application of warmth, and some oedema may be present, but the information is as yet rather vague, and additional observations are necessary to establish it.

In my view the close similarity between an area of pain and tenderness due to local causes and one of visceral pain and tenderness render it extremely probable that the same underlying condition is present in both of them. I have found that an area of fibrous and muscular pain

and tenderness due to local causes may be abolished by the local injection of a small amount of normal saline solution. The mode of its action is uncertain; presumably it helps to get rid of the "p substance" which is present. It is known that areas of heterotopic visceral pain and tenderness can be relieved by the local injection of anaesthetics, and, further, Dr. Forman has found the striking fact that normal saline solution injected into these painful and tender areas can act in the same way, and relieves them.

This procedure can act in no other way than by modifying the local condition, and the observations demonstrate that in "heterotopic areas" the same underlying condition is present—namely, that there has been a local production of a "pain-producing" substance. So far we know of the production of a "p substance" from muscle by local causes. On the evidence provided it seems probable that this substance may be produced in other ways, as by a visceral reflex, and I think that we shall find that in the areas of "heterotopic" visceral pain and tenderness there is formed the same pain-producing substance as that which is formed from local conditions, gives rise to pain, and, in a lesser degree of concentration, causes hyperalgesia.

Summary

Pain, as I understand it, is a definite form of sensation, not to be confused with unpleasantness or with discomfort or mental conflict, served by its own nerves, which are part of the cerebro-spinal nervous system. The various tissues and organs show a wide range of difference in their capability of exciting a pain response; some do so in response to mechanical stimulation, others respond only to a special chemical stimulus.

There is evidence to show that in areas of pain and tenderness from local causes there has been formed locally a "pain-producing" substance, which acts upon the terminals of the pain nerves.

This substance is liberated where there has been skin injury and in muscles under certain conditions. Probably it is liberated in fibrous tissues also.

We know little as yet of the way it is produced nor whether it is liberated from other than local causes. The close resemblance of areas of "homotopic" pain and tenderness to those of "heterotopic" pain and hyperalgesia, and the relief to both conditions afforded by local injection of normal saline solution, point to its being occasionally liberated locally from reflex sympathetic impulses from viscera, and this would afford a satisfactory explanation of Mackenzie's "viscero-sensory reflex."

Citing the various ill effects of a sedentary life, G. Laroche, de Chaisemartin, and A. Grigaut (*Bull. de l'Acad. de Méd.*, October 16th, 1934, p. 291) present a study of the changes in the chemical composition of the blood caused by exercise in twenty-one cases. Tests made at the beginning and end of a six-weeks' course of regulated exercises showed a return to normal of the blood cholesterol, urea, and uric acid; the blood content in these substances is evidence respectively of fat, nitrogenous, and purine and protein metabolism. An increase of weight, due possibly to an increased density of the tissues produced by the exercise, and a stabilization of the blood pressure, due to activation of the general circulation, were also noted. As no dietary or medicinal treatment was given, these effects can only be ascribed to the exercise, which is taken to have a regulating influence on metabolism. It is emphasized that the exercises were regulated, and the authors suggest that sports undertaken without due preparation and medical control may have harmful effects.

"ARTERIAL EMBOLECTOMY"*

BY

GEOFFREY JEFFERSON, M.S.LOND., F.R.C.S.ENG
HONORARY SURGEON, SALFORD ROYAL HOSPITAL, ETC.

From time to time it falls to the lot of most of us to advise on the treatment of an embolus lodged at some high level in a peripheral artery (subclavian, axillary, brachial, iliac, femoral, popliteal, and even at the aortic bifurcation).

The ideal treatment for arterial embolism, which is a grave emergency calling for intervention as early as, or even earlier than, that in respect of a perforated viscus, is immediate arteriotomy, removal of clot, and suture of the vessel. This procedure, when successful, restores the circulation, and gangrene is averted. Experience drawn from other types of gangrene, such as the senile, arterio-sclerotic, and diabetic types, is quite useless; the rarer embolic form is a distinct and separate entity, which can often be prevented by immediate and decisive surgery.

Several tentative attempts to this end were made during the first decade of this century (Lejar, 1902; Moynihan, 1903; Sampson Handley, 1907; Proust and Lecène, 1908; Carrel and Leriche, 1909), but without success. At the turn of the first decade Carrel's experimental work on the surgery of the blood vessels demonstrated that, given a careful technique, very fine silk suture material, and the use of anticoagulants in the wound, vessels could be incised and closed again without thrombosis at the suture line. His work, and that of others in the same field, paved the way for successful embolectomy, and it was but a matter of opportunity before some more venturesome surgeon would be able to claim a success. This fell to the lot of Labey, who in 1911 removed an embolus arrested for six hours in the femoral artery. Since that date numerous cases have been put on record, some successful, others not, and at the present day embolectomy can be regarded as a standardized and useful addition to surgery. This is in no small degree due to the Swedish surgical school, led by Einar Key, whose masterly papers in 1922 and 1927 laid the foundations on which all else has been built up. In recording my own successful case in 1925 I was able to collect from the literature seventy-three cases, of which twenty-eight had done well. Since then the literature has grown prodigiously, and important analyses have been made by Petitpierre (118 cases, 1928), H. E. Pearse (296 cases, 1933), and Max Danzis (detailed analysis of all cases reported, 1922-32). The time has arrived when general compilations have done their very useful work in driving home the lessons of embolectomy: future general studies are likely to be concerned with embolisms of individual vessels rather than discussions of the whole subject comprehensively.

I do not intend, therefore, to make a new survey of the whole field as I did in 1925, for Danzis's paper, in particular, has brought the whole subject sufficiently up to date. A better purpose will be served by an account of my personal experiences of embolectomy. The 1925 case was the first successful one in this country, and I have now five new cases to report. Two other British successes have, in the meanwhile, been obtained individually by A. G. Banks and G. E. Larks, and others will be recorded to-day.

* Read in opening a discussion in the Section of Surgery at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

Personal Cases

The six cases which follow record embolisms in the axillo-brachial junction, brachial, common iliac, and femoral arteries, four of which have been diagnosed and immediately referred to me by my colleague Dr. G. J. Langley.

CASE I

This case has already been reported, being my original success of 1925. It concerned a man of 42 years of age, operated upon at Salford Royal Hospital on April 23rd, 1925, for radical cure of an umbilical hernia. Twenty-six hours after operation he complained of pins-and-needles in the left arm, with increasing numbness and paralysis of all muscles below the elbow. The pain rapidly became intense. The arm was blanched, cold, and pulseless below the anterior fold of the axilla. Palpation of the subclavian artery above the clavicle gave free pulsation there, and pulsation was felt again, but not so distinctly, in the axilla. Under local anaesthesia the junction of the axillary and brachial arteries was cut down upon two and a half hours later, a 2 cm. long incision was made in its wall, and a clot removed. The artery was sewn up with fine paraffined silk, with immediate return of colour and muscular power, and cessation of pain. The patient made a perfect recovery, and is well nine years later.

Comment.—This was a completely successful case, pulsation returning at once, and all symptoms disappearing immediately. Banks and Larks have published very similar and equally successful cases since; both were axillo-brachial, both occurred in hospital, and both were post-operative.

CASE II

W. P., male, aged 49 (date, 10/12/31), after a period of ill-health, developed an acute and semi-gangrenous ischio-rectal abscess. He was seen by Dr. Langley, who found a very high blood sugar, and the patient was removed to a nursing home in order to have the abscess opened by my colleague Mr. Garnett Wright. In the early hours of the morning, about 3 o'clock, the patient was awakened from sleep by severe pain in the left arm, which he attributed to a draught. When seen by Dr. Langley later in the morning the patient complained of exceedingly severe pain, and on examination the arm was found to be pale, cold, and pulseless—indeed, no pulse could be felt in the axilla. The projected

opening of the ischio-rectal abscess was therefore postponed until the arm could be dealt with. I saw the patient with Mr. Wright and Dr. Langley at noon. All the classical signs of acute arterial obstruction were present—a cold, pallid, marbled limb, with wrist-drop, and absence of all finger movements. Flexion and extension of the elbow could be feebly carried out. No pulsation could be detected in any artery of the limb, but above the clavicle, on deep inward pressure, a muffled beat could be felt. The embolus was evidently lodged in the subclavian artery in its first or second part, and operation was decided upon. At 6 p.m., fifteen hours after lodgement, the left subclavian artery was exposed through a transverse incision under omnipon, scopolamine, and gas-oxygen anaesthesia. The clavicular head of the sterno-mastoid muscle was divided, the phrenic nerve retracted inwards, and the scalenus anticus cut through at its

attachment to the first rib. This gave excellent exposure of the artery, in which an embolus could be both seen and felt. The artery was isolated, and two fine controlling bands of rubber tissue threaded round it above and below the clot. A short incision was made in the vessel and the main clot milked out in one piece. A glass suction tube was inserted, and more clot fragments obtained by judicious release of first one and then the other ligature. The arterial incision was closed with interrupted vaselined fine silk, a difficult task in this situation. The immediate result was good, the pulse returning feebly at the wrist, but next morning it could not be felt, though the pain had largely gone and movement had returned in some measure to the hand. During the ensuing days this power disappeared again, and in the long run a considerable amount of tissue had to be removed from the hand, including all the fingers.

Comment.—A point of considerable interest is the origin of the clot in cases such as this with a surgical lesion. The thrombus might come from the auricle, as presumably occurs in the cases of auricular fibrillation. Bull showed that most arterial emboli are cardiac in origin, and only come from great vessels when there is gross disease in the intima. But paradoxical embolism has to be considered, for a patent foramen ovale is present in a number of cases. It seems unlikely that an aseptic clot will arise from a septic area, such as was present in this case, but it is not impossible, for I have seen the median cephalic vein thrombose slowly along its whole length in the arm of a man with a septic wound of the dorsum of the hand. No sign of infection and no tenderness, certainly no cellulitis, developed over the vein, so that a propagating clot, which is in large part at least aseptic, may arise from a septic area. Case II cannot be regarded as a complete failure; for without operation an amputation above the elbow-joint would certainly have been required. The patient's arm now is vastly superior to any artificial limb that was ever invented.

CASE III

S. T. J., male, aged 42 (date, 3/2/32), was admitted to the Salford Royal Hospital under the care of Dr. G. J. Langley suffering from auricular fibrillation. He was treated

with massive doses of digitalis, and on 3/2/32, at 9 p.m., complained of sudden violent pain and weakness in the left hand. On examination no pulses could be felt at the wrist or in the hand; pulsation in the brachial artery could be felt in the lower third of the arm, but ceased in the antecubital fossa. Diagnosis was made of embolus at the bifurcation of the brachial artery, and two and a half hours later, under local anaesthesia, this vessel and the upper ends of the radial and ulnar arteries were exposed. A clot was removed by incision into the brachial artery, and recovery ensued, but with feeble pulses at the wrist. There was a slight degree of ischaemic contracture of the hand and the wrist in this case, a point of considerable pathological interest. This patient was lost sight of on leaving hospital, but he died of syncope whilst on holiday six months later.

Comment.—This case furnished an interesting example of the damage which an embolus will do as compared with arterial ligature at the same level. In the antecubital fossa the brachial can be tied with impunity, yet an embolus, by blocking all collaterals, causes a very severe circulatory disturbance, and the hand may well be lost. In this case collaterals were undoubtedly freed, but I doubt if the full blood stream was restored in the brachial artery past the point of embolism and arteriotomy. At the present day I should not open the brachial artery as soon as it was exposed, as I did in actual fact. It is better to conserve the main trunk and to milk the clot,

Showing collateral circulations.

under rubber ligature control, into a vessel of lesser importance, as I did in Case v, and as Nyström, Schmorell, and Westerborn have so brilliantly done in their cases of aortic embolism. I shall refer to this point in technique again later.

CASE IV

Mrs. Y., aged 66 (date, 20/10/33), a doctor's wife, was admitted to a nursing home under the care of Dr. Langley with high-speed auricular fibrillation. At 6 a.m. she complained of severe pain in the left lower limb. Seen three and a half hours later the limb was cold to the touch, pallid, and powerless, with no pulse in the femoral artery at Poupart's ligament. The right femoral pulse was strong. It was probable, therefore, that the embolus was lodged at the bifurcation of the common iliac artery, and operation was advised and accepted. Under spinal anaesthesia the left common iliac artery was exposed, five hours after embolism, extraperitoneally by cutting through the flat muscles of the abdomen. A large embolus could be felt riding the bifurcation of this vessel, with short limbs projecting into the external and internal iliac arteries. The common iliac was lightly controlled with improvised forceps covered with rubber tubing, and the other two branches controlled by tension bands of thin rubber ("stitch") tubing. An incision 1.5 cm. long was made into the external iliac artery, below the embolus, a suction nozzle was introduced into the empty artery, and an attempt made to break up the clot. This failed until a blunt pituitary spoon was used, when, in a moment or two, the whole Y-shaped embolus came away. Momentary release of the controlling forceps verified the absence of any further clot. The artery was sutured with interrupted sutures of arterial silk, and proved to be watertight after three sutures had been placed. Recovery was complete and perfect. In spite of a small cerebral embolism two months later, the effects of which passed away completely, she is alive and well ten months later, and walks well.

Comment.—This was a completely successful case. It was in many respects a severe test of the operation. There was complete arterial block, and a high-level amputation would have had to be done if the arteriotomy had failed. Amputation in a case with severe cardiac disease is a more difficult obstacle to surmount than an embolotomy, not only immediately, but later on. To a patient with heart disease the loss of a lower limb is a most serious thing, because of the added exertion on movement.

CASE V

Mrs. E., aged 52 (date, 28/2/34), was admitted to Salford Royal Hospital by Dr. G. J. Langley, who had seen her in consultation with Dr. Andrew Clarke. Some years ago she had an attack of aphasia, but, apart from recent auricular fibrillation on an old-standing mitral stenosis, had been reasonably well and active. At 10.30 a.m. on 28/2/34 she felt sudden severe pain in the left leg, and signs of embolism at the level of the profunda femoris were classically present. The clot, which made a palpable and visible swelling in the artery, was easily removed under spinal anaesthesia through a 1.5 cm. incision under full control. The immediate effect appeared to be good, though the absence of feeling in the legs prevented discriminating observation. The vessel below the

arteriotomy wound had been noted to be unduly small before the skin was sutured, but this is not uncommon, as vessels contract primarily when stripped. Next day she still complained of pain in the foot, though higher up the circulation had greatly improved. During the next few days the pain became so intense that 1/2 to 1 grain of morphine a day did not control it. Finally, fifteen days after embolism, the patient consented at last to amputation above the knee. A second embolism was found blocking the posterior tibial and an abnormal peroneal artery. Two days later she suddenly developed signs of embolism in the femoral artery of the other side, but just as operation was about to be undertaken all signs and symptoms disappeared, and colour and pulsation returned to the leg. Evidently the embolus had side-tracked into the profunda artery. On 21/3/34 the patient died, with signs suggesting an aortic embolus.

Comment.—This case was a failure, and exemplifies the disadvantages of spinal anaesthesia. There is no escaping its use in iliac and aortic embolism, but in the limbs infiltration anaesthesia is far preferable, as it allows of immediate observations of the effect of the operation on pain and mobility in the limb. Had it been used here we should at once have been sure that something else was wrong, and either an arteriogram would have been made or the popliteal artery exposed. A small embolus was found in the amputated leg in the posterior tibial artery. I believe these distal embolisms to be most serious. Arteriograms in cases of thrombo-angiitis obliterans show how apparently trivial deficiencies will lead to distal gangrene. To be sure, the conditions are not entirely parallel, for there is no general arterial disease involving small vessels in the embolic cases. The pain experienced by this patient was pitiable in its severity, and would have been an object-lesson to those few who think that embolisms are best left alone.

CASE VI

Mrs. M., aged 48 (date, 13/4/34), a patient of Dr. Sissons of Lymington, had long suffered from thyrotoxicosis and auricular fibrillation. Three weeks prior to the present attack she had had a sudden attack of pain in the right leg, which became pale, dead, and powerless. At the end of two or three hours, after having kept it warm, and after vigorous massage, it recovered spontaneously. At 2 a.m. on April 13th, 1934, she experienced the same pain in the right arm. Thinking

that the symptoms would pass off as they had done in the leg, she did not send for Dr. Sissons until six hours later, when he at once diagnosed a brachial embolism, but she appeared to be dying. As the day wore, on she slowly improved generally, and as her physical condition improved so the pain in the arm became more distressing. At 9 p.m., nineteen hours after embolism, a clot was removed under local anaesthesia from the upper end of the right brachial artery at the level of the superior profunda branch. The clot was extracted without incident, but although there was a free flow of blood from the upper end further clot was felt and seen lower down. A second incision was made in the lower third of the arm, and a further small incision made, and the long clot milked out. The pulses still did not return to the wrist, and by this time the patient had developed increasing pain in the abdomen, suggesting an embolism of the mesenteric vessels. The attempt to restore the circulation in the arm was therefore abandoned. Next morning the arm was warm as low as the wrist, and pulsation was present in the antecubital fossa. Pain in the abdomen was by this time very severe, and blood-stained diarrhoea set in, confirming the suspicion of intestinal embolism. She died the next day, forty-eight hours after the embolism.

Comment.—This case would, I think, have been a failure had the patient survived. Of course, her mesenteric embolism made recovery impossible. But this was an interesting case, showing how rapidly secondary thrombus formation occurs in the distal part of the vessel; for, nineteen hours after occlusion, the brachial artery, and no doubt the more distal vessels too, contained long rods of clot. Her medical attendant had wished for an embolectomy at once, but her immediate state of collapse prevented an intervention; no blame therefore attaches to him.

To these cases of proven embolism must be added one in which the left iliac bifurcation was exposed under a mistaken diagnosis. The condition found was uncommon, and the indication for exploration and the decision to operate were, I think, not unsound.

CASE VII

J. C., male, aged 33 (date, 14/12/29), consulted his medical attendant, Dr. Young of Kersal, for pain over the heart. Dr. Young made a diagnosis of ulcerative endocarditis and aortic disease, and sent him to bed. At the end of a week his dyspnoea improved, and he got up on his own responsibility. At 8 p.m. he experienced a sudden pain in the left leg, and at 8.30 p.m. was seen in consultation by Dr. Langley, who found the leg to be pulseless and cold. The very proper diagnosis of acute arterial occlusion was made, no doubt embolic, and he was sent into a nursing home. At 11.15 p.m., three and a quarter hours after the presumed embolism, I explored the left common iliac artery. No pulse was present in the left common femoral, and as the right leg was quite unaffected the occlusion should not have been aortic, but somewhere in the iliac arteries, probably at the bifurcation of the common iliac. Under general anaesthesia an oblique incision was made above the inguinal ligament, and the muscles divided. By blunt dissection the bifurcation of the iliac arteries was brought into view, and free pulsation found there. Following the external iliac down, there was seen to be a dark haemorrhage, 4 cm. long, occupying the anterior half of the circumference of the vessel. This had caused so much swelling of the arterial wall that no blood could get past it. This haematoma was incised, but was found to be in the middle as well as the adventitial coat of the artery. The pathology of the condition was clearly the earliest possible stage of a dissecting aneurysm, due to softening of a segment of the artery by lodgement of an infected particle (such as is a commonplace of ulcerative endocarditis) in a vas vasorum. It seemed that nothing useful could be done, though, to be sure, after the relief of tension in the wall by incision feeble pulsation was detected in the femoral but not in the popliteal artery nor at the ankle. The wound was closed, and next day the leg was slightly warmer but far from normal. The patient died on the third day, the combination of unfavourable circumstances being too much for him.

Clinical Picture

The clinical history of the patients in the foregoing series is remarkably constant, and there has been no great difficulty in arriving at a diagnosis (except, of course, in Case vii). This is important, because it is the general practitioner who sees these cases first, and everything depends on the promptitude with which he makes his decision and acts upon it, for he has at best four hours, and at most ten hours, in which to have an arteriotomy performed.

Most of the subjects are sufferers from heart disease with some form of myocardial damage, and auricular stasis with unsuspected clot formation. They stand the relatively benign operation very well. A smaller number occur as post-operative disasters in hospital, and this group undoubtedly has the best chance of survival, for reasons which will occur to everyone.

The picture can best be summed up as consisting of pain, pallor, and paralysis, with absent pulsation in the vessels of the limb. The mechanism of the production of pain of the intensity experienced by these patients is difficult to explain. For the moment we may rest without an explanation, because it is an unescapable fact that diminution in the blood supply to a limb invariably produces pain. Raynaud's disease, intermittent claudication, and even the vaso-constriction produced by cold are all obvious examples. Muscular paralysis is a less familiar result of the same thing, and may puzzle the clinician who has had no experience of embolism. In a case only partially relieved, contracture of the muscle can occur through death of some of its fibres (as happened in Case iii). Cutaneous anaesthesia is also found in embolism, sometimes in a known anatomical distribution, and more often with a less recognizable pattern. Nerve endings require an efficient circulation for their proper function; the anaesthesia is therefore more apt to have a vascular distribution than a purely nervous one, though anaemia of nerve trunks as well as of nerve endings must be taken into account in explaining the distribution of anaesthetics and paralyses.

Localization of the Embolus

There have been no mistakes in the localization of the embolus in my own cases. Difficulties are only likely to arise in cases with multiple embolisms (such as Case v), or when the clot slips from its first point of lodgement to be arrested at a lower level. Emboli usually lodge at bifurcations, because the arterial lumen narrows suddenly at the points where large branches are given off. Clots are usually of some size, and on the whole it is more probable that a large rather than a small vessel has been obstructed, otherwise the symptoms would not have arisen.

The ictus is not always as dramatic as in the cases described above, but develops from relatively small beginnings, with paraesthesiae and considerable, but not intense, pain associated with pale blotching of the limb. In these cases the embolus has not completely blocked the vessel, and rides the spur at an important bifurcation, allowing a diminished blood stream to flow past. Some such cases make a sudden and spontaneous recovery (as in the first embolism in Case vi), and this occurrence has puzzled some observers, who have invoked spasm rather than clot obstruction as the explanation. In such cases it is justifiable to assume that the clot, after riding for a time and impeding the flow in the main nutrient artery of the limb, suddenly disappears into the less important of the two branches. Thus with a clot insecurely lodged at the common iliac or common femoral bifurcations, the thrombus might on occasion pass into

the internal iliac or profunda femoris arteries, where it would do little harm. When the embolus is large, and at once firmly and definitively plugs the vessel, the pain and all other symptoms and signs are instantaneous, and steadily worsen as the hours pass.

A, Clot, chiefly in large branch, partly occluding the main blood supply. B, clot hammered into branch releasing circulation to distal limb.

If there is great difficulty in localizing the site of embolism, help may be obtained from an arteriogram, an idea already put into successful practice by Pearse (see also Abbeloos). Failure to find the obstruction at the expected point is remedied by injection of thorotrast or uroselectan into the artery and a radiograph taken as the solution is injected. I have so far no experience of the method, but it is sound practice.

Treatment

Treatment need not detain us long, for most of the points are inherent to what has gone before. The artery should be exposed with as little delay as is compatible with making the diagnosis and the removal of the patient to a suitable place. The time factor is important, because secondary clot formation beyond the embolus sets in after a few hours, but not immediately. I am no believer in the view advanced by some that it is not until secondary thrombosis occurs that the signs become definite. The vessel distal to the point of occlusion is empty during the first few hours, and ready to accommodate the blood stream as soon as the obstruction is removed.

I believe that the failures that sometimes follow early operation are due to there being more than one embolus, rather than because of coagulation at the point of incision into the artery. The use of local anaesthesia as opposed to spinal is important, as the patient's subjective sensations are most helpful in deciding whether immediate success has been achieved. I have indicated briefly what should be done if the result is not at once satisfactory. There is one point remaining which requires discussion, and it arises out of the treatment of aortic embolism. I have seen three such cases, but in none of them was operation possible for various reasons (the patient's state too desperate or the embolus lodged too long). Nyström and Key both advise the massaging or "milking" of the clot from the aortic bifurcation down into the common femorals under direct vision (the femoral arteries having both been exposed and controlled by rubber bands to prevent the broken clot lodging at some less convenient site). In a case of Hildebrandt's, reported by Schmorell, the clot suddenly and unexpectedly disappeared into the internal iliac artery as it was being massaged down to the exposed femoral artery, with immediate return of function to the limb. I have referred to such a side-tracking as the explanation of the sudden recoveries that may undoubtedly occur in embolisms before such time as the clot becomes adherent to the intima, but it seems to me that a practical hint might be taken from these happy chances, and that when it does not happen of itself we should try to compel it. The first step would therefore be the exposure and temporary control of the main vessel above and below the embolus

in the ordinary, followed by a deliberate attempt to massage the clot into the subsidiary branch. If this failed the operation would be proceeded with on normal lines and the artery opened. It is likely that the alternative method will not always succeed; in the late cases it certainly cannot, but it is worth a trial. I must be very explicit as to my exact meaning, for I think that no greater disservice could be done a patient than a haphazard breaking up of the clot by finger pressure, allowing the resulting smaller emboli to go free in the circulation. We should then have multiplicity and small size of emboli, two factors which I have come to regard as most unfavourable. It is far easier to remove an embolus from the femoral artery than from the posterior tibial, so that if the clot cannot be persuaded into the profunda femoris, for example, it must at once be removed by arteriotomy without for one instant relaxing the clamps or temporary ligatures which are preventing the escape of the clot.

According to P. Esch (*Zentralbl. f. Gynäk.*, October 27th, 1934, p. 2530), many cases previously described and accepted as osteomalacia have in reality been examples of generalized osteodystrophia fibrosa (von Recklinghausen's Disease). He gives details of two cases in which this mistake had been made; in both, radiological examinations of the skeleton, and in one necropsy, showed the characteristic signs of generalized bony fibrosis, with "brown cysts" in certain bones. The patient who died had adenomata in three parathyroid glands. Distinction between osteomalacia and von Recklinghausen's disease is important: in one of Esch's cases of the latter, removal of one and irradiation of the other ovary had been unnecessarily done for a supposed osteomalacia, and on the other hand successful treatment by parathyroidectomy is possible in some cases of osteodystrophia fibrosa. In diagnosis radiology is the most important measure. The pelvic deformity in von Recklinghausen's disease, if symmetrical, causes marked lateral flattening: the pubis projects forward beakwise, the ascending rami of the pubis are nearly parallel, and the inlet takes the shape of the heart on a playing card. Accepting the view that Paget's disease and von Recklinghausen's disease are different varieties of osteodystrophia fibrosa, Esch points out finally that the non-generalized form of the former may begin in the lumbar vertebrae or the pelvis, so that early cases may come first to the gynaecologist.

RUPTURED SPLEEN AFTER TRIFLING MISHAPS

A RECORD OF TWO CASES

BY

HAROLD DODD, M.Ch., F.R.C.S.

The cases described below are of interest, owing to the apparently trivial domestic incidents which excited a serious abdominal lesion—that is, a ruptured spleen. These accidents initiated slight but progressive symptoms and physical signs, necessitating splenectomy. Fortunately, judging from the literature, the condition appears to be an uncommon one.

Case I

Frank P., forty-eight hours before admission to hospital, fell against a gas-oven door and bumped his left lower ribs. This accident gave rise to no immediate effects beyond temporary pain. A few hours later he vomited several times and had diarrhoea, but he stated that he saw no blood or slime in the stools. In twelve hours he had developed general abdominal pain, slightly worse in the upper region. After the initial looseness there was no further action of the bowels, so that when he was admitted to hospital he had been constipated for about forty hours.

When I saw him first his general condition was good; he was complaining of abdominal discomfort, but not of definite

FIG. 1.—Shows the transverse incision.

pain. His temperature was 100°, pulse 110, and respirations 20. The abdominal reflexes were normal, and there was no hyperaesthesia. In the right iliac fossa was a visible fullness with a vaguely defined soft swelling; he was tender on pressure here—that is, over the appendix and caecum. He was slightly sensitive over the lower left ribs external to and below the nipple, the point of contact with the oven door, but this was apparently outside the abdominal area. The diagnosis of an atypical acute appendix or "something odd" in the abdomen was made. The possibility of the fall having caused an intra-abdominal traumatic lesion, such as a ruptured spleen, was considered and rejected on account of the seeming slightness of the mishap, and also of the clinical picture.

Immediate operation was advised, and was performed under a percaine spinal anaesthetic. Owing to the element of doubt in the diagnosis, the abdomen was opened through a right paramedian incision centred at the umbilicus. Blood shone through the peritoneum and poured out freely when it was opened. This recalled the abandoned suspicion of a ruptured spleen. The peritoneum was rapidly closed and a transverse incision made through the upper left abdomen (Fig. 1). Through this approach the spleen was easily delivered from its surroundings of blood clot; its vessels were ligatured, and it was quickly removed. On dividing the peritoneum the second time the patient collapsed, became pulseless, and seemed as if he were dead. Intracardiac adrenaline and intravenous saline were administered, and after these his pulse faintly returned. The entire procedure was brief, and while the abdomen was being closed the patient was turned into the Trendelenburg position, extra blankets being tucked around him, and electric stoves placed near by. In an hour's time

he was sufficiently recovered to be levelled up, moved on to his bed; and taken back to the ward. A blood transfusion shortly afterwards established the improvement, and his recovery was uneventful.

The spleen was enlarged to twice its size by several closely adherent layers of thrombus. It was possible to peel these off like the skins of an onion. The surrounding space was filled with a large amount of fluid and clotted blood. Apparently the blow caused a subcapsular injury and haemorrhage, whose waxing and waning stripped up, distended, and ruptured the capsule, forming the laminated perisplenic haematoma.

Deliberating on the sequence of events since, it appears to me that the bleeding from the lacerated spleen irritated the splenic flexure and the descending colon into contraction, thus explaining the diarrhoea. Later, this segment of the bowel became paralysed by aseptic peritonitis, causing partial intestinal obstruction, followed consequently by distension and tenderness of the caecum in the right iliac fossa. It was the latter sign, coupled with the previous history of three weeks' indigestion, which urged the pre-operative diagnosis of acute appendicitis.

Case II

A woman aged 56, while standing on the sill cleaning a window, slipped, and in falling to the floor struck her left side on a chair-seat. She was faint, and felt sick for a time, but continued her duties as a housewife for two days, although admitting that she did not feel well. On the third day she went to bed, owing to weakness and being short of breath. The next day she consulted her doctor, and he sent her to hospital.

FIG. 2.—Shows the incision and the elevation of the loin.

On admission she complained of breathlessness and of pain in the lower part of her left chest, which was worse on coughing and on movement. In addition, for two days she had experienced stomach-ache and constipation. Her temperature was 99°, pulse 110, and respirations 25. She was placid and did not appear to be anaemic. There was a slight bruise over the ninth and tenth ribs at the mid-axillary line, but, apart from impaired resonance at the left base, the chest was considered to be within the normal. A radiograph of the ribs revealed no injury. The abdomen showed moderate generalized tenderness, and some shifting dullness in the flanks. The next and the following day the pulse increased slightly, averaging 120, and the signs were indefinite. When I saw her first on the seventh day after the accident she was much worse, and was undoubtedly very ill; her pallor was striking. The abdomen was distended, visible peristalsis was observed, and at the left upper quadrant was rigidity, tenderness, and dullness. Shifting dullness was still an equivocal physical sign. The haemoglobin was 55 per cent.

The diagnosis of a ruptured spleen was submitted, and confirmed at immediate operation, when the torn organ was removed. The abdomen was filled with blood clot. A transverse abdominal incision was made, and with the bridge of the table raised under her lower ribs as for a gall-bladder operation the exposure was ideal; the entire procedure took fifteen minutes (Fig. 2). She collapsed as the peritoneum was incised, but responded to an immediate intravenous saline and to a blood transfusion two hours later.

An Epitome of the Clinical Picture

This condition—that is, “delayed haemorrhage following traumatic rupture of the spleen”—has recently been very carefully studied by A. H. MacIndoe.¹ With his permission some of his findings are used here. The con-

dition is rare, for he found only forty-five cases in the literature, and reported one of his own.

The Exciting Injury.—This varies from being mild to severe in character. It is usually to the left upper abdomen or to the base of the left side of the thorax. Ruptured spleen from contrecoup is very rare. In chest injuries ruptured spleen complicates fracture of the lower left ribs sufficiently often for the possibility of its occurrence to be always seriously considered. Consequently, these patients should be observed in bed for at least fourteen days. The immediate effect of the accident may be marked temporary shock, grading to almost nothing, so that the patient has forgotten about an injury when questioned a few days later.

Latent Period.—In the article referred to, MacIndoe remarked on the period of “symptomatic silence” after the accident, termed by Baudet the “latent period,” and well illustrated by my second case. Two to eight days is the usual time; it has been as long as six months. Although the term “symptomatic silence” is applied to this interval and patients have continued to work, they usually admitted experiencing a persistent dull left upper abdominal pain, and examination showed slight rigidity as well. Less frequently, slight acceleration of the pulse rate, pallor, weakness, dizziness, or faintness are present.

Symptoms and Signs.—The picture may be a dramatic one, patients exhibiting collapse from a sudden torrential bleeding, as in Case II, or one not so striking, but nevertheless equally serious, where slow, progressive bleeding causes a gradual yet persistent deterioration of health (Case I). Varying degrees of pain in the splenic region are present in every case; my patients experienced it. Further pain is referred to the left shoulder, and is of diagnostic significance. Ballance's sign²—“a dull note in both flanks, but on the right it can be made to shift, whereas on the left it is constant”—and increased splenic dullness are sometimes observed. There is rigidity in the epigastrium, at the left costo-vertebral angle, and below the left costal margin; fullness may be noted in the last area. Appreciation of the tender fullness in the region of the caecum, resulting from inhibition of the colon about the spleen, is important; I have also seen it in a case of torsion of the spleen. It may proceed to centralized distension—that is, from small intestine obstruction—with visible peristalsis (Case II). Signs of pneumonia, pleurisy, or an effusion may be found at the base of the left lung.

Haemorrhage.—Faintness occurs as the bleeding progresses. An abdominal catastrophe with agonizing pain may be precipitated by a large sudden haemorrhage. It sometimes occurs spontaneously, or after a slight strain such as coughing. Great collapse may follow, causing a perforation of a hollow viscus to be suspected, and sudden death has followed. The power of the bleeding usually increases the original damage to the spleen, proceeding to the gross changes, occasionally morcellement, found at operation. It is quite the exception for a splenic wound to heal.

Summary

1. Two cases of ruptured spleen with delayed acute symptoms are described.

2. An epitome of the condition is added.

3. Emphasis is laid on: (a) the possibility of a ruptured spleen occurring with fracture or bruising of the lower left ribs, (b) the significance of persistent left upper abdominal pain and muscular tension after even a trivial injury, and (c) the facility with which splenectomy can be performed through an upper abdominal incision with the loin well elevated (Fig. 1).

A CASE OF CONGENITAL HEART-BLOCK

BY

JOSEPH LEWIS, M.R.C.P.I.

ASSISTANT VISITING PHYSICIAN, MERCER'S HOSPITAL, DUBLIN

Congenital heart-block appears to be a comparatively rare condition, and so few cases have been confirmed by electrocardiogram that I am prompted to make an addition to the sparse literature on this interesting abnormality.

Before heart-block can be considered to be of congenital origin it must conform to the criteria laid down by Yater¹ in his exhaustive review of the literature on this subject in 1929. There must be some evidence of the existence of a slow pulse at an early age. A graphic record soon after birth would further establish its existence in the absence of a history of an acute infection such as

A. Auricular 75, Ventricular 43.

diphtheria, scarlet fever, chorea, influenza, rheumatic fever, or other causes of myocarditis. The knowledge of syncopal attacks at an early age, combined with a slow pulse and graphic evidence in later years, would lend support to its congenital origin, while the coexistence of other congenital cardiac abnormalities would support a diagnosis of congenital heart-block.

Case Records

A girl, aged 8½ years, was brought to the cardiac outpatient department for examination to ascertain the present condition of her heart. Her mother stated that the child was born with a slow pulse, and that her doctor had said she had had a murmur in her heart from birth. Born at full term, the patient never at any time exhibited cyanosis or fits of any kind. There was a complete absence in her history of an attack of tonsillitis, diphtheria, chorea, etc., likely to interfere with the conduction through the bundle of His. There were no obvious stigmata of congenital syphilis.

A bright, vivacious, and intelligent girl of more than the average size, she suffers no distress whatever from her condition. There is complete absence of cyanosis, even with exertion at games. Her pulse rate was regular at 42 a minute. To all outward appearances she does not differ from any other girl of her age; in fact, she might be considered to exceed the average, both physically and intellectually.

RESULTS OF EXAMINATION

The apex beat was not displaced, and the cardiac impulse was not abnormal. There was no thrill palpable over the præcordium, even after exertion. A continuous murmur was audible all over the præcordium; this was thought to be due to a defect in the interventricular septum. The blood Wassermann test was negative. The pulse rate at rest was regular at 43 a minute, and increased to 48 after slight exertion.

X-ray and screen examinations were reported on as follows by Dr. F. G. Stewart: "Heart shows some transverse enlargement, the heart-lung coefficient being 1 to 1.87. The apex lies above the diaphragm, and is rounded. Pulsation good. The shadow of the right auricle is not enlarged. The pulmonary area is prominent and pulsation marked. First

oblique shows the left auricle to be enlarged backwards to a moderate degree. The conus is rather prominent. Aorta not enlarged. Findings: Enlargement of the left and right ventricles and of the left auricle. There is no enlargement of the aorta, but the pulmonary artery is enlarged.

The electrocardiograms revealed the following (see Figs.):

A. Complete heart-block of roughly 2 to 1 rate, the auricular rate being 75 and the ventricular 43 a minute.

B. Films taken three months later show the persistence of the block without alteration in the auricular rate, and a ventricular rate of 45 a minute.

C. Atropine sulphate (1/100 grain) was injected subcutaneously, and this record was made when the patient was under its influence: about three-quarters of an hour after Tracing B and half an hour after injection of the atropine. A very definite alteration is seen, especially in Lead II, showing the P wave superimposed on the T. The effect of the atropine on the auricular rate was obvious, increasing it from 75 to 90 a minute, whilst the ventricular rate was entirely unaffected.

B. Three months later. Auricular 75, Ventricular 45.

C. After 1/100 grain atropine sulphate. Auricular 90, Ventricular 45.

Comment

The literature contains about forty cases of congenital heart-block, the great majority of them having a patent ventricular septum. One is struck by the paucity of symptoms in most of these cases. In roughly half of them there was an absence of cyanosis, in others it was mild, whilst in a few it was noticed at birth, but disappeared in later years. This cyanosis can justly be attributed to the coexisting cardiac defects. Fainting fits or syncopal attacks were rare, occurring in only seven cases, one of which had a pulse rate of 20. This case, reported by D'Espine and Cotton,² showed the slowest rate of any of the recorded cases; while that of Nicholson,³ with a rate of 80, showed the highest. The average rate in congenital heart-block is roughly 43 a minute.

The commonest coexisting lesion is a patent interventricular septum, and was observed in twenty-five cases, while pulmonary stenosis accompanied three of them. It is extremely difficult to give a prognosis on account of the limited literature available. It is highly doubtful if the heart-block itself would influence the prognosis to any great extent. The other cardiac abnormalities must interfere with the outlook considerably.

Of the recorded cases some deaths occurred at a very early age, while others have been known to reach the age of 21 (Calandre⁴), 20 (Smith⁵), and 18 (Myer⁶) years.

Dr. Aitken,⁷ in her excellent survey of the literature, described two cases of this abnormality, and suggests an overgrowth of fibrous tissue between the auricle and ventricle as the possible cause, leading to interference with the conduction through the bundle of His.

SUBLEUKAEMIC LYMPHADENOSIS IN A CHILD

BY

G. STEWART SMITH, M.D.

ASSISTANT PATHOLOGIST, MANCHESTER CITY HOSPITALS

Lymphadenosis in children is a rare condition, and the case reported here has some unusual and interesting features. Gittins,¹ in a recent review of the condition, states that the average duration of lymphadenosis in children is under two months, and the most chronic case recorded lasted not more than eight months. Cases of myelogenous leukaemia may, however, give a longer history. The following case, definitely of lymphatic type, lasted at least ten months, and a special feature was the presence of deposits of lymphoid cells in the subcutaneous tissues of the eyelids. Subcutaneous deposits are not very uncommon in lymphatic leukaemia in adults, but in children they are extremely rare, and in a review of 100 cases Ramsay² records only one, that of a case reported by Ward³ in 1912.

Case Record

The patient, a male aged 4½ years, was admitted to Booth Hall Hospital on January 17th, 1933, with a history of loss of weight and anorexia for several weeks. The child was fat and flabby, and the skin yellowish; the gums were ulcerated, the lips excoriated, and the breath foul. Local and dental treatment sufficed to clear up the mouth condition, and the child was discharged one month later, no blood examination having been made.

On June 16th, 1933, he was readmitted, having been ill almost constantly since discharge, with listlessness and tiredness, repeated attacks of pain in the limbs, slight fever, and occasional night sweats. At this time the skin was definitely yellowish and waxy, and there was marked gingivitis. Neither the lymph glands nor the spleen were enlarged. A blood examination showed a severe anaemia, with a colour index of unity and 7,000 leucocytes per c.mm., of which 82 per cent. were lymphocytes. The possibility of a primary anaemia of pernicious type was considered. Fractional gastric analysis showed complete achlorhydria, but the exhibition of a potent liver extract given intramuscularly failed to produce any reticulocyte response. Subsequent blood counts (see table) showed great variation in the total number of leucocytes from 5,000 to 33,000, but always with a high proportion of lymphocytes and generally some lymphoblasts, which nine days before death constituted 84 per cent. of the total white cells. The hypoplastic anaemia, improved for a time by a blood transfusion, was present throughout, and blood platelets were very scanty. A somewhat similar blood picture of lymphadenosis commencing with hypoplastic anaemia has been reported by Weber and Weisswange.⁴

Date	R.B.Cs. ($\times 1000$)	Hb. %	Colour Index	W.B.Cs. (total)	Differential Count: Percentages									Blood Platelets

After four weeks in hospital the mouth was normal, but a slight swelling appeared in the right upper eyelid, and shortly afterwards discrete shotty glands were palpated in the neck and groin. The glands varied much in size at different times during the illness, but tended to become larger. Three weeks after the appearance of the nodule in the right upper eyelid a similar swelling appeared in the left upper eyelid. The child was noticed to bruise easily, and at one time a fine purpuric rash appeared on the limbs and persisted for two days. X-ray examination of the long bones showed osteoporosis, a condition which has previously been noted in this disease. During the last month the spleen became palpable, and a week before death reached almost to the umbilicus, while the liver was one inch below the costal margin. A swinging temperature, 97° to 100.2° F., was present throughout the illness, and the general condition, which was fairly good for the first three months, gradually deteriorated. The urine contained neither albumin nor Bence-Jones's albumose. Death occurred on November 19th, 1933.

If it be admitted that the illness in January was due to the same cause as that found in June, which seems extremely probable, the duration of the illness was at least ten months.

POST-MORTEM FINDINGS

The chief features at the post-mortem examination were as follows. Skin: minute petechial haemorrhages present; almond-shaped subcutaneous nodules, approximately half an inch in length, present in each upper eyelid. Lymph glands: submental, cervical, axillary, inguinal, and mesenteric glands definitely enlarged. Pericardium: multiple subpericardial haemorrhages. Lungs: many haemorrhagic infarcts throughout all lobes. Liver: weight 1,000 grams; pale yellow in colour and of increased consistency. Spleen: weight 170 grams; definitely enlarged and of increased consistency. Meninges: small recent subdural haemorrhage on left side. Marrow of femur: dark red. Other organs: nothing of note.

MICROSCOPICAL REPORT ON TISSUES

Microscopically the subcutaneous nodules are of moderate vascularity and not encapsulated. They consist of large numbers of fairly widely spaced mononuclear cells, which have a large nucleus, slight chromatin differentiation, and a rim of basophilic non-granular cytoplasm. The stroma is loose and coarse, and in it are many voluntary muscle fibres between which the invading cells have infiltrated, giving almost the appearance of a sarcoma. Mitotic figures are present in small numbers. The oxidase reaction on the cells in these rabbits and on similar cells found in the bone marrow and elsewhere in the tissues is completely negative, and as the cells are similar to those found on many occasions in the blood they must be regarded as lymphocytes or their precursors. Fresh films of bone marrow from the femur show an almost entire replacement of erythroblastic tissue by primitive lymphocytic cells, very few normoblasts being present. No myelocytes can be seen.

The lymph glands show massive accumulations of similar cells, and the lymph follicles are poorly defined. The pulp

of the spleen consists chiefly of cells similar to those found in the bone marrow. There is an extensive central fatty change in the liver, and a moderate amount of free iron in the cells around the portal area. Some well-circumscribed periportal collections of lymphoid cells are present.

Summary

The blood and post-mortem examinations and the histological findings leave no doubt that the case was one of lymphadenosis, for the greater part of its course subleukaemic, the special features being the relative chronicity and the presence of subcutaneous deposits of lymphoid cells, both extremely rare occurrences in this disease in children.

I wish to thank Dr. J. D'Ewart, medical superintendent of Booth Hall Hospital, for permission to publish this case.

A PRACTICAL NOTE ON SUICIDE

BY

FREDERICK DILLON, M.D.Ed.

MEDICAL SUPERINTENDENT, NORTHUMBERLAND HOUSE MENTAL HOSPITAL;
CHIEF ASSISTANT IN THE DEPARTMENT OF PSYCHOLOGICAL
MEDICINE, UNIVERSITY COLLEGE HOSPITAL

It is an aphorism among psychiatrists that every case of depression is a potential suicide. Yet how difficult it is to get the general public to realize this fact. Reports of inquests on suicides, even when the verdict is the usual one of unsound mind, contain as a rule singularly little indication that the relatives had observed in the victim previous to the act the existence of any abnormality of mind. On inquiry by the coroner it may transpire that the deceased was "worried" or sleepless or suffered from pains in the head. But the depression, almost always present, is usually minimized or completely overlooked, and the act of suicide invariably takes the relatives by surprise. Depression is the commonest precursor of suicide, but even when it is recognized by those about the patient as a sign of mental disorder it still remains a problem to persuade them of the danger of suicide that consequently exists. They generally consider they know better. They tell you they understand the patient so well and are sure that he, or she, would never think of doing anything like that.

A case which emphasizes this difficulty was that of a woman who had become depressed after the death of her husband some weeks previously. The sister, who was looking after the patient, was warned that a definite danger of suicide existed. She plainly thought an alarmist view was being taken, although admitting that the patient was "not herself." It was agreed that she should be sent without delay into a home on the South Coast, and in the evening another relative telephoned to say that final arrangements had been completed and that he would accompany the sick woman the following day to the nursing home. The warning was repeated to him, but little notice was taken of it, and in the train next day he allowed the patient to leave the carriage. She opened a door in the corridor, threw herself on to the line, and was later found dead. At the inquest no reference was made to the warnings that had been given.

Suicide may be actuated by a variety of motives depending on the nature of the mental disorder and the mechanisms at work in the patient's mind. Our insight into these motives will obviously depend on the depth of our psychological analysis of the mental state. I do not intend in this article to consider the influence of the deeper levels of mental activity. The introduction of the concept of the unconscious has thrown much light on the whole subject of mental disorder, an instance of great importance being the discovery that motives which are apparent on the surface may be no true indication of those existing deeper in the mind. But the development of unconscious psychology has brought about also many complexities of theory and technical problems which can

more appropriately be dealt with in journals specially devoted to the subject. Melancholia is the condition in which suicide is most to be feared, and the periods of greatest danger in the majority of cases are at the beginning of an attack and when the patient is showing signs of recovery. At these stages psychomotor inhibition, which puts a brake on suicidal impulses, is less developed, and supervision commonly tends to be relaxed.

Suicide a Means of Escape

Speaking generally, we may say that suicide is a way of escape from a situation that has become intolerable. Mental conflict may reach such a degree of intensity that deliverance from the unbearable conditions seems an imperative necessity. People vary in their capacity to tolerate conflict, anxiety, or "worry," and an accidental accumulation of troubles or an incident which to others seems comparatively unimportant may, in unstable types, precipitate an attempt at self-destruction. Sometimes a transient condition of confusion may develop at the critical moment or a short phase of automatism may occur when the act is committed. In these cases, if the attempt is unsuccessful, there is an amnesia of varying duration, and the patient may "come to" and discover himself the victim of injuries with no recollection how they occurred.

Worry from external circumstances, unless the latter are of an extraordinary or exceptionally disturbing character, cannot be said to be sufficient in itself to arouse a suicidal attitude of mind. Other components are always present, the external conditions acting only as accumulative and precipitating factors. Guilt and self-reproach are the commonest motivating elements in melancholia, and may develop to an extreme and overwhelming degree. In these cases suicide is a punishment for sin, an atonement and washing out of guilt. In other cases fear or apprehension of something terrible about to happen is the dominating feature. The grounds for the fear may be unknown or may be definite, though irrational, such as the conviction of being about to be tortured. In this condition the suicidal attempt is made to avoid the horrors that are thought to be imminent.

A belief that they are injuring those they love is a common motive in another class of depressed patients which may produce great mental distress and lead to determined efforts at suicide. It may be some spiritual injury they feel they are the cause of, or they may believe they are unclean and in danger of transmitting some dreadful disease. Self-pity and the hypochondriacal attitude may be accompanied by suicidal attempts, and in these cases an exaggerated egoism seems to be a constant feature. They frequently tend to dramatize themselves and appear to obtain a distinct satisfaction in the process. Savage¹ declared that as a rule the hypochondriac is not actively suicidal, although he made an exception in the case of sexual hypochondriasis, and certainly when suicidal attempts do take place in these cases they appear often to be curiously unconvincing. Other writers, however, are not of this opinion, and it is probable that there are at least two forms of this disorder which differ considerably so far as the danger of suicide is concerned.

Suicidal and Homicidal Impulses

The paranoid psychoses are more commonly associated with homicidal than with suicidal tendencies. Mercier went so far as to say that no paranoiac should be allowed at large, and that if he were so allowed his perpetration of a murder was merely a matter of time and was certain to take place.² However that may be, these cases with their morbid suspiciousness and persecuted outlook on the world sometimes find the strain of a life of victimization too much for them and make an end of it to obtain relief. When the mental conflict turns in this direction it generally is put into effect with great thoroughness and determination. The relation between suicidal and homicidal impulses in cases of mental disorder is a problem of great interest and importance. They may occur together as in the not infrequent case of murder

¹ *Insanity and Allied Neuroses*, fourth edition, 1907, p. 146.

² *Text Book of Insanity*, second edition, 1914, p. 20.

and suicide by the same individual. Or they may alternate, and a patient from being suicidally inclined may become violent towards others, the impulse apparently, instead of being directed inwards towards the self, is directed outwards as aggressiveness.

A woman who became depressed after her father's death described how a tragedy very nearly took place one night when, after lying in bed thinking that it was no use for her and her two sisters to go on living as it all ended in nothing, she got up with the intention of killing her sisters and herself. She obtained a pair of scissors with which to carry out her design, but an acute mental conflict supervened which ended by her cutting off her hair.

How commonly a history of suicidal attempts is found in convicted murderers I am unable to state, but cases of considerable interest in this connexion occur from time to time.

Phobias and Obsessions

Phobias and obsessions most commonly develop as symptoms of the psychoneuroses. Their relation to the major psychotic states is not yet clear, although they are quite frequently associated and in particular may usher in an attack of insanity. In regard to the danger of suicide in these cases two problems require to be considered. The first refers to the mental conflict which is the usual accompaniment of these disturbing symptoms. This may be of a very distressing nature and may cause a reactive condition of depression with suicidal impulses.

A case in point was that of an unmarried lady of 60 who, on the occasion of a visit to a cinema, saw a picture of a number of small boys bathing naked in a river. There came into her mind immediately some obscene words which she was unable to banish despite all her efforts. The condition soon became established with the typical characters of an obsessional neurosis. She struggled with it for some time until she became convinced that she must be a wicked woman to harbour such thoughts and attempted to end her life by taking poison. In another case a woman of 28 developed the obsession that she must find the meaning in everything. She felt compelled to ask herself this question about all the most ordinary acts of her life and to analyse everything with this end in view. She always arrived, as she put it, at a dead end and spoke of suicide as the only way out. After a few months she ended the strain of the constant questioning by putting her head in the gas oven.

The other problem concerns the seriousness with which a phobia ought to be regarded. Cases occur, for example, in which a fear of committing suicide exists or a fear of travelling in a train or a fear in a mother that she will injure her child. The doctor may be faced with a grave responsibility. Is he to take the phobia at its face value and deal with the situation as if a real danger existed? Or is he to rely upon the teaching of those who say that phobias are never translated into action, and advise the patient to court the occasions of his fear and "conquer" it? The answer will depend to some extent on the nature of the phobia. It may be one of little practical importance to the individual such as a fear of heights, but if it involves another person it assumes a more serious aspect. Bearing in mind that a fear commonly denotes a wish in the unconscious, that we can never be sure a reactive state of depression will not develop, and, further, as we cannot exclude the likelihood that the phobia may be the incipient stage of a psychosis, the wise physician will be alive to the possibilities and act with caution in the advice he gives.

A woman of 28, some months after the birth of her first child, developed the fear that she would injure it. She was afraid to touch it in case she might do it harm; phrases such as "a nice little throat to cut" came into her mind and distressed her greatly. She had to keep looking at the baby to assure herself she had not done something to it. In this case it was considered advisable to separate the mother and the child, but the condition proved persistent, and four months later she committed suicide by taking poison.

Impulsive Suicide

Suicide is occasionally attributed to mere impulse—that is to say, to a sudden action that appears quite unmotivated and is carried out in the absence of any grounds or reason for it. Attempts of this nature are said to take place particularly in schizophrenia, but it is

very doubtful if such an anomaly can ever with any assurance be said to occur. Our knowledge of mental mechanisms and of mental life in general enables us to draw the highly probable conclusion that a motive exists in every case of suicide, although it may not be easily discoverable. Guilt and anxiety, for example, are factors which are very prevalent in all forms of mental disorder. They may exist concealed and buried and so unapparent to ordinary examination, and may be the source of suicidal tendencies in seemingly unlikely cases. Impulsiveness in this sense must, however, be distinguished from the impulse which is the final step in a suicidal attempt. Many cases of mental abnormality contemplate suicide long before it is put into effect. In other instances a background of depression exists as the predisposing condition, and in both cases the actual attempt may take place as the result of a sudden impulse.

This is well illustrated in the case of a man of 53 who became depressed after an attack of influenza. Following upon a sleepless night his depression increased and he developed the idea that a crowd had gathered outside his house and were clamouring for the return of certain club moneys he had in his control. He was greatly distressed at this, but declared that the idea of suicide had not up to that point entered his mind. He went into the bathroom, happened to see his razor lying on a shelf, and, impulsively seizing it, drew the blade across his throat, inflicting a serious wound.

Suicide may also be associated with the occurrence of hallucinations. These are most commonly of the auditory type and constitute as a rule only part of the mental syndrome. Sometimes "voices" explicitly instigate a person to kill himself, and the situation then becomes a particularly anxious one, as the injunction is generally conveyed in the form of an order or command. These voices have a peculiarly convincing and compelling effect upon the mind, considerations of reality being of little weight in comparison. They are of graver import in this respect than delusions and seem to lead to action of the most direct and dangerous type.

Other Aspects of Motivation

There are other issues of importance in connexion with the problem of motivation in suicide, in particular the significance of unconscious factors. Motives that are apparent at the clinical level of mental activity are never the sole or essential elements at work. As was mentioned earlier in the article, deeper psychological investigation always reveals additional and generally more significant causes. A common constituent, for example, of melancholia, is hate, but it is repressed and concealed as a rule. The mechanism of identification with another—which makes suicide equivalent to homicide—and such motives as the desire for rebirth into a happier state of existence are revealed in most cases only by special methods of investigation. The relation of suicide to the death instinct and to the super-ego—the nucleus of the moral sentiments—are other problems of intrinsic importance. But it is impossible here to enter in any detail into a consideration of this aspect of the subject; too many technical problems are involved and too many points that are still open to dispute. Concerning the importance of sexual disabilities in these cases Savage¹ remarked that no class of patients is more suicidally inclined than those who believe themselves to be impotent, and none are more dangerous than those who believe themselves to be "tapped," "drawn," or "emasculated" by others—an interesting adumbration of modern views on the significance of sexual factors.

Individual Preferences

An important fact about suicide is the individual preference for particular methods that is exhibited in practically all cases. Suicides, consciously or unconsciously, select certain modes of death and restrict themselves more or less to these, even neglecting opportunities that may arise in other directions.

A case in point was that of a depressed and apprehensive woman who believed she was going to be murdered. She pleaded frequently to be given chloroform and killed quickly

¹ Loc. cit. p. 281.

instead of being tortured to death, and on one occasion swallowed a large coin, which fortunately was recovered without much difficulty. She discovered one day a window open and unattended on an upper floor and climbed through on to a small balcony. Instead, however, of precipitating herself to the ground she dropped from the balcony on to a garden table, and was brought back little the worse, having sustained nothing more than a few bruises. Shortly afterwards she was again pleading to be put out of her misery.

Another woman who was depressed and abnormally suspicious threw herself from a first-floor window, fracturing her pelvis and femur. She was offered brandy by her sister but refused it, saying she believed it was poisoned.

This selectivity is a source of security in most of these cases and lightens the anxiety of supervision. If it were not so the difficulties of treatment would be greatly increased, as it is probably impossible to prevent suicide in the case of a wholly determined person on the look out to seize any means of achieving his end. At the same time it cannot be entirely relied upon in practice, as we can never be sure that our insight into particular cases is sufficiently complete.

The different methods that are adopted—poisoning, hanging, precipitation, and the others—have in all probability a special psychological significance in each individual case. It is this that leads to the development of the preferences we have mentioned, but further consideration of this subject would lead us too far into the region of unconscious psychology. Suggestion is a significant factor in this connexion, and it is generally held that newspaper accounts of suicides provide a dangerous source of stimulation and encouragement. "Epidemics" have been described of multiple cases of suicide carried out by the same means, originating apparently as the result of the prominent and sensational reports appearing in the Press. This is, without doubt, an exaggerated view, for our knowledge of psychological causation makes it obvious that a pre-existing tendency must invariably be present and that suggestion is but the end link in a chain of determining conditions. A family history of suicide may have a strong suggestive influence in unstable persons. In the case of a man who became depressed and hypochondriacal two of his sisters had committed suicide and his father had attempted it unsuccessfully. The brother and father of another similar case had committed suicide, and the patient on several occasions remarked that the only way out of his misery seemed to be "to do what the others did." Both of these cases were lost sight of, but the influence of the family history was looked upon very seriously while they were under treatment.

Threat and Performance

It is commonly believed that those who speak openly of suicide and threaten to carry it out are not really dangerous in this respect, and seldom or never put the threats into effect. Sometimes patients suffering from depression irritate and exhaust their relatives by referring frequently to suicide while ignoring daily opportunities, and the impression is received that it is done merely to attract attention and obtain sympathy. It is important to realize that this is an erroneous view, as experience shows that persons of this type are quite as likely to commit suicide as those who are more inhibited and reticent on the subject.

A striking example was that of a woman who became depressed and frequently threatened to end her life. The husband was advised not to take the threats seriously, and allowed her on one occasion to open the carriage door of the train in which they were travelling when she said she wanted to throw herself out. She did nothing at the time, but later precipitated herself from an upper-floor window and fractured her skull. Another patient of the same kind was permitted by her husband to open the window on an upper floor of the house and look down after she had said she would jump out and kill herself. She did not carry out her threat on that occasion, but some weeks later made a serious attempt at suicide by swallowing a number of sedative tablets.

Some depressed patients are very theatrical in the expression of their misery and dramatize themselves in a way that looks unreal and artificial. It is often thought that this attitude denotes a lack of seriousness and a desire to draw attention to themselves, and that in consequence little danger of suicide need be apprehended.

This is a mistaken opinion and may, if acted upon, lead to tragedy.

A case which well illustrated this fact was that of a woman who had been under care for some time suffering from melancholia. She made the most theatrical manifestations of grief and remorse, going down on her knees, clasping her hands before her, and begging forgiveness from the doctor for imaginary sins. A strong-minded aunt came from abroad and, after a visit to the patient, said the histrionics were just "put on," that she would look after her and talk the nonsense out of her. The patient was taken to a hotel in London and the following day was found dead, having thrown herself from a top-floor window.

Unsuccessful attempts at suicide very frequently occur and are often taken to imply a lack of serious intention. It is not an uncommon thing to meet cases in which two or more attempts have been made, sometimes to all appearance of a doubtful or even trivial character. It is unwise, however, to label these mere exploits or "demonstrations" made simply for the purpose of attracting the notice and gaining the solicitude of others. The suicidal impulse seldom occurs in a free and uninhibited form. Generally the tendency is in conflict with other restraining tendencies, which accounts for the irresolution so often displayed, the sudden change of mind, and the reduction of an attempt, begun in earnestness, to insignificant proportions. The mental state is generally double-sided or ambivalent, consisting of opposing impulses, and the issue will depend on the relative strengths of these conflicting forces. Indecision, therefore, or apparent insincerity should not blind us to the existence of dangerous proclivities, as a situation may develop which increases the tension and tips the balance with fatal results.

A case in which this condition was well displayed was that of a woman who became depressed and acted in a manner that was looked upon as merely foolish and unbalanced. She waded into the sea and came out again of her own accord, making demonstrations, as it was thought, to draw attention to herself. These episodes occurred on two or three occasions and were not looked upon as indicating a true suicidal tendency. One day, however, she threw herself from an upper floor over the staircase and fractured her spine.

On the other hand, occasionally the act is carried out in a very determined and even over-determined way, as in the case of a man, reported some time ago from France, who took poison, mounted a chair with a rope round his neck, the other end being attached to a chandelier, stabbed himself in the chest and, as he kicked the chair away, shot himself in the head.

In conclusion, an aspect of the subject of great moral and practical importance calls for consideration—namely, the responsibility that attaches to the relatives or others in a case of mental abnormality when warnings have been disregarded or obvious indications of danger ignored and a tragedy ensues. The problem was illustrated in the first case described in this article, but it applies not only to persons with suicidal tendencies but to others also, in particular those with dangerous proclivities. A striking instance in point was the celebrated McNaughten case, which aroused a great deal of discussion at the time and led to the famous ruling of the judges—the basis of our present law on criminal responsibility.

In 1843 Daniel McNaughten shot and killed Edward Drummond, Sir Robert Peel's private secretary. The crime was readily recognized to be the outcome of McNaughten's abnormal state of mind. He had never, in fact, seen Mr. Drummond before, and seems to have met him accidentally in the street just before the tragedy took place. The singular fact, however, that appears in connexion with the case is that for at least two years before the crime McNaughten had been known to be suffering from delusions. Incredible as it may seem, he had consulted on the subject of his delusions not only his father but also, among others, a clergyman, the Provost of Glasgow, the Sheriff of Lanark, a member of Parliament, and the Commissioner of Police for Glasgow, and not one of them had felt called upon, in the public interest, to take any action in respect of the man's obvious mental abnormality. As a legal commentator on the case remarks: "Who was morally responsible for Mr. Drummond's death? Was it the unfortunate prisoner himself, who was suffering from a diseased brain? Was it not rather his relations and those others whom he consulted in his misery, and who yet took no steps to have him placed under medical care?"

The Defence of Insanity in Criminal Cases. An Essay by F. Lancelot Everest, Barrister-at-Law.

Clinical Memoranda

JACKSONIAN ATTACKS IN CONNEXION WITH EXTRADURAL ABSCESS OF THE FRONTAL LOBE

In both of the cases reported below the progress was extremely rapid—approximately one week. There was a history that the patients had been swimming and diving on several occasions during the week previous to the onset. The inability to demonstrate any direct spread through bone in Case I seems to indicate that the infection travelled in the blood stream, possibly by way of the anterior ethmoidal vein. It would appear that even abscesses in the frontal lobe frequently give rise to no localizing signs in this silent area of the brain. It is therefore interesting to note the occurrence of Jacksonian attacks in connexion with an extradural abscess in this region. A possible explanation is suggested by the microscopical examination of the frontal lobe in Case II—namely, that a non-infective inflammatory reaction is set up in the cerebral tissue adjacent to the extradural abscess, and causes the motor phenomena.

CASE I

E. S., male, aged 9½ years, was seen at Moorfields on July 27th, 1933, and was referred to the Central London Throat Hospital. Previous history: nothing of note. Present history: patient was quite well until July 20th, on which day he swam twice. It was noticed in the evening that he looked slightly flushed. On July 21st he was kept in bed, but was not complaining of anything. On July 22nd the patient felt better and got up. On July 25th he complained of pain in the right eye and round the right cheek. He went to the seaside and bathed; afterwards he was languid. On July 26th a slight swelling of the upper right eyelid was noticed. On July 27th the swelling of the eyelid had increased, and he was drowsy.

On examination the same afternoon the patient was found to have oedema below the right eyebrow extending on to the upper eyelid; tenderness was marked above the inner canthus. Examination of the nose showed it to be congested, but no pus was seen. On transillumination the right side was dull. An x-ray photograph was taken and the patient put to bed, and treatment with three-hourly cocaine and adrenaline sprays was ordered. X-ray report: Thickened lining membrane of both antra and of anterior ethmoids. Frontal sinuses absent. Thickened lining membrane of both sphenoids and posterior ethmoids.

On July 28th the child's condition was much the same; he was not complaining of any pain. Temperature 102°0, pulse 100. At 7.30 p.m. he gave a short cry of pain, and started clonic spasms of the left side of the body, commencing with the face and spreading to the arm and leg. He vomited, bit his tongue, and breathed stertorously. The spasm became generalized and less severe. The attack was continuous, with quieter intervals, until 9.30 p.m. Lumbar puncture carried out the same evening showed cerebro-spinal fluid under pressure, but quite clear.

Operation, July 29th: An incision extending from the middle of the supraorbital ridge carried medially down the side of the nose to a distance of three-quarters of an inch below the inner canthus of the eye. The tissues were oedematous, but no pus was encountered on cutting down to the bone, the outer wall of which appeared normal. The frontal sinus was absent, but a large anterior ethmoidal cell filled with pus was found situated approximately where the frontonasal duct opens into the frontal sinus; the inner wall of this cell was intact and appeared normal. On its removal a large extradural collection of pus under considerable tension was discovered, and the dura mater was found to be thickened. The entire ethmoidal labyrinth and sphenoidal sinus contained pus. The lamina papyracea was almost entirely absent, and pus was issuing freely from the peristoma of the orbit. The opening in the orbital periosteum

was enlarged to facilitate drainage. The wound was packed with flavine and paraffin gauze, and left widely open.

The patient made an uninterrupted recovery; the temperature, coming down by lysis, was normal on the eleventh day after the operation. He complained of diplopia for the first week; this subsequently recovered.

CASE II

L. R., male, aged 13 years, was admitted to the West London Hospital on July 12th, 1932. Previous history: nothing of note. Present history: the patient commenced with headaches and pain over the left eye on August 6th. He had been swimming and diving on several occasions during the previous week. The pain and headaches persisted, and slight swelling above the left eye was noticed on August 8th. On August 9th the patient was seen by his doctor in the evening; his temperature was 102°0, and the supraorbital swelling had increased.

The patient was seen at the hospital on August 10th. Temperature 102°0, pulse 120. Oedema over left frontal sinus and upper eyelid. Very tender on pressure over this region. Transillumination showed the left side to be dark. No pus was seen in the nose. X-ray: left frontal and ethmoid cells opaque.

August 10th, 9 p.m.: sudden onset of Jacksonian attack commenced with twitching of the face and spread down the right side to the arm, lasting one and a half hours. Operation the same evening. Left frontal sinus explored, full of pus; anterior and posterior ethmoids also contained pus. The following morning right-sided Jacksonian attacks recommenced, passing into generalized spasms and lasting two hours, when the patient died.

Post-mortem Report.—Slight cellulitis above the left frontal sinus between bone and scalp. Right frontal sinus and right ethmoids were grossly infected. An extradural abscess 1½ in. by 1½ in. was found over left frontal pole. Pia arachnoid over this area was purulent. The meninges over left cortex appeared to be a little more opaque and oedematous than on the right side, but there was no macroscopic purulent meningitis at the base or vortex. There was no cerebral tumour or abscess on sectioning the brain. Both maxillary antra, sphenoidal sinuses, and middle ear were clear.

Cerebro-spinal fluid was taken just before death, and it contained 150 cells, 95 per cent. polymorphs and 5 per cent. lymphocytes. Section of the cerebral cortex well away from the lesion in the frontal lobe showed well-marked inflammatory reaction.

For permission to report Case I I am indebted to Mr. Gill-Carey, and for Case II to Mr. Hamblen Thomas.

DOUGLAS Y. RICHARDSON,
Late House-surgeon, Central London
Throat Hospital.

TRAUMATIC RUPTURE OF THE HEART WITHOUT EXTERNAL INJURIES

In the *Journal* of November 24th Dr. H. O. Gunewardene records a very interesting case of traumatic rupture of the heart without external injuries, death taking place ten days after the accident. The circumstances of the case are certainly unique.

The following case is similar in some respects; but, the violence being more severe, the damage to the heart was more extensive and death took place immediately.

In 1922 the body of a girl, aged 7 years, was brought to the Cumberland Infirmary, Carlisle, by the driver of a Daimler car, who stated that a front wheel of the car had passed over the child's chest. External examination revealed a slight abrasion on the forehead, but nothing more.

At the post-mortem examination all the ribs were found to be intact; the left pleural cavity contained approximately 24 oz. of blood; the pericardium was split longitudinally on the left side and both ventricles were ruptured, the right one to a greater extent than the left.

Both cases illustrate the very marked resilience of the ribs in young children, which permits of extensive internal damage without fracture of the ribs taking place.

Southport.

J. A. HAMILTON, M.B., Ch.B.

Reviews

SIR ROBERT MORANT

The publication of the life of Sir Robert Morant is a little belated, and the book itself more than a little disappointing. *Sir Robert Morant: A Great Public Servant*,¹ by BERNARD M. ALLEN, LL.D., is not without its merits. It is interesting almost throughout, and is written in a clear, straightforward fashion. Excellent use has been made of correspondence placed at the author's disposal, and the earlier chapters contain an account of formative experiences which were hitherto very imperfectly known even to many of Sir Robert Morant's acquaintances and associates with him in his later work. Nevertheless, the author, though he clearly realizes that his subject is a great one, scarcely ever rises to the height of his opportunities, seems to lose a sense of proportion, and does not succeed in presenting that vivid, impressive, and inspiring picture of the man that many had been hoping for. It must be admitted that the life of a civil servant can never be very easy to write. His own personal official work is necessarily merged in that of his Government Department as a whole, and can be known in full and in detail only to a small company of fellow administrators and to the succession of Ministers whom he serves. A great civil servant is perforce immersed in his job, and, by the traditions of his profession, takes but a relatively small and reserved part in other public activities. Sir Robert Morant's surpassing qualities as a civil servant, and his greatness as a man, penetrated this screen to an extent much more than is usual, but the limitations are still there for a biographer to surmount. Dr. Allen has not surmounted them: perhaps no one could in any adequate degree. There is one passage beginning on page 202, just too long to quote conveniently, which catches fire and illuminates the portrait of a resplendent character; and the author quotes a little later a letter from Mr. Augustine Birrell which, in the circumstances in which it was written, constitutes a fine tribute to the unique position which Sir Robert Morant had attained in the Civil Service; but we doubt whether anyone who did not know Morant would gather from this book an accurate appreciation of his outstanding personality.

To medical readers certainly, and probably to others, Dr. Allen's perspective will seem perplexing. His biography follows in due order the four periods of his subject's activities—childhood and youth, Siam, education, public health. Morant was officially connected with the Board of Education for nine years, though, of course, for a few years previously he had been associated in several capacities with educational administration. He was chairman of the National Health Insurance Commission for England, and afterwards permanent secretary to the Local Government Board and to the Ministry of Health (when established) for eight and a half years in all. Dr. Allen devotes 173 pages to Morant's educational work, and forty-five to his work for public health. This last section of the book is not inaccurate, and mentions many of the salient points requiring notice, but it fails to bring out the full significance of the final phase and the position this held in Morant's life-work as a whole. The present reviewer happens to have been associated with Morant, not exactly intimately, but in a not unimportant fashion, both in his educational aims and struggles and in those connected with his visions of an efficient and complete public health service; and great as he knows Morant's devotion to the former to have been, he can testify that

the latter were no less dear to his heart and part of his life. Even in the educational chapters of the book the author seems to be occupied unduly with a history of the developments of educational administration somewhat to the obscuring of what should have been his main theme. The exposition is well done and is quite interesting to those who had some part in the movement. It is true, too, that Morant was one of those men who, with a sacrificing zeal for his vision and ideal of the public good, combined a care for detail and a driving force of an altogether exceptional character. But some of the minutiae relating to the Cockerton judgement and other matters of but little present importance could well have been spared to make room for a fuller account of Sir Robert Morant's activities in his strife for an effective medical service.

Yet we would not seem unappreciative of Dr. Allen's service in producing this book. It is almost certainly the best presentation we shall now have of Morant's life and work. If his personality is not set forth so completely and vividly and proportionately as we could wish, it is still there. Those who knew Morant personally will like to have it, and will be grateful for facts of which they had not previously been aware, and for glimpses which they had not hitherto been privileged to obtain. To them a fuller portrait of the man might have been welcome, even if it had revealed some of his minor faults, mostly endearing, but occasionally exasperating. To others, perhaps, no biographer could succeed in conveying a real sense of the greatness of a man with whom in his lifetime they had not even a passing acquaintance.

NEWER OPHTHALMOLOGY

The third edition of *Recent Advances in Ophthalmology*,² by Sir STEWART DUKE-ELDER, is to all intents a new book. It might fairly be described as a volume in succession to the previous editions in its record of continuous research and current work. The opening chapters deal with the intricate and fascinating problems of the vascular circulation, the intraocular fluid, the vitreous body, and intraocular pressure. The chapter on the vitreous shows how far apart are modern views of the structure of this glistening jelly and the part it plays in the economy of the eye from the old idea that it was no more than a convenient packing material. Under the heading of tumours there is a good account of the radiation treatment of intraocular neoplasms. In the chapter on the cornea there is a critical summary of the recent development of keratoplasty, interest in which has been so much stimulated by the work of Tudor Thomas. There is also a discussion on the value of contact glasses in cases of corneal astigmatism so extreme that correcting by spectacles is of little value, and their occasional utility in the treatment of degenerative keratitis, severe corneal ulcers, and in plastic operations. The author gives a first-class review of the several methods of operating for the reduction of detachment of the retina.

"At the moment most of these procedures are too recent to allow any final verdict upon them; they are still in the experimental stage. . . . As the position stands, it is probable that the ideal operation has not yet been devised. The impetus to new work which the initial success of Gonin's procedure provided has not yet been expended, and further developments will without doubt arise. So far as the ultimate results of these operations are concerned, nothing can yet be said. The position may be summed up by saying that the prognosis of a detachment of the retina is always grave.

¹ *Sir Robert Morant, A Great Public Servant*. By Bernard M. Allen, M.A., LL.D. London: Macmillan and Co. Ltd. 1934. (Pp. 311 12s. 6d. net.)

² *Recent Advances in Ophthalmology*. By Sir Stewart Duke-Elder, D.Sc., M.D., F.R.C.S. Third edition. London: J. and A. Churchill, Ltd. 1934. (Pp. 434; 150 figures, 3 plates (2 coloured). 15s.)

but in the case of recent detachments with small and few accessible retinal holes in a relatively healthy eye it is brighter to-day than it has ever been."

By the ability and willingness of the author to gather together an immense amount of material, sift it out, and present the substance of it all in a comprehensive form, he has rendered yeoman service to his colleagues.

BACTERIOLOGY

Textbooks of bacteriology which prove useful to successive generations of students have a tendency to grow bigger and bigger with each new edition. This has been noticed in the work originally written by Hiss and Zinsser, and now brought up to date again by Dr. HANS ZINSSER with the assistance of Dr. STANHOPE BAYNE-JONES.¹ The book is well known in this country, more perhaps as a reference work for laboratory workers than for students preparing for examinations. Since the last edition was published two years ago bacteriological research has been particularly fruitful in two directions. In the first place, there has been a rapid increase in our knowledge of ultramicroscopic viruses. The different way in which viruses may be studied and the immunological reactions which they induce are described more fully in this than in previous editions. The second direction in which bacteriological ideas have developed has been in the study of bacterial variability. This has unexpectedly brought to light curious examples of dissociation of pathogenic and non-pathogenic strains. This question also is discussed fully in the new edition of Zinsser's textbook.

In order to make room for the new material the chapters on the bacteriology of milk, water, and soil have been eliminated. This sacrifice seems at first sight to deprive the book of some of its usefulness, but we notice that a good many paragraphs on milk, water, and the soil have crept unobtrusively into the chapters in the section on the general biology of bacteria. As in previous editions, the illustrations are excellent, the references are generous, and the index accurate.

MEDICAL PSYCHOLOGY

A translation into English of Dr. KRETSCHMER's *Text-Book of Medical Psychology*² will be welcomed by psychiatrists in this country. In his introduction the author observes that the more subtle-minded physician is aware of a double lacuna in his professional training; his primary need is for a psychology derived from, and applicable to, the science and practice of medicine. But, over and above this, his desire to possess a psychology often arises from a vaguely apprehended urge to extend his field of vision beyond the four walls of his narrow profession into the vaster realm of mind, and consider the problem of epistemology, ethics, and the evolution of the life of the race in such a way as to effect a satisfactory synthesis between the science of medicine and a true science of mind. Many members of the medical profession in this country would agree with Dr. Kretschmer's suggestion that the medical curriculum should be infiltrated throughout with psychological teaching.

This work is divided into five sections, dealing respectively with the psychic functions and their anatomical and psychological basis, the psychic apparatus and its

evolution, instinct and temperament, personality and reaction types, and practical psychotherapy. Dr. Kretschmer insists that psychotherapy is a matter not only for specialists but equally for the medical practitioner. In innumerable cases, he maintains, the physician is called, not because a complete cure is either necessary or possible, but in order to help the patient and his family to surmount the negative affect arising out of the illness—hypochondria, worry, uncertainty, despondency. Many doctors are in possession of considerable psychological insight, but in others this is entirely lacking. It would thus seem to be most desirable that the general practitioner during his student days should have "absorbed into his very blood stream the most important rules governing the psychological handling of his fellow men."

If it were felt that the medical curriculum should include instruction in medical psychology it would seem that such instruction might well be on lines similar to those suggested by Dr. Kretschmer in his admirable book.

BILHARZIA DISEASE

Dr. RAMESES GIRGES, author of a monograph on *Schistosomiasis (Bilharziasis)*,³ is a surgeon at Tanta, the centre of "the biggest endemic area of schistosomiasis in the world." Only one experienced in Egyptian hospital practice can adequately portray the suffering and misery, the devastating tissue destruction, the human abasement, produced by this formidable disease. It has been appropriately called "our universal scourge" (Madden). Repeated reinfection from infancy causes chronic illness involving years of disablement and degradation, and we must now add Egyptian splenomegaly to the list of bilharzia evils.

This carefully prepared and presented monograph records original work of great biological and clinical interest, carried out by the author, who has made the fullest use of his exceptional opportunities; but it is a little unfortunate that he has wrapped up his argument in a volume which contains so much other work which is classical and well authenticated. If Dr. Rameses's theory of unisexual infection by *Schistosoma mansoni* finds general acceptance a most important "forward step" in our conception of the bionomics and bionosis of bilharzia must be registered. The work, written in English and published in London, merits sympathetic and considered judgement. Speaking generally, the English does credit to the author, though European names are sometimes spelled wrong, and such words as cacogeusia, polydipsia, anaemating, and expressions like autochthonous infection might be replaced by simpler phraseology. Rameses's disease, masculine mansoniiasis, and shaafa schistosomial splenohepatomegaly appear to be new names. We notice also the sentence "his studies were carried out in Egypt which had its origin in the courtyard of the Kasr-el-Aini Hospital in December, 1919."

The monograph is well arranged in ten parts. Part I (historical) appears overburdened with quotations, which destroy the even flow of the narrative. The items taken from the writings of Professor A. Looss tend, unnecessarily, to emphasize the bilharzia errors of a parasitologist who will be remembered gratefully by Egyptians for his work on ankylostomiasis: truly "the evil men do lives after them..." Part VII deals with the author's theory, which he announced in the *Lancet* of April 20th, 1929—namely, that the clinical aspect of *Schistosoma mansoni* presents two distinct types—intestinal and visceral (hepatic), the visceral being Egyptian splenomegaly.

³ *Schistosomiasis (Bilharziasis)*. By Dr. Ramezes Girges. With a foreword by Professor Ernest Carroll Faust. London: John Bale, Sons and Danielsson Ltd. 1934. (Pp. 527; 183 figures. 25s. net.)

Reviews

SIR ROBERT MORANT

The publication of the life of Sir Robert Morant is a little belated, and the book itself more than a little disappointing. *Sir Robert Morant: A Great Public Servant*,¹ by BERNARD M. ALLEN, LL.D., is not without its merits. It is interesting almost throughout, and is written in a clear, straightforward fashion. Excellent use has been made of correspondence placed at the author's disposal, and the earlier chapters contain an account of formative experiences which were hitherto very imperfectly known even to many of Sir Robert Morant's acquaintances and associates with him in his later work. Nevertheless, the author, though he clearly realizes that his subject is a great one, scarcely ever rises to the height of his opportunities, seems to lose a sense of proportion, and does not succeed in presenting that vivid, impressive, and inspiring picture of the man that many had been hoping for. It must be admitted that the life of a civil servant can never be very easy to write. His own personal official work is necessarily merged in that of his Government Department as a whole, and can be known in full and in detail only to a small company of fellow administrators and to the succession of Ministers whom he serves. A great civil servant is perforce immersed in his job, and, by the traditions of his profession, takes but a relatively small and reserved part in other public activities. Sir Robert Morant's surpassing qualities as a civil servant, and his greatness as a man, penetrated this screen to an extent much more than is usual, but the limitations are still there for a biographer to surmount. Dr. Allen has not surmounted them: perhaps no one could in any adequate degree. There is one passage beginning on page 202, just too long to quote conveniently, which catches fire and illuminates the portrait of a resplendent character; and the author quotes a little later a letter from Mr. Augustine Birrell which, in the circumstances in which it was written, constitutes a fine tribute to the unique position which Sir Robert Morant had attained in the Civil Service; but we doubt whether anyone who did not know Morant would gather from this book an accurate appreciation of his outstanding personality.

To medical readers certainly, and probably to others, Dr. Allen's perspective will seem perplexing. His biography follows in due order the four periods of his subject's activities—childhood and youth, Siam, education, public health. Morant was officially connected with the Board of Education for nine years, though, of course, for a few years previously he had been associated in several capacities with educational administration. He was chairman of the National Health Insurance Commission for England, and afterwards permanent secretary to the Local Government Board and to the Ministry of Health (when established) for eight and a half years in all. Dr. Allen devotes 173 pages to Morant's educational work, and forty-five to his work for public health. This last section of the book is not inaccurate, and mentions many of the salient points requiring notice, but it fails to bring out the full significance of the final phase and the position this held in Morant's life-work as a whole. The present reviewer happens to have been associated with Morant, not exactly intimately, but in a not unimportant fashion, both in his educational aims and struggles and in those connected with his visions of an efficient and complete public health service; and great as he knows Morant's devotion to the former to have been, he can testify that

the latter were no less dear to his heart and part of his life. Even in the educational chapters of the book the author seems to be occupied unduly with a history of the developments of educational administration somewhat to the obscuring of what should have been his main theme. The exposition is well done and is quite interesting to those who had some part in the movement. It is true, too, that Morant was one of those men who, with a sacrificing zeal for his vision and ideal of the public good, combined a care for detail and a driving force of an altogether exceptional character. But some of the minutiae relating to the Cockerton judgement and other matters of but little present importance could well have been spared to make room for a fuller account of Sir Robert Morant's activities in his strife for an effective medical service.

Yet we would not seem unappreciative of Dr. Allen's service in producing this book. It is almost certainly the best presentation we shall now have of Morant's life and work. If his personality is not set forth so completely and vividly and proportionately as we could wish, it is still there. Those who knew Morant personally will like to have it, and will be grateful for facts of which they had not previously been aware, and for glimpses which they had not hitherto been privileged to obtain. To them a fuller portrait of the man might have been welcome, even if it had revealed some of his minor faults, mostly endearing, but occasionally exasperating. To others, perhaps, no biographer could succeed in conveying a real sense of the greatness of a man with whom in his lifetime they had not even a passing acquaintance.

NEWER OPHTHALMOLOGY

The third edition of *Recent Advances in Ophthalmology*,² by Sir STEWART DUKE-ELDER, is to all intents a new book. It might fairly be described as a volume in succession to the previous editions in its record of continuous research and current work. The opening chapters deal with the intricate and fascinating problems of the vascular circulation, the intraocular fluid, the vitreous body, and intraocular pressure. The chapter on the vitreous shows how far apart are modern views of the structure of this glistening jelly and the part it plays in the economy of the eye from the old idea that it was no more than a convenient packing material. Under the heading of tumours there is a good account of the radiation treatment of intraocular neoplasms. In the chapter on the cornea there is a critical summary of the recent development of keratoplasty, interest in which has been so much stimulated by the work of Tudor Thomas. There is also a discussion on the value of contact glasses in cases of corneal astigmatism so extreme that correcting by spectacles is of little value, and their occasional utility in the treatment of degenerative keratitis, severe corneal ulcers, and in plastic operations. The author gives a first-class review of the several methods of operating for the reduction of detachment of the retina.

"At the moment most of these procedures are too recent to allow any final verdict upon them; they are still in the experimental stage. . . . As the position stands, it is probable that the ideal operation has not yet been devised. The impetus to new work which the initial success of Gonin's procedure provided has not yet been expended, and further developments will without doubt arise. So far as the ultimate results of these operations are concerned, nothing can yet be said. The position may be summed up by saying that the prognosis of a detachment of the retina is always grave.

¹ *Sir Robert Morant. A Great Public Servant.* By Bernard M. Allen, M.A., LL.D. London: Macmillan and Co. Ltd. 1934. (Pp. 311 12s. 6d. net.)

² *Recent Advances in Ophthalmology.* By Sir Stewart Duke-Elder, D.Sc., M.D., F.R.C.S. Third edition. London: J. and A. Churchill, Ltd. 1934. (Pp. 434; 150 figures, 3 plates (2 coloured). 15s.)

but in the case of recent detachments with small and few accessible retinal holes in a relatively healthy eye it is brighter to-day than it has ever been."

By the ability and willingness of the author to gather together an immense amount of material, sift it out, and present the substance of it all in a comprehensive form, he has rendered yeoman service to his colleagues.

BACTERIOLOGY

Textbooks of bacteriology which prove useful to successive generations of students have a tendency to grow bigger and bigger with each new edition. This has been noticed in the work originally written by Hiss and Zinsser, and now brought up to date again by Dr. HANS ZINSSER with the assistance of Dr. STANHOPE BAYNE-JONES.² The book is well known in this country, more perhaps as a reference work for laboratory workers than for students preparing for examinations. Since the last edition was published two years ago bacteriological research has been particularly fruitful in two directions. In the first place, there has been a rapid increase in our knowledge of ultramicroscopic viruses. The different way in which viruses may be studied and the immunological reactions which they induce are described more fully in this than in previous editions. The second direction in which bacteriological ideas have developed has been in the study of bacterial variability. This has unexpectedly brought to light curious examples of dissociation of pathogenic and non-pathogenic strains. This question also is discussed fully in the new edition of Zinsser's textbook.

In order to make room for the new material the chapters on the bacteriology of milk, water, and soil have been eliminated. This sacrifice seems at first sight to deprive the book of some of its usefulness, but we notice that a good many paragraphs on milk, water, and the soil have crept unobtrusively into the chapters in the section on the general biology of bacteria. As in previous editions, the illustrations are excellent, the references are generous, and the index accurate.

MEDICAL PSYCHOLOGY

A translation into English of Dr. KRETSCHMER's *Text-Book of Medical Psychology*³ will be welcomed by psychiatrists in this country. In his introduction the author observes that the more subtle-minded physician is aware of a double lacuna in his professional training; his primary need is for a psychology derived from, and applicable to, the science and practice of medicine. But, over and above this, his desire to possess a psychology often arises from a vaguely apprehended urge to extend his field of vision beyond the four walls of his narrow profession into the vaster realm of mind, and consider the problem of epistemology, ethics, and the evolution of the life of the race in such a way as to effect a satisfactory synthesis between the science of medicine and a true science of mind. Many members of the medical profession in this country would agree with Dr. Kretschmer's suggestion that the medical curriculum should be infiltrated throughout with psychological teaching.

This work is divided into five sections, dealing respectively with the psychic functions and their anatomical and psychological basis, the psychic apparatus and its

evolution, instinct and temperament, personality and reaction types, and practical psychotherapy. Dr. Kretschmer insists that psychotherapy is a matter not only for specialists but equally for the medical practitioner. In innumerable cases, he maintains, the physician is called, not because a complete cure is either necessary or possible, but in order to help the patient and his family to surmount the negative affect arising out of the illness—hypochondria, worry, uncertainty, despondency. Many doctors are in possession of considerable psychological insight, but in others this is entirely lacking. It would thus seem to be most desirable that the general practitioner during his student days should have "absorbed into his very blood stream the most important rules governing the psychological handling of his fellow men."

If it were felt that the medical curriculum should include instruction in medical psychology it would seem that such instruction might well be on lines similar to those suggested by Dr. Kretschmer in his admirable book.

BILHARZIA DISEASE

Dr. RAMESES GIRGES, author of a monograph on *Schistosomiasis (Bilharziasis)*,⁴ is a surgeon at Tanta, the centre of "the biggest endemic area of schistosomiasis in the world." Only one experienced in Egyptian hospital practice can adequately portray the suffering and misery, the devastating tissue destruction, the human abasement, produced by this formidable disease. It has been appropriately called "our universal scourge" (Madden). Repeated reinfection from infancy causes chronic illness involving years of disablement and degradation, and we must now add Egyptian splenomegaly to the list of bilharzia evils.

This carefully prepared and presented monograph records original work of great biological and clinical interest, carried out by the author, who has made the fullest use of his exceptional opportunities: but it is a little unfortunate that he has wrapped up his argument in a volume which contains so much other work which is classical and well authenticated. If Dr. Rameses's theory of unisexual infection by *Schistosoma mansoni* finds general acceptance a most important "forward step" in our conception of the bionomics and bionosis of bilharzia must be registered. The work, written in English and published in London, merits sympathetic and considered judgement. Speaking generally, the English does credit to the author, though European names are sometimes spelled wrong, and such words as cacogeusia, polydipsia, anaemating, and expressions like autochthonous infection might be replaced by simpler phraseology. Rameses's disease, masculine mansoniiasis, and shaafa schistosomial splenohepatomegaly appear to be new names. We notice also the sentence "his studies were carried out in Egypt which had its origin in the courtyard of the Kasr-el-Aini Hospital in December, 1919."

The monograph is well arranged in ten parts. Part I (historical) appears overburdened with quotations, which destroy the even flow of the narrative. The items taken from the writings of Professor A. Looss tend, unnecessarily, to emphasize the bilharzia errors of a parasitologist who will be remembered gratefully by Egyptians for his work on ankylostomiasis: truly "the evil men do lives after them . . ." Part VII deals with the author's theory, which he announced in the *Lancet* of April 20th, 1929—namely, that the clinical aspect of *Schistosoma mansoni* presents two distinct types—intestinal and visceral (hepatic), the visceral being Egyptian splenomegaly.

⁴ *Schistosomiasis (Bilharziasis)*. By Dr. Rameses Girges. With a foreword by Professor Ernest Carroll Faust. London: John Bale, Sons and Danielsson Ltd. 1934. (Pp. 327; 183 figures, 25s. net.)

² *A Textbook of Bacteriology. With a Section on Pathogenic Protozoa*. By Hans Zinsser, M.D., and Stanhope Bayne-Jones, M.D. Seventh edition, rewritten, revised, and reset. London and New York: D. Appleton Century Company Inc. 1934. (Pp. 1,226; 174 figures 30s. net.)

³ *A Text-Book of Medical Psychology*. By Dr. Ernst Kretschmer. Translated with an introduction by E. B. Strauss, M.A., M.D., M.R.C.P. London: H. Milford, Oxford University Press. 1934. (Pp. 274. 15s. net.)

Authorities incline, no doubt, to the opinion that Egyptian splenomegaly is a schistosomatic infection: Dr. Rameses advances a reasoned statement in support of this view. Having established its aetiology the author formulates his conception of the origin of Egyptian splenomegaly, the "syndrome which for a long time was obscure": male cercariae (issuing from a single snail or snails producing the same sex), reaching the liver, grow into immature males; finding no, or insufficient, females, they remain in the liver, their presence provokes an immunity preventing the arrival of other parasites, and the case is still a masculine infestation. Intestinal symptoms remain negligible. The toxins excreted by the males produce the lesions in liver and spleen. The author writes with great confidence, and finds biological, pathological, and clinical evidence in support of his thesis.

Parts IX and X—devoted to treatment, specific and prophylactic—are excellent. It being impossible to exterminate the carrier snails, an increase in the number of mobile hospitals offers the most hopeful measure. The hospital doctors, in the author's opinion, should be prohibited private practice, and morning and afternoon injections should be instituted, in order to treat the greatest possible number. The staff should be permanent and experienced, and be paid adequate salaries. Medical and surgical measures are discussed, and the great efficacy of antimony tartrate confirmed. "Tartar emetic has no disadvantages if given with proper care." The numerous illustrations and line drawings are good, particularly the plates by the photo-offset process. The half-tones, printed on text paper, are perhaps somewhat disappointing. Figures 162, 163, and 164 show the remarkable effect of tartar emetic, testifying to the schistosomatic aetiology of Egyptian splenomegaly.

Notes on Books

The call for a second edition of BOYD'S *Text-Book of Pathology** within the comparatively short interval of two years has given the author the opportunity to arrange the subject-matter of the sections on general pathology in a more logical order. After discussing degenerative conditions, the subject of circulatory disturbances, especially those of histamine shock due to tissue injury, leads up to the subjects of inflammation and repair, whilst immunity, allergy, bacterial infections, and animal parasites follow in logical sequence, and disorders of growth are placed in relation with tumours. Several of the sections dealing with these subjects have been rewritten. A new chapter has been added on dental pathology, and among other new material may be mentioned sections on trauma, von Gierke's glycogen-storage disease, lead poisoning in children, the localization of infection, rhinosporidiosis, Oroya fever, the causation of angular pain, duodenitis, stasis of the gall-bladder, renal infantilism, and Cushing's work on basophilic invasion in hypertension. More than a hundred new illustrations have been added. These changes will enhance the value of the book to students of medicine, for whom the work is primarily intended.

Ronald Ross: *Dragon Slayer*† is a sympathetic account of the discovery of the part played by the mosquito in malarial infection written by Mr. J. O. Dobson, who first met Sir Ronald Ross in 1917 as a consultant in malaria at Taranto in Italy during the war. In addition to his work, Ross's life is pleasantly sketched in the last chapter, entitled "The Hero as Scientist." The words "dragon slayer," which are perhaps somewhat dramatic, are taken from the *Times* of September 17th, 1934. It is appro-

* *A Text-Book of Pathology*. By William Boyd, M.D., F.R.C.P. Second edition, thoroughly revised. London: H. Kimpton. 1934. (Pp. 1,047; 416 figures, 8 coloured plates. 45s. net.)

† *Ronald Ross: Dragon Slayer. A Short Account of a Great Discovery and of the Man who made it*. By J. O. Dobson. London: Student Christian Movement Press. 1934. (Pp. xiii + 112; frontispiece and 2 figures. 3s. 6d. net.)

prate that this little book should appear in the same year as the union of the Ross Institute with the London School of Hygiene and Tropical Medicine, a description of which is given by Sir Malcolm Watson in the Introduction.

A new and revised edition has appeared of Dr. WARREN T. VAUGHAN'S book on *Allergy and Applied Immunology*.* The subtitle of this work, which was reviewed in these columns on its first appearance three years ago, is: "A handbook for physician and patient, on asthma, hay fever, urticaria, eczema, migraine, and kindred manifestations of allergy."

The two chapters in *To Remind: A Biological Essay*† are the only records which illness allowed the late Sir WILLIAM HARDY to finish of the informal lectures he delivered at Vanderbilt University in February and March, 1931, as the second holder of the lectureship endowed by Mr. Bernard Flexner to commemorate the services rendered to the Medical School in its reorganization and development by Mr. Abraham Flexner. Hardy was a genius with a wide and exceptional knowledge of biology and physical chemistry, and in a brief but masterly survey he starts with Dujardin's discovery in 1835 of sarcode, afterwards called protoplasm by Moll, and carries the subject up to "the modern period in which the physical and organic chemist has taken possession of biology." Of the great problem of the origin of life he says "the most striking feature is its improbability"; and later "to follow the chemistry of life is like treading a maze where the paths twist and turn . . . but the pattern is, so far as human experience goes, fixed for all time." Pasteur's work on molecular asymmetry and its relation to the origin of life were discussed at some length, and he inclined to the belief that the hypothesis of special creations is almost as valid as that of continuous evolution.

Drs. D. SANYAL and R. GHOSE have just published a second edition of their volume *Vegetable Drugs of India*.‡ The book gives a full account of the reputed medicinal properties of some hundreds of indigenous Indian plants. In each case the Latin name is given, followed by a list of the commoner vernacular names, together with a description of the plant and an account of its reputed actions and uses, while in many cases a special paragraph is added mentioning the Ayurvedic uses. The volume therefore constitutes an excellent work of reference for those who desire to obtain information about the reputed therapeutic properties of Indian plants.

Preparations and Appliances

CIRCUMCISION CLIP

Dr. BENJAMIN BEST (Liverpool) volunteers a description of the small spring clip illustrated here. Advocating its adoption in practice, he writes: "I use it instead of the usual circumcision

shield. It is small and light enough to retain itself in position, and has no moving parts, yet it is easily adjusted to allow the correct oblique cut to be made. It was made at my suggestion by the Holtorn Surgical Instrument Company, Ltd., London, at an extremely moderate cost.

THE MARIE CURIE HOSPITAL

PRIME MINISTER'S TRIBUTE

The drawing-room at No. 10, Downing Street was crowded on December 6th for a meeting in support of the Marie Curie Hospital at Hampstead. The Prime Minister, who presided, paid a tribute to the genius of the late Mme Curie, a lady, he said, of great personal charm, vigorous intellect, and one who seemed able to find her way by instinct through the intricacies of the science of chemistry. It was good to have her name associated with a hospital, not a merely sentimental memorial but a severely useful institution, staffed by women of great medical and scientific capacity. Its history, though brief, was sufficient to show how sound and purposive was its work. The Medical Research Council had the fullest confidence in it, and, having been given by the War Office a certain amount of radium which was used for gun-sights during the war, the Council had handed over a substantial proportion, though actually amounting only to a small quantity, to the workers at the Marie Curie Hospital.

LORD HORDER'S SPEECH

Lord Horder said that the disease of cancer, which the Marie Curie Hospital set itself to combat, was by far the greatest of the remaining problems of medicine, and was still in many of its worst aspects unsolved. This hospital dealt only with cancer in women, and, in the way of treatment, only by irradiation. He had been since its inception a member of the British Empire Cancer Campaign, and was now chairman of its scientific advisory committee, whose chief function was to select institutions and individuals for the disposal of such funds as the public bestowed. The confidence which this important body felt in the Marie Curie Hospital was shown by the fact that ever since the hospital was founded in 1929, and for five years before that, when the preparatory work was being done by a cancer research committee of the London Association of the Medical Women's Federation, the Campaign had made grants, totalling now to £5,340, together with the loan of radium of a value approximately of £3,000. The days had gone by, Lord Horder continued, when radium or other treatment could be used with reckless empiricism in regard to technique—had gone by, at least, except in the ranks of quacks, and the quack, he supposed, must remain so long as some of the British public thought it a finer thing to work on disease without expert knowledge than with it, and that because a man was not qualified therefore he must be exceptionally clever. The technique of radium, as also of x rays, had become in itself an applied science. He had always thought that there was a great sphere for women in medicine—and that, of course, was now beyond discussion—but he could not help feeling that there were certain spheres in medicine, particularly in therapeutics, in which women showed an exceptional bent, and were able to produce specially good results. Whether it was that women were more painstaking, or were more accustomed to attention to detail as part of their daily routine, the fact remained that in this particular branch of treatment they did excel, and there was definite evidence that they got their results, not by the application of different principles from others, but by the more careful application of the same principles. In a summary by the Medical Research Council of the results of radium treatment of cancer of the uterus, results from seven different institutions were tabulated, and although the names were not stated he knew which of those institutions was the Marie Curie because the figures coincided with those given in the report of the British Empire Cancer Campaign under the name of that hospital. In the other six institutions the average percentage of cures in the first and second stages of the disease was 50 per cent., and at Marie Curie

83 per cent., while for the third and fourth stages the other institutions gave an average percentage of cure of 27 per cent., and Marie Curie 40 per cent. The cases were of the same type, the disease was at corresponding stages, the same principles of treatment were applied, and the answer to the question as to why the results were so different was to be found, he believed, in the fact that this was one of those spheres of treatment in which scrupulous care and observation during and after the application made considerable difference to the eventual result.

METHODS AT THE MARIE CURIE HOSPITAL

Miss Louisa Martindale, honorary surgeon at the hospital, said that over 1,000 cases of cancer of the uterus had now been treated, a special study being made of cancer of the cervix with a modification of the treatment first elaborated by Heyman of the Radiumhemmet, Stockholm. The success in treatment was apparently due to team work and perhaps superior asepsis. The application of the radium was made by the surgeon herself, the technique was controlled by the pathologist, and the screen and measuring of the dosage by the physicist, the director examining every patient and being present at a great number of the treatments. The follow-up was regularly done, and the nursing was also carefully supervised. In January last a new x -ray department was opened, with an apparatus capable of generating 300,000 volts. It employed a modification of Professor Henri Coutard's method—a long, fractional treatment extending over two or three months for each patient. To treat all patients adequately at least four more cubicles were needed, with consequent extension of plant, or alternatively a one- or two-gram bomb of radium. Out of 997 patients with uterine cancer, treated since 1925 88 per cent. of the early operable cases and 79 per cent. of the borderline cases were living and well. It was now becoming possible to compare the five-year survival rate with that of other leading clinics, and the results were most encouraging. A higher percentage living for five years could be reported than in any other international clinic except Paris, whose figure was equal to that of the Marie Curie in London.

ROYAL SURGICAL AID SOCIETY

The seventy-second annual meeting of the Royal Surgical Aid Society was held at the Mansion House on December 10th. The Lord Mayor (Sir Stephen Killik), who presided, referred to the resignation of the society's senior surgeon, Mr. E. Muirhead Little, who has served the society for thirty-nine years. He was very glad to state that Mr. Little would retain his connexion with the work as honorary consulting surgeon and as a member of the committee. The income for the past year showed a slight fall, mainly due to a decrease in special donations, although the patients' own payments showed an increase of almost £1,300. Nearly 30,000 cases had been relieved during the year, and 36,000 appliances supplied. These appliances included over 7,000 trusses, a similar number of stockings and knee-caps, more than 3,000 abdominal belts, and about the same number of pairs of spectacles. The Lord Mayor said that the society had won public confidence for itself, and the gratitude of patients was abundant. The work already accomplished was its best appeal for continued support. Mr. Sheriff Twyford and Dame Beatrix Lyall spoke in support of the work. Mr. Girling Ball moved a vote of thanks to the surgeons—Mr. Muirhead Little, Mr. E. Laming Evans, and Mr. B. Whitchurch Howell—and paid a high tribute to Mr. Little's services, which had extended over more than half the period of the society's existence. To fill the vacancy on the surgical staff caused by Mr. Little's resignation, Mr. Cecil Flemming has been appointed. Mr. Laming Evans acknowledged the vote of thanks on behalf of the surgeons. Donations to the amount of about £200 were announced at the meeting.

British Medical Journal

SATURDAY, DECEMBER 15th, 1934

THE ENDOWMENT OF CLINICAL SCIENCE

In his Presidential Address delivered before the Royal Society at their anniversary meeting, Sir F. Gowland Hopkins dealt at some length with the subject of clinical science and its endowment. He was glad to recognize that practice in the wards and activity in the laboratory, which but a generation ago made few contacts, have now come into close relations with a degree of mutual respect that was perhaps lacking in the past. But he suspects that some clinicians fear that the introduction of multitudinous laboratory methods into the domain of diagnosis is tending to destroy the true clinical art. We should prefer to say that the risk lies in undue dependence on laboratory tests to the neglect of clinical observation, instead of the co-ordination of both methods of attack. Apparently Sir Gowland Hopkins is somewhat alarmed by the claim that distinct from all the laboratory science that is ancillary to medicine there is clinical science *sui generis*, the progress of which depends on the direct and intimate study of disease as manifested by human beings. It might, however, be considered that the claim was rather that in addition to the help of laboratory methods the clinical evidence should be assessed with the same exactitude, as far as possible, as those methods demand.

Sir Gowland proceeds to consider the three main activities of clinical science as defined by Sir Thomas Lewis. The first is the "discovery of disease," or the clear description of specific diseases or states, so that these may be identified by others. This conception of disease as an entity is submitted to an illuminating criticism from the historical standpoint in the presidential address. He shows clearly how the pendulum has swung through the centuries: at one time the centre of interest is the patient who has the disease; at another, attention is focused on the disease which the patient has. While admitting that the conception of individual maladies, however abstract such a conception might be, is essential in bedside practice, if only for clear description and guidance in treatment, he asks: Does it mean more than this? Broussais strenuously maintained that diseases are not actual entities but convenient metaphysical abstractions; that no two cases displaying certain morbid symptoms in common are ever really the same. It might be added that the popular use of the expression "an attack" of a disease bears witness to the deeply ingrained conception of its being something imposed upon the organism from without, instead of the more scientifically accurate view of its being the reaction of the organism as a whole to some change

in its external or internal environment. It must be admitted that so far Sir Gowland Hopkins has the best of the argument, for at the moment the philosophy of "holism" is in the ascendant. Sir Thomas Lewis's second category comprises experimental work on clinical cases. The method of controlled experiment, wherever it can be applied, is a shorter route to knowledge than the slow path of recorded observations. So far as it can be applied at the bedside, to pursue it there to-day is one of the most praiseworthy of scientific aims, there being, of course, no thought of experiments which can do harm to the patient. Sir Gowland's opinion is that the fields in which really controlled experiments can be carried out on the intact human body are limited, and he feels that the same difficulty applies to Sir Thomas Lewis's third category—the application of physiological discoveries to human material. While appreciative of the great services to knowledge that have been rendered by Dr. J. S. Haldane's applications of this method, he is nevertheless of the opinion that "anyone who has followed the progress of physiology during the last twenty years knows that it has developed in wide fields where experiments on the intact body of man could have had no possible application." Therefore, while bearing testimony to the brilliant work of such men as Dr. Edward Mellanby and Sir Thomas Lewis as illustrating the interaction of clinical and experimental study, he harbours a suspicion that experimental fields for clinical science are relatively few. On the other hand, he is sure that there are many very wide fields in laboratory science the cultivation of which will continue to benefit medicine, and that the pursuit of pure science may at any time contribute to unexpected progress in entirely new directions. Since this has been so in the past, that is a fairly safe deduction for the future.

These criticisms demand serious attention, especially as they come from one whose own purely laboratory work has opened out entirely new fields in nosology and treatment. No man has done more than the President of the Royal Society to place the conception of deficiency diseases on a sound basis. Moreover, there is a disarming moderation in the whole tenor of his remarks which adds weight to them. But he goes on to say that he has sensed the beginnings of a definite movement, not, of course, to ignore the laboratory, but in the distribution of funds provided for medical research to endow the clinic on a scale which might endanger the future of research in fundamental biological science. This, he is convinced, would in the long run sterilize advance. Here we think Sir Gowland shows an unnecessary fear. We have indeed heard exactly the opposite criticism made as to the distribution of funds specifically earmarked for medical research—namely, that too much goes to subjects of which the medical aspect is somewhat remote. It may be hoped that when competent authorities express diametrically opposite views the conclusion may fairly be drawn that a safe middle course is being successfully steered. Clinical research may be difficult, and few

may be adapted for it, but the very instances Professor Hopkins quotes in his interesting and thoughtful address encourage us to feel that when its technique is more fully grasped it will yield more results of equal value. In the meantime, there fortunately seems little fear of pure scientific research being neglected or starved in comparison.

THE NATION'S CHILDREN

The school medical service for England and Wales is responsible for the health of approximately five million children. Of this school population between 70 and 80 per cent. are normal children, and it is a feature of Sir George Newman's report for 1933—a summary of which appears at page 1115—that he urges fuller concentration on the legitimate claims of this section. "Are we," he asks, "doing all that is practicable for the nutrition, physical education, nurture, and health of the normal child?" And he answers himself emphatically: "I fear we are not." This is a clear admission that to some extent the public health authorities of this country are failing to ensure the physical health of the normal child under 14 years of age. All complacency that things are much better than they were twenty-five years ago will not counteract this admission, and it is clear that medical science has not yet entirely succeeded in translating its discoveries and advances into practical measures in the homes and in the schools. There is a "lag," as Sir George Newman himself pointed out in another report, and it is true to say, as he does on this occasion, "there are signs of public anxiety on this subject."

With this introduction the Chief Medical Officer to the Board of Education plunges straightway into the vexed question of nutrition and school feeding, and the intelligent reader of this chapter will find it difficult to get into clear perspective the issues that are raised. The term "malnutrition" is of comparatively recent origin in these reports, and it is clearly stated that as used by school medical officers it "should include only the children whose nutrition was reported as 'bad,' prolonged, or serious undernutrition." On this strict basis the returns for 1933 include 20,579 children found to be malnourished and requiring treatment, and a further 23,760 also returned under the "malnutrition" heading as requiring "observation." At this point it is pertinent to ask how "observation" of children in this badly nourished category is going to help. Moreover, these are the returns of the routine inspections in the specified age groups. To them must be added the results of special inspections—namely, 19,400 children with malnutrition requiring treatment, and 8,407 children in the same category requiring observation. On this basis there are over seventy thousand children in the public elementary schools of England and Wales with bad, prolonged, or serious undernutrition, half of whom may possibly, since only observation was con-

sidered necessary, be included in some less well-defined "subnormal" category. On this Sir George Newman comments that in 1933 there was no general or widespread malnutrition among children attending public elementary schools. Since the proportion for the whole five million is somewhere in the region of 1.4 per cent. such optimism is, perhaps, justified, but it must surely mean that in those areas where there are admittedly "patches of serious undernutrition," areas where there is also "evidence of a slight increase in undernutrition," things cannot be quite as rosy as the general tenor of this chapter might lead one to suppose. Fortunately there was a substantial increase in the number of school meals provided in 1933, amounting to over 6,500,000 in round figures, and the scheme of the Milk Marketing Board, which came into operation on October 1st, may be expected to make some differences in the next report. The method of selecting children for school meals is another vexed question which has been frequently discussed in these reports. It is again asserted that the provision of free meals (including milk) must only be allowed through a system of selection by the school medical officers, and while this should secure that available funds are used for the children most in need of extra nourishment, it still appears to be regrettable that the teacher is not allowed more responsibility in choosing children for such help, since school meals are undoubtedly intended, in the words of the governing Act, "for children who are unable, by reason of lack of food, to take full advantage of the education provided for them."

In another section of the report Sir George Newman's stress on the importance of physical education and hygiene, more especially for the well-being of the healthy child, will be applauded by those whose daily work brings them more especially into contact with the adolescent. The new syllabus of physical education, issued in the autumn of 1933, has attained the sales of a best-selling novel, and there are hopeful signs of a new eagerness in securing the "mental and spiritual" benefits which physical training on a sound physiological basis must bring. "Games are not enough" is a phrase for which we must be grateful. Sir George Newman wisely points to the State efforts of other countries in preserving and maintaining adolescent physique, although there are many products of voluntary aspiration and effort available in this country for those who can make use of them. The open-air school is another adjunct towards preserving health as distinct from treating disease to which the present report directs special attention, but there are only 146 schools available, and the local authorities are clearly urged to a greater extension and practice of the principles upon which these institutions are based. The third point upon which emphasis is laid is effective training in hygiene, to which last year's report gave great attention. The "habits of health" which it is desired to encourage will do much to carry the advantages received in school into adolescence and adult life. It is this aspect of the health and well-being

¹ The Health of the School Child. Annual Report of the Chief Medical Officer of the Board of Education for the year 1933. H.M. Stationery Office. (3s.)

of the nation's children which is of the greatest importance. Open air, physical training, and hygiene can build a nation of healthy adults, always providing that the children are maintained in such a state of nourishment as to be able to benefit by them.

TUBERCULOUS RHEUMATISM

The problem of whether the tubercle bacillus can give rise, on the one hand, to a symptom-complex clinically indistinguishable from acute rheumatic fever and, on the other, to a chronic non-suppurative polyarthritis resembling rheumatoid arthritis has been attracting much attention during recent years. The evidence for and against is very fully marshalled and examined by Drs. Brav and Hensch in the October number of the *Journal of Bone and Joint Surgery*. The idea has received little support in this country; but abroad, and especially in France, many physicians of the highest repute as clinicians now admit that chronic polyarthritis may be tuberculous in origin. The subject was extensively discussed at the third International Congress on Rheumatism, held in Paris in 1932. Reitter and Löwenstein claim to have isolated the bacillus of Koch from the blood stream in a considerable number of cases of rheumatic fever by a special method of culture which they have devised, and their work gave a fresh stimulus to the subject. Many other workers have investigated cases by this method with varying results, but the majority have failed to confirm these findings, while several observations have been recorded in which the bacillus has been cultured from the blood in conditions definitely not tuberculous, and in some of these post-mortem examination revealed no evidence of tuberculosis in the body. It must be admitted, therefore, that the discovery of acid-fast bacilli in the blood stream of rheumatic patients cannot be accepted as proof that the rheumatic symptoms are of tuberculous origin. Many cases have, however, been recorded of chronic polyarthritis in which acid-fast bacilli have been isolated from the synovial fluid, and others in which microscopical examination of synovial tissue obtained by biopsy has shown histological appearances considered to be tuberculous. These appearances did not include actual tubercles or giant cells, but a preponderance of large endothelial cells together with swelling and vacuolation of the intima of the small arteries. Cases in which giant cells and other characteristic lesions are observed must be regarded as true tuberculous arthritis as distinguished from the so-called tuberculous rheumatism. Accounts have been given of cases of chronic polyarthritis in which one joint has developed into typical "white swelling," and have been cited as evidence of the tuberculous origin of the whole disease, but it would appear probable that a secondary infection with tubercle bacilli had been implanted on the original joint disease. True tuberculous rheumatism is believed to be due to an attenuated form of the bacillus, possibly the granular filter-passing form demonstrated by Mellon and Fisher, among others. Calmette and Valties state that synovial effusion appears to be caused by "ultravirus," and many other workers have shown that if guinea-pigs are inoculated with this attenuated form or with material

from the joints affected with tuberculous rheumatism glandular enlargement results, but only after some months; and this effect is overlooked if the animals are killed after a month or six weeks, as is the usual practice. If this glandular material is inoculated into other guinea-pigs, after one or two passages typical lesions are produced with acid-fast bacilli. In the endeavour to diagnose tuberculous rheumatism cutaneous tests are unreliable, since they indicate nothing more than the existence of a focus somewhere in the body, and this applies equally to agglutination and complement-fixation tests. Subcutaneous inoculation, however, of a very dilute tuberculin has in some cases given rise to foetal reactions in the shape of increased joint pains, and this must carry weight. On the whole, the balance of evidence is in favour of the view that a certain proportion of cases of chronic polyarthritis are of tuberculous origin; cautious observers place it at 10 per cent. Further investigations are required, and the subject deserves to receive more attention in this country. There will be general agreement with the view advanced by Coste, Forestier, Saenz, and Costil that the proof of tuberculous origin of a polyarthritis must depend on positive laboratory results in subjects in whom no other active tuberculous focus can be detected, and that the tubercle bacillus should be discovered in the joint fluids or in portions of tissue obtained by biopsy, or positive results obtained by inoculation of suspected material.

MENTAL STATES ASSOCIATED WITH EPILEPSY

As Kinnier Wilson has said, we ought no longer to talk of epilepsy but of the epilepsies, and if the exact pathogenesis in certain patients who exhibit this symptom cannot be elucidated, ignorance should not be cloaked by the elevation of a symptom into a disease entity. There can therefore be little justification in attempting to identify an epileptic mentality, and this is the thesis advanced by Dr. Bridge¹ in a recent article. Pierce Clark and others, however, have sought to establish an epileptic personality possessing certain constitutionally determined characteristics which in their view are responsible not only for the particular form of personality but also for the convulsive attacks themselves. It will be readily admitted that the type described by Clark as domineering, asocial, egocentric, restless, and of a violent temper does exist; but not all such people exhibit epilepsy nor are all those who suffer from epileptic attacks of this type, though it is probably true that the two coincide quite often. Bridge quotes cases to show that these personality traits may equally be the result of the social and family disabilities consequent upon the epilepsy. Also he points out that such characteristics may wax and wane with the frequency and severity of the attacks, and may even disappear altogether if medicinal treatment leads to control of the convulsions. The mental changes, therefore, may not after all be constitutionally determined, but may represent phasic alterations in brain function dependent upon the same pathological changes—whatever they may be—that determine the convulsions. If this is so, it helps to explain the frequently observed fact that in some cases psychological treatment which succeeds in

¹ *Arch. Neurol. and Psychiatry*, October, 1934, p. 723.

improving the mental attitude of the patient improves the convulsive state as well, while in other cases medicinal treatment which improves the convulsive state will alter the personality for the better. The functional derangement of the cortex which results in the epileptic attack—with or without certain significant mental changes—may be due to all sorts of underlying causes. Where these are of far-reaching structural import there is likely to be some degree of intellectual enfeeblement. Or the derangement may be due to comparatively transitory disturbances, and here no intellectual deficiency will be discoverable, although in such cases there may be temporary mental changes simulating mental defect. Observers would be wise, therefore, not to be too dogmatic in the assertion that epilepsy is always or even often accompanied by amentia, and especial care must be taken to scrutinize the evidence of formal intelligence tests, which may be very misleading in such cases. Similarly, the effects of the disturbance responsible for the convulsion will vary considerably. In some instances permanent changes occur which lead to mental deterioration and dementia; but in others convulsions may recur for years without inducing the slightest permanent damage in the cortex, and in these no mental deterioration ensues. Just as one must think of epilepsies and not of epilepsy, so must one think of mental changes not as necessary cause or effect of the convulsion but as a function of the cerebral disturbance responsible for both: this may or may not be associated with gross cerebral maldevelopment, and may or may not result in gross cerebral deterioration.

A FIVE DAYS WEEK

The hours of work and the use of leisure are obviously two factors which may greatly affect both individual and public health. In present-day economic conditions, especially as influenced by widespread unemployment and by the rapid mechanization of the production and distribution of goods, they have both become of vast national importance. The exploitation of leisure, especially by large interests established to make financial profit by the provision of various forms of occupation, excitement, or amusement, has so far outstripped instruction and experience in the proper use of leisure. The problems thereby raised are very serious, and some would say that they should be faced before any further attempts are made to increase that leisure. Experiments in the reduction of hours of labour have, however, been made for a long time, and careful investigations as to the results of some of them, both as to their bearing on economics and as to their influence on health, have been undertaken. The latest of such investigations is that of Sir Richard Redmayne on the experiment which Messrs. Boots of Nottingham have recently made of having only a five days working week in their main productive works in Nottingham and Beeston.¹ The report is a very interesting document, and deserves the attention of medical practitioners and public health medical officers as well as of those concerned with industry and other forms of social service. Sir Richard Redmayne reports in detail about the

various departments, and his general conclusions are that the experiment "has proved an unqualified success both from the business point of view and from that of the employees"; that the cost of production "has not been enhanced and certainly there has been attained a higher efficiency on the part of the employees"; and that "the effects in regard to enhancement of health and contentment, regularity of attendance at work, and diminution of absenteeism have been very marked." It should be added that there has been no lowering of the weekly earnings of any employee, that overtime has been almost completely abolished, and that a holiday period with full pay is allowed each year, the duration of this period being dependent upon length of service, nature of the work, and age. Generalization from these results as to the application of a similar system to other forms of industry is obviously dangerous, but Sir Richard Redmayne indicates that "there are many works at which the experiment might be applied—at large printing works, for instance, and at works where the production and distribution are vested in the same concern and where the wages cost does not constitute a very high proportion of the selling price of the commodity."

PROPHYLAXIS IN WHOOPING-COUGH

We recently¹ called attention to the heavy incidence in England of whooping-cough in infancy and to the two or three thousand deaths that occur each year. It is now generally accepted that, to make a protective vaccine with any promise of success, it is essential to use the haemolytic "S" form of the bacillus, toxic to animals. G. S. Shibley and H. Hoelscher,² in their study of approximately 100 strains of *H. pertussis*, have confirmed many of the earlier observations, and have noted that the desired "S" form travels more slowly in the electric field and that its iso-electric point is at a higher pH. J. M. Frawley³ and his co-workers also employ recently isolated smooth strains for their vaccine. Among 505 children vaccinated, eighty were intimately exposed to infection: forty-nine escaped entirely, while in thirty-one pertussis developed. Frawley records that the attack was mild, and in twenty-five of the thirty-one children the whooping lasted less than a week, whereas of 174 unvaccinated children who became infected 116 whooped for two weeks or longer. The results are described as "encouraging but not entirely satisfactory." Frawley, following the work of Anson and Mirsky on denaturation of proteins, attaches considerable importance to mechanical disruption of the washed bacterial cells and to filtration through collodion membranes. At no stage is heat applied. It is difficult to know what importance to attribute to these points. At one period of bacteriology high hopes were entertained that mechanical disruption of bacteria, or other methods avoiding possible denaturation, would provide antigens of unexampled effectiveness, but the harvest has not been great, and the Madsen and Sauer vaccines, which apparently gave good protection, were not thus made. Krueger⁴ and co-workers record that they immunized rabbits which tolerated lethal doses of culture injected intravenously. If a parallel vaccine

¹ A Review of the Experimental Working of the Five Days Week by Boots Pure Drug Company at Nottingham. By Sir Richard A. S. Redmayne, M.Sc., K.C.B. Nottingham: Boots Pure Drug Co. 1934. (1s.)

⁴ Journ. Amer. Med. Assoc., 1934, ciii, 960.

⁵ Proc. Soc. Exper. Biol., 1933, xxx, 1097.

made from the same strains by the usual methods had failed to immunize, a strong case would have been made out for the necessity of the disruption of bacilli and collodion filtration. It is essential that the vaccine should be truly protective, and desirable that one should be able to test the vaccine before it is used clinically. Lawson¹ states that the toxin of smooth strains produces an intradermic reaction in guinea-pigs which is neutralizable by immune serum. If it is possible regularly to immunize animals actively—and recent work in England tends to support the results of Lawson and Krueger—the immunologist should be in a position to guarantee antigenic efficiency when he hands over a vaccine to the clinician. This desirable stage appears to be in sight, but how shall we in England test this rich hope that vaccination will protect infants? There are probably members of our Association troubled annually with outbreaks of pertussis in infants' homes under their care. Is it possible to pool their opportunities?

BACTERIOPHAGE THERAPY

Among the more novel forms of treatment now being exploited commercially is the use of bacteriophage. Those familiar with the history of the subject are aware that the original startling discovery of a "principle" (whether virus or something inanimate) capable of destroying bacteria so thoroughly that they simply disappeared from cultures has had subsequent results which are more of interest to the theorist than of value to the clinician. When it was asserted that the diminution in numbers of typhoid bacilli in the faeces during recovery from enteric fever coincided with an increase in the quantity of bacteriophage, there seemed good reason for believing that the latter, if not part of the regular mechanism by which the disease is overcome, could at least be employed to partake in it. It is actually in intestinal infections, and particularly in dysentery, that bacteriophage therapy appears to breed most conviction of its utility at the present day. But this is by no means its only field. The first lytic action of this type ever recognized was observed by Twort in a culture of staphylococci, and staphylococcal infections have not escaped attention from this point of view. Those involving the skin have the great practical advantage that direct application is possible and the study of its effects comparatively simple. Jern, Howes, and Meleney² have treated 110 cases of furuncle and carbuncle by this method, and have investigated its effects in some detail. They found that susceptibility to lysis was unrelated to the type of staphylococcus (whether haemolytic or non-haemolytic); only three of their 110 strains proved resistant. Cultures obtained from the lesion twenty-four hours after treatment exhibited lysis; but, later than this, evidence of lytic activity diminished. The conclusion was reached that bacteriophage had not multiplied in the tissues, and far from increasing in potency, as it may *in vitro*, it "grew progressively weaker." Bacteriophage being itself antigenic, it is conceivable that antibodies to it developed by the patient may interfere with its further action; antiphage was demonstrable in the serum of some of these patients, but its existence appeared to be

unrelated to the survival of bacteriophage in the lesion. If some of these conclusions are correct, and if the bacteriophage used was fully active, it is evidently misguided to expect staphylococci to be devoured in the body with the same avidity as in the test tube. These authors are commendably reluctant to pronounce in favour of this form of treatment, and propose to defer judgement until "two absolutely parallel series of cases" have been treated with and without bacteriophage. Would that all other clinical investigators followed this example.

THE HEALTH OF THE R.A.F.

The Air Ministry's report for 1933 on the health of the Royal Air Force¹ shows a slight increase of sickness as compared with the previous year, amounting to 53 per 1,000 of strength for cases admitted to hospitals and sick quarters only, and 76 per 1,000 for all cases of medical non-effectiveness. The greater incidence of influenza is quoted as the chief reason for the figures being larger for 1933. The incidence of deaths for 1933 was 3.7 per 1,000 of strength (3.6 in 1932, 4.1 and 4.4 for 1927-32 and 1921-6 respectively), while invalidings from the Service fell to 6.1 per 1,000 (6.8 in 1932). There was a very slight rise in the incidence of venereal disease above the lowest figure yet recorded—namely, 11.3 per 1,000 in 1932. As well as presenting a very full statistical picture of the state of health of the Service, the report deals with such subjects as the special departments, with the physical efficiency of personnel, the medical examination of recruits, the transfer of casualties by air, dental treatment, etc. In detail it makes interesting reading. During the year under review disease accounted for 82.1 per cent. of the total sickness, and injuries for 17.9 the more or less constant relation between disease and injury as a cause of sickness having thus been maintained. As regards invaliding, the same conditions—tuberculosis and psychoneurosis—proved the chief causes of invaliding from the Service as during previous years. It is also of interest to note the increase, as a cause of final invaliding, in the number of cases of mental disease, for which no reason is obvious. Two other points of note are the decrease in the number of cases of chronic suppurative otitis and the marked fall in final invaliding for heart disease as compared with the two previous years. An analysis of the fifty-one deaths from injury shows that sixteen occurred from motor accidents off duty. Among the other matters with which the report is concerned, one may pick out the following. No conclusion has yet been drawn from the incidence of pulmonary tuberculosis classified by age groups, trade groups, length of service, and type of unit. There were forty-eight deaths due to flying accidents during the year—two less than in 1932. 43 per cent. of the total flying casualties resulted in death. The nosological tables show injuries, gonorrhoea, and influenza as the chief causes of sickness.

At the distribution meeting of King Edward's Hospital Fund for London, held on December 11th, with the Prince of Wales in the chair, it was announced that £320,000 would be awarded in grants to hospitals and convalescent homes for the current year.

TREATMENT IN GENERAL PRACTICE

This article is one of a series on the management of some of the major medical disorders met with in general practice

TREATMENT OF ACUTE BRONCHITIS

BY

R. A. YOUNG, C.B.E., M.D., B.Sc., F.R.C.P.

Bronchitis is often regarded as a minor malady. In reality, even in its milder forms, it often involves serious risks, particularly in the early or late periods of life. The care, management, and medicinal treatment of patients suffering from it should always receive the closest attention. A common fallacy is to expect recovery in a week or less. It often lasts longer than more acute and more immediately serious conditions, such as pneumonia.

Unfortunately, although the pathological basis of bronchitis as an infective catarrhal or suppurative process affecting the bronchi is definite and clear-cut, the clinical manifestations are varied and ill defined. Clinically the term "bronchitis" comprises conditions varying from a simple mild tracheo-bronchitis to grave involvement of the small bronchioles—a condition indistinguishable at the bedside from bronchopneumonia. In discussing the treatment of acute bronchitis it is therefore necessary to make some attempt to separate different clinical forms, at the same time premising that any of the mild varieties may merge into or progress to the gravest forms. It is also necessary to point out that bronchitis is often a secondary manifestation, either as an essential feature or as a complication of many other primary conditions, such as the infectious fevers, tuberculosis, glanders, and septicaemia, or after injury, anaesthetics, or gassing. Treatment in such cases may have to be subordinated to that of the primary condition or modified in various ways.

Although the general principles of treatment in the various forms are the same—namely, to combat the cause, whether mechanical or bacterial, to treat the inflamed mucous membrane, and to promote the evacuation of the products of the inflammatory process—yet the actual treatment varies with the degree and the extent of the inflammation. With the reservation that the classification adopted is chiefly clinical and in some senses artificial, we may for convenience recognize the following varieties:

1. Inflammation of the larger bronchi, or more accurately tracheo-bronchitis.
2. Bronchitis of the medium-sized tubes.
3. Inflammation of the bronchioles.
4. Suppurative bronchitis or "suffocative catarrh."
5. Fibrinous bronchitis.

A condition of fetid bronchitis has been described, but this is in most cases due to unsuspected bronchiectasis, or to bronchitis associated with empyema, abscess, or gangrene.

Tracheo-bronchitis

This condition is perhaps the commonest malady met with in family practice in these islands. Climatic conditions from the late autumn to early spring tend to promote the incidence of catarrhal infections, and the widespread neglect of elementary precautions favours their spread.

The best treatment is clearly that of prevention or protection. The common cold or infectious coryza which so often progresses to the conditions under consideration is the basis of the favourite gibe at the expense of our

profession—that we are supposed to be unable to prevent or to cure it. The facts are that patients too often regard it as trivial or negligible, and do not consult the practitioner till it has spread to the bronchi or lungs, when they quite rightly speak of a "neglected cold." A day—or perhaps two in severe cases—in bed at the onset of a coryza will usually tend to limit the process to the nasopharynx, and incidentally avoid spread to others by preventing the droplet infection, which the stage of sneezing is so peculiarly adapted to promote.

The value of prophylactic vaccines is still open to discussion and even to doubt, in view of the fact that the cause of upper air passage infections is probably a filter-passer. In my opinion, though vaccines may not prevent coryza and catarrhal bronchitis, they often serve to protect from the attacks or to mitigate them, and to avoid complications. The use of antiseptic applications to the nasal cavities is also one about which there is no consensus of opinion. I am not in favour of watery saline nasal douches, but I believe that solutions or suspensions of antiseptics and astringents in oil or liquid paraffin may be useful, such as adrenaline or chloretone inhalant, adrephine, metaphedrin, or ephregel.

TREATMENT

The patient should remain strictly in bed, though the decubitus should not be too flat, especially in older patients. The room should be well ventilated, free from draughts, and kept at a temperature not below 60° F. nor above 65° if possible. In the "dry" stage, when ineffective painful cough with retrosternal soreness is a prominent feature, the air of the room may be kept slightly moist by means of a steam kettle, placed well away from the patient. To each pint of water in the kettle five drops of oil of eucalyptus or terebene may be added, or some other volatile oil. Steam tents should not be used, as the object is to moisten the air slightly, not to make the neighbourhood of the patient damp and misty. A moist inhalation is, however, sometimes soothing, and the time-honoured friars' balsam, one drachm to the pint of water at a temperature of 140° F., is often soothing in this stage. The preliminary Turkish bath or hot bath is to be avoided unless the patient can go straight to a warm bed without exposure. A hot footbath, with or without mustard, may be comforting and useful, provided it can be given in the patient's bedroom.

Even though there may be little fever, the diet in the dry stage should be largely fluid, and solid food, for which as a rule the patient has little inclination, should be avoided. Milk, hot milk and water, milk and soda-water, jellies, beef tea, soups, custards, tea, and cocoa, to the total of two or three pints, with hot and warm demulcent drinks—such as hot lemon water, linseed tea, fruit *tsisanes* made by adding fruit syrups up to half an ounce to the pint, or glucose lemonade—may soothe the inflamed bucco-pharynx and shorten the dry stage in the trachea and bronchi. Marshmallow or glycerin and black currant lozenges are soothing. A hot or cold compress to the neck may be comforting. A mustard leaf over the sternum or rubbing in a liniment, such as liniment terebinth. aceticum, may also be helpful. A preliminary purge is usually advised, such as calomel at night followed by a saline in the morning—either a drachm of Epsom salts or sulphate of soda and water, or some effervescent saline.

The most useful medicines at the outset are saline diaphoretics and diuretics: for example, give six-hourly:

R Pot. cit.	gr. xx
Liq. ammon. acetat.	5 j
Vin. ipecac. (tinct. ipecac.)	℥ x
Syr. tolu.	5 j
Aq. chlorof.	ad 3 j

For the first night at least it is desirable to give some soporific; 10 grains of Dover's powder is that most commonly employed, but codeine phosphate, grain 1/2 to 1, medial grains 7, phanodorm 3 grain tablets, or heroin grain 1/12 may be used as alternatives. If prescribed on subsequent nights after the first they should be stopped at the earliest opportunity.

In cases with severe pain or with much dry ineffective cough, 3 minims of vinum antimoniale may be added to the diaphoretic mixture or substituted for the vinum ipecacuanhae. Apomorphine is also useful in this type of case, and may be given in the form of syrup, apomorphinae co. (B.P.C.) in 1-drachm doses every six hours for four doses. Each drachm contains 1/36 grain of apomorphine. One-drop doses of tincture of aconite in water were formerly recommended in such cases, especially if there was much fever. When the dry stage gives place to copious expectoration of mucoid material, and later of muco-purulent sputum, simple expectorant mixtures may be given every six hours, such as:

R Vin. ipecac.	℥ x
Tinct. camph. co. (tinc. opii camph.)	℥ x-℥ xv
Syr. tolu. (or syr. pruni virgin.)	5 j
Aq. chlorof.	ad 3 j

In elderly patients at this stage ammonium salts may be helpful in the form of either the chloride or the carbonate.

R Ammon. carb.	gr. iv
Vin. ipecac.	℥ x
Syr. tolu.	5 j
Aq. chlorof.	ad 3 j

Stimulants are not necessary as a rule unless patients are accustomed to them, when usually small amounts may be allowed. In the later stages patients are often left with a troublesome and persistent cough, particularly at night and in the early morning. This is frequently due to some residual tracheitis, and may be relieved by elixir diamorphinae et terpinii c. apomorphina (B.P.C.) in 1-drachm doses. Each drachm contains 1/40 grain of diamorphine, 5/18 grain of terpine, and 1/32 grain of apomorphine. Collosol bromoform co. in 1-drachm doses may also be helpful, or some similar proprietary preparation. If cough persists in spite of treatment the nasal sinuses should be investigated and the sputum be examined for tubercle bacilli. If these prove negative a simple acid tonic mixture may be tried, such as

R Liq. strych.	℥ iij
Acid. phosph. dil.	℥ x
Syr. aurant.	5 j
Aq. chlorof.	ad 3 j
t.d.s., p.c.	

The most effective convalescent treatment is often afforded by a few days at a coast resort.

Bronchitis of the Medium-sized Tubes

The clinical manifestations begin as a rule like those of tracheo-bronchitis, but the fever and systemic disturbance are greater and the local symptoms and signs more severe. The same general management, diet, and treatment should be employed at first. Depressant expectorants, like antimony and apomorphine should be avoided, except

perhaps in the earlier stage of dryness of the mucous membrane.

Stimulant expectorant mixtures may be prescribed as soon as the cough becomes loose, such as:

R Ammon. carb.	gr. iij ad v
Pot. bicarb.	gr. x
Tinct. scillae	℥ x
Syr. tolu.	5 j
Aq. chlorof.	ad 3 j

In patients with bronchial spasm or with asthmatic tendencies, potassium iodide in doses of 3 to 5 grains may be added to this mixture, and 5 to 10 minims of tincture of stramonium or of tincture of belladonna.

A careful watch should be kept on the pulse and blood pressure. Digitalis may be added in suitable doses or Nativelle's digitaline given. Coramine may be taken by the mouth or hypodermically in doses of 1 c.cm. from once to four times a day. If cyanosis or dyspnoea develops oxygen should be administered at once. The most suitable method and the most economical is the continuous administration by a No. 9 nasal catheter or by a special rubber nasal plug. The oxygen cylinder should be fitted with a fine adjustment, and the oxygen should be bubbled through warm water in a Woulfe's bottle at the rate of three to five bubbles a second.

After the first night or two special care must be taken in regard to the use of hypnotics, especially those like opium, morphine, heroin, and codeine, since they tend to lull the cough reflex. It is important, especially in elderly patients, to avoid accumulation of bronchial exudate, particularly at the bases of the lungs. It is sometimes useful to give first thing in the morning the well-known Brompton Hospital "hot-water mixture":

R Sod. chlorid.	gr. iij
Sod. bicarb.	gr. x
Sp. chlorof.	℥ x
Aq. anisi	ad 3 j

This should be taken in an equal quantity of hot water.

Alteration of position is to be advised in these cases. The patient should have a bed rest or extra pillows, and not be allowed to slip down in the bed. Counter-irritants and hot applications to the skin are frequently of use in this condition. The acetic turpentine liniment is pleasant, and not unduly rubefacient. Antiphlogistine may be applied, or poultices or turpentine stupes. These should be applied to the back and side, and but rarely to the front, owing to the fact that the weight impedes inspiration. The Gamgee jacket, formerly so popular, is, I think, of little use, and often causes discomfort by promoting undue sweating. Stimulants are more often necessary in this type of case.

Inflammation of the bronchioles or capillary bronchitis is a condition which is indistinguishable clinically from bronchopneumonia, and should be treated as such.

Acute Suppurative Bronchitis or Suffocative Catarrh

This condition, though rare, is grave, and is usually due to the pneumococcus. In general its manifestations are similar to those of bronchopneumonia, but cough with copious expectoration, marked dyspnoea, and extreme cyanosis develop very rapidly, while dangerous prostration is a very early feature.

The treatment is similar to that for severe bronchitis of the medium-sized tubes, but oxygen inhalation should be started early; stimulant expectorants should be given freely. Digitalis may be necessary from the start, and coramine may be administered up to 1 c.cm. every four to six hours, either by the mouth or hypodermically, or

even intravenously. Pituitrin, adrenaline, or ephedrine may be prescribed if the blood pressure falls. If marked cyanosis develops early and the heart is beating forcibly, venesection may be tried to the extent of ten to fifteen ounces. If the bronchitis is due to the pneumococcus, and this can be typed, Felton's serum may be injected if the organism proves to be either Type I or Type II. Skilled nursing with careful observation of changes with regard to pulse, colour, position, and cough, are of great importance in all cases of severe bronchitis.

Fibrinous or Plastic Bronchitis

This condition, though rare, may easily be overlooked. In all cases with cough and sputum, especially where cough is violent and paroxysmal, and where there are signs of local collapse of the lung, the sputum should be poured into water in a large transparent glass vessel. In this condition characteristic tree-like casts may be recognized. The treatment is similar to that for severe bronchitis. A mixture containing iodide of potassium and antispasmodics like belladonna and stramonium should be used. Lime-water and olive oil by intratracheal injection have been recommended, but are of doubtful value.

ANNUAL CONGRESS OF RADIOLOGY

The eighth annual congress and exhibition of apparatus under the auspices of the British Institute of Radiology was held at the Central Hall, Westminster, on December 5th and following days. Two medical sessions were held, also a session for papers on physical subjects, and two memorial lectures were given, one by Sir William Bragg on "X Rays in the Study of the Coarse Structure of Materials," and the other by Dr. H. H. Berg of Dortmund on "The Digestive Mucosa." The crowded exhibition included many installations of self-protective shock-proof x-ray apparatus, motor-driven movable tables for diagnostic work, new sets for deep therapy, and ultra-short-wave installations.

PHYSICIST AND RADIOLOGIST

Sir HUMPHRY ROLLESTON, in opening the congress, said that the art of medicine was inspired by applied science, but carried on with due consideration for the special circumstances of the individual patient. This might seem a truism, but it was often forgotten. Undoubtedly it was scientific to remove, destroy, or neutralize the cause of disease, but if this were carried out regardless of the patient the result might be disastrous. Radiological treatment of cancer was in some degree exposed to this danger; the patient and his individual circumstances were liable to recede into the background and treatment to be directed solely to the malignant growth. The relation of the pure physicist to the medical radiologist somewhat resembled that of the bacteriologist in the laboratory to the physician in the sick-room. The medical radiologist should not demand too much of the physicist. Each of the two parties had his own field. The proper dose of radiation and the mode of its application were in the province of the medical radiologist, and the role of the physicist was to supply data bearing on those problems which the medical radiologist must finally settle.

ARTIFICIALLY INDUCED RADIOACTIVITY

One of the most interesting demonstrations was by Professor F. L. HOPWOOD of St. Bartholomew's Hospital, on induced radioactivity. He began by reading a sentence of remarkable prescience from H. G. Wells's *The World Set Free*, published in 1914, in which Wells prophesied that the problem of inducing radioactivity in the heavier

elements, and so tackling the internal energy of atoms, would be solved by a wonderful combination of intuition and luck in 1933. And in fact it was in 1933 that Mme Curie's daughter, Mme Curie-Joliot, and her husband demonstrated the phenomena. Professor Hopwood reminded the congress of what had already been shown by Rutherford and others to occur on the bombardment of the nucleus of a stable atom, causing it to become unstable and to emit a disintegrating particle. This idea had been carried further in the Curie laboratory. If beryllium, for example, were irradiated by gamma rays or x rays of suitable voltage, this metal gave off neutrons, which, being allowed to fall on bromine, rendered it temporarily radioactive. Recently some bromine which had been treated in this way was sent by aeroplane to Professor Hopwood's laboratory from Berlin, and here its radioactivity was found to persist and its period was measured—the first time, he thought, that radioactivity had been induced in a substance in one country and demonstrated in another. The elements to which the radioactivity was imparted had various periods, the half-life activity being in some cases thirty minutes, in others six hours. Many of the elements occurring in the human body could be transmuted temporarily into radioactive substances; the only notable exceptions were hydrogen and calcium. Substances commonly used as drugs, such as manganese, could be similarly treated. By means of a very delicate "counter," connected to a telephone which emitted clicks as the stream of electrons arrived, Professor Hopwood demonstrated induced radioactivity in aluminium and silver and other materials, including, thanks to its phosphorus, an elephant's tusk. He believed that within a few years materials to which this transient radioactivity had been imparted would be available for transmission from laboratories in quantities suitable for therapeutic purposes. Whether they would prove desirable in therapeutic use remained to be seen, but it seemed to him that a vast new field of therapy was being opened up. There was one great advantage in the artificially induced radioactive elements over naturally occurring radioactive elements—namely, that they quickly died or transformed to some stable element, so that a dose could be repeated indefinitely and an uncertain amount of radioactive material would not be accumulated in the body.

CONSTITUTIONAL EFFECTS OF X RAYS

A joint paper by Dr. S. GILBERT SCOTT and Dr. F. HERNAMAN-JOHNSON on the constitutional effects of x rays as determined by blood-serum tests was presented by the latter. It was extremely probable, said the authors, that x rays, like ultra-violet light, had constitutional as well as local effects. In the case of ultra-violet light, however, a knowledge of its physical properties made it reasonably certain that constitutional action could only be through the skin, and this narrowed the investigation to chemical changes in the surface tissues. All these possibilities were present in x-ray action also, but many more, for even with x rays of medium wave-length there was not an organ or tissue in the path of the beam which might not be affected. Clinical radiology had so far concerned itself mainly with direct action, but a study of constitutional or indirect effects might yet yield results of great value, perhaps in unlooked-for directions. Recently the vanadic acid blood-serum test, originally introduced by Bendien for the diagnosis of cancer (for which purpose it had not yet been proved reliable), had shown itself of great value in the control of x-ray treatment, indicating constitutional reactions to x rays and the state of the patient's resistance. Asthma was the first condition to be investigated on these lines. The fact of overdose could be recognized from the serum picture. These allergic patients were very sensitive to radiation, and the

vanadic acid test could indicate when it was wrong to increase the dose. With this test it had been shown that 40 per cent. of asthma cases were likely to benefit from radiation, in another 40 per cent. it was of doubtful efficacy, and in 20 per cent. no good results were achieved. Asthma had furnished the best example up to the present of the value of the vanadic acid test in prognosis and treatment, and the effects of x rays, which were undoubtedly constitutional, as opposed to local, could be watched in an objective manner. It was of interest to note that the thorax could be excluded without prejudicing the result. In the case of breast cancer, with wide field x-ray therapy of low intensity and medium voltage, a normal curve for the reaction might even be found in the presence of small-scale recurrences or involved glands. On the other hand, a patient going downhill showed a markedly abnormal curve. The appearance of an abnormal curve in a patient apparently well was of bad prognostic import. Once the primary growth had been got rid of, whether by radiation or by operation, the problem of preserving the patient from metastasis was a constitutional one, and the vanadic acid test of blood serum gave results of sufficient constancy to furnish a guide.

THE DIGESTIVE MUCOSA

In his Silvanus Thompson Memorial Lecture, delivered to the congress by Dr. H. H. BERG, who has lately been appointed professor of internal medicine at Hamburg, the speaker described how he had followed up the work of Forssell on the movements of the intestinal mucous membrane, and that of Åkelund in increasing the accuracy of the radiological diagnosis of peptic ulcer. A preliminary condition for the demonstration of mucosal details was complete emptiness of the viscus. In cases of retention of food or fluid it might be necessary to use a stomach tube; for colon examinations several enemas were required. Generally, for oral administrations of barium a watery suspension was used, but for demonstration of details of the oesophagus a jam-like mixture was preferable. As a general rule, only small amounts should be given, sufficient to fill the depressions of the mucosal pattern with a thin layer of the contrast medium. The less the material it was necessary to use the better was the mucosa visible. In the majority of cases three or four swallows of the watery suspension were sufficient to demonstrate the mucosal relief of the stomach walls. Adequate distribution of the thin layer was obtained by varying the amounts, changing the position of the patient, and applying graduated compression. Quick change from horizontal or oblique to erect position was of special value. Screen work and radiography were used in such close connexion that a radiogram of every important detail could be taken instantaneously. Professor Berg paid a tribute to the work of A. E. Barclay: no one had better summarized the general postulates for examination. He then described the theory of Forssell that the different formations of mucosal relief were the result of active movements corresponding to the requirements of digestion, and passed on to indicate some pathological aspects of the condition of the mucous membrane, best set out as follows:

Causes	Symptoms
Pressure from without.	Displacement, flatness, disappearance of folds.
Inflammation.	Elevation, swelling, coarseness, stiffness of rugae.
Ulcer.	Crater with smooth, elevated border; cicatrization with stellate folds converging on the ulcer.
Growth.	Tortuosity and loss of folds; sudden discontinuance of folds; irregular protuberances, craters, etc.

With the aid of lantern slides he discussed the various appearances, and concluded with the remark that in the diagnosis of every organic lesion of the digestive tract this new method had proved its value, but nowhere more than in the diagnosis of malignancy. The smallest carcinoma of the stomach he had seen was the size of a thumb-nail; nobody believed him when he said that it was a carcinoma. Six months later, when removed, it was the size of a goose's egg. The problem of cancer, however, was not solved by the detection even of the smallest growth, because small growths had often extensive metastases, and big growths sometimes none. Progress had been made in the differentiation of malignant and benign changes. Chronic ulcer of the prepyloric area could give a very similar picture to malignancy. Chronic gastritis of different types could be suggestive of cancer because of the stiffness of the coarse mucosa. It was always necessary to bear in mind that histological work could not be carried out with the x-ray tube. Careful screen work was always the best safeguard against error.

CINERADIOGRAPHY

Dr. RUSSELL J. REYNOLDS gave a demonstration of cineradiography. We have already (*British Medical Journal*, May 5th, 1934, p. 813) described Dr. Reynolds's ingenious methods. He showed films illustrating movements of the joints, of the heart and lungs, of the stomach and duodenum, both in normal and in pathological conditions. One film showed an artificial pneumothorax of the right lung, 500 c.cm. of kaolin having been injected on the morning when the film was taken. He also showed a slow-motion film correlated with graphic records of the heart's action. Within the last fortnight he had been able to incorporate the electrocardiograph tracing on the films. In that connexion, of course, the difficulty had been the elimination of current interference, particularly in view of the fact that he had been working on alternating current cycles.

Dr. Reynolds suggested that there was a large and varied field for research opened up by this new method. It should prove of immense value in investigating lesions of the lungs and pleurae, especially after lipiodol injections, or in cases where artificial pneumothorax had been induced. As regards movements in the alimentary tract in pathological states, the advantages of being able to study such movements indefinitely after the administration of an opaque medium were obvious. In orthopaedic lesions the range of movements in limbs and joints could be observed. He summarized the advantages by saying that the cinematograph method enabled a rapid, inexpensive, and permanent record of the functioning of active organs to be obtained; the continuous "band" made it possible to study movements for an indefinite period, and permanent records might be used for diagnostic purposes, for comparison with previous records, for teaching, or for transmission to other places.

OTHER PAPERS

A therapy generator operating six x-ray tubes in parallel was described by Dr. J. STRUTHERS FULTON. By suitably arranging the controls it was possible for the apparatus to be operated by one person. Communication between patient and operator was arranged by a simple telephone circuit; there was also an elaborate timing arrangement. He showed dispositions in which as many as four tubes were simultaneously irradiating a patient, or in which five patients were being treated at the same time on different milliamperages.

Dr. J. RALSTON PATERSON made a plea for the more scientific estimation of dosage in radiation therapy. The use of biological units of dosage was only a temporary though necessary phase in the development of technique.

to be succeeded as soon as possible by the more reliable phase of physical measurement. In radiation therapy this measurement was actually of the x rays or gamma rays used, and must be stated in terms of some physical unit. The choice of unit in which quantity of x rays should be expressed had been settled by the international adoption of the "r." The problem of dosage as it affected radium presented rather different considerations. To describe radium dosage by "milligram hours" was an empirical guide only. No gamma ray unit had as yet received international adoption, but the matter was under discussion, and he hoped it would come about within the next three years. Much more attention should be paid clinically to the time factor in radium dosage.

Three papers on radiographic subjects concluded the congress. Dr. A. C. JORDAN gave a radiological study of asthma due to toxæmia. Granting, he said, the spasm and the oversensitiveness to certain substances, it was still necessary to ask why asthma patients were sensitive in their particular ways. His radiological studies of the gastro-intestinal tract had supplied an answer, in many cases a complete answer. In the course of years a certain number of patients sent to him for gastro-intestinal investigation had been asthmatic; other results of chronic intestinal stasis had been there too, but in every case of asthma the general aspect of the patient had been that of pronounced stasis. To prove his contention that the asthma was due to the toxæmia of stasis, and that it could be cured by thorough treatment of the stasis, he brought forward the x -ray evidences of twenty-seven cases, and sketched the subsequent history of those that had been treated systematically.

Professor J. PRESTON MAXWELL described some studies on osteomalacia and foetal rickets. Radiology had played a large part in the elucidation of the subject. On his last visit home from China he had had very little to offer on the subject of osteomalacia, save radiological evidence, but he had now been able to obtain pathological specimens of what he termed "adult rickets." He showed a series of slides depicting Chinese women and babies, and drew attention to the shrinkage of the body, the neck disappearing, as it were, into the chest, and the standing height sometimes being reduced by as much as six inches. Radiology had played a large part in the discovery of foetal rickets, and he had now sixteen proved cases of that disease.

Dr. J. DUNCAN WHITE read a paper on "Familial Marble Bone." Thirty years ago Albers-Schönberg first described a case of "marble bone," a condition in which there was a transformation of the spongy part of the skeleton into compact bone, resulting in thickening and density of cortical bone at the expense of the medullary canal. Since then about forty cases had been added to the literature. In view of the rarity of the condition Dr. Duncan White brought forward four more cases, all members of the same family, two of them requiring surgical intervention for the relief of cerebral symptoms.

The Therapeutic Union, a new international organization which has come into being this year under the auspices of the Therapeutic Society of Paris, has for its president Professor Maurice Loeper, while one of its vice-presidents is Dr. E. P. Poulton, physician to Guy's Hospital. The Union will include medical practitioners and physiologists who are particularly concerned with therapeutic problems, and will aim at establishing closer mutual relations between them in various countries. There are already some 250 members. It is proposed to hold a congress next year, some time between June and August, at Berne. Those desiring further information about the Union or the congress should apply to the secretary of this society, Dr. G. Leven, 24, Rue de Téhéran, Paris VIII.

THE HEALTH OF THE SCHOOL CHILD

SIR GEORGE NEWMAN'S REPORT

The School Medical Service was founded in 1907, and had therefore completed its first twenty-five years of work at the end of 1933. The occasion is seized by the Chief Medical Officer for a review of the purpose and achievement of the service. The foundation provided the authority first of all with a means of ascertainment, for up to then the local authorities did not know what the physical condition of children actually was. Secondly, there followed arrangements for attending to the health of both groups—the sick and the healthy. For some years the ailing child was referred to the family doctor, but experience showed that certain disorders, such as defective vision, dental decay, and minor ailments, fell outside his sphere or his facilities, or else that the parents were unable to pay his fee. The authorities therefore began to establish means of treatment under their own control. So steadily has this process grown that in 1933 inspection was made of 1,855,499 children in the routine age groups, and of 1,239,427 specially referred on account of sickness. Many of these were treated under the local authority, and certain morbid conditions have been substantially reduced by this treatment. The anaemia of girls has almost vanished. Ringworm is steadily disappearing. Blindness is being prevented. A verminous child does not expect admission to school, and the malnourished child now forms only 1 per cent. instead of 10 or 20 per cent. Heart disease, rickets, and tuberculosis have been steadily reduced; and the condition of teeth is improving. The physical condition of the children has been reformed beyond all comparison with the past. A third national advantage of profound importance is that children have been rendered more fit for education, and education has been more closely adapted to individual needs. Finally, a health consciousness has been developed among parents, who almost universally support the school medical service.

Sir George Newman insists, however, that nothing is being so well done that it cannot be better done, and deprecates any tendency to become static or routine. In some districts there is urgent need for effective co-ordination of the various means of treatment available. Moreover, experience and research are constantly disclosing new aspects of disease and new methods of dealing with it. The school medical officer must be alive to all these. Again, the pre-school child still presents a problem to which more attention should be devoted. Finally, much more consideration should be given to the health of the normal child, so that every child is trained in the way of healthy living. "We have devoted much labour, time, and public money," says Sir George Newman, "to the treatment of the defective child; are we doing all that is practicable for the nutrition, physical education, nurture, and health of the normal child? I fear we are not."

NUTRITION AND SCHOOL FEEDING

The enactment providing for school feeding dates from 1906, and the succeeding years have demonstrated three facts: (1) that a substantial number of children come to school inadequately nourished; (2) that such undernourishment is due to a variety of causes; and (3) that undernourishment does not depend on lack of food alone. It depends upon the natural powers of the body to assimilate suitable food, and these depend upon a properly functioning body. Over many of the indirect causes of undernourishment the local authority has no power, but it is empowered by Parliament to feed and to teach, and every local education authority should examine with the utmost care its moral duties and its legal power in regard to all that this implies. Recent criticism has suggested that undernourishment may be missed by the school doctor, and that his methods are insufficiently thorough or exact. While doctors and other officers of the school service are no more infallible than other specialists, it is unlikely that all of them in any district are incompetent or continually misled. The determination of under-

nutrition is in any case one of exceptional difficulty, as there is no accepted standard of nutrition. In practice, however, the results are sound and relatively uniform, though it may be difficult to tabulate them in a mathematical form. Of the children submitted to routine examination during 1933 1.11 per cent. were found to be malnourished and requiring treatment, while 1.28 per cent. were undernourished and requiring observation. It is obvious from the reports, many of which are quoted, that there is no widespread malnutrition among children attending public elementary schools. In some districts there was a decline in undernutrition, and in others a slight increase.

During the year under review the provision of school meals continued to expand, and at the end of that period 192 authorities were exercising their powers in this way. Generally speaking, the only authorities not providing meals were certain rural counties, some comparatively prosperous seaside towns, and small country towns. The total number of meals provided was 68,800,000, an increase of 6,500,000 on the previous year. The number of children who received meals was 414,800, as compared with 399,400 in 1932-3. More than half the meals provided were in the form of milk, and this has been found to be the most valuable food. The Milk Marketing Scheme came into force on October 1st, 1934; the surplus milk is to be supplied to children at school at $\frac{1}{4}$ d., instead of 1d., for one-third of a pint. The result of this cannot yet be estimated. The Board of Education has issued a circular to local authorities pointing out the value of the scheme. The provision of school meals was never meant to be a form of poor relief; its object is to secure that public funds are not wasted in an attempt to educate children who, owing to subnormal nutrition, are unable to obtain full benefit from their education. The children must be selected for the milk or meal by the medical officers. It must be remembered that malnutrition is not the only morbid condition following insufficient or unsuitable food. The recent marked decline of deficiency anaemia, tuberculosis, rickets, dental caries, and infective disease is due in part to the greatly improved general nutrition.

PHYSICAL EDUCATION AND HYGIENE

It is the business of the local education authority to ensure that every child receives an appropriate education in health and physical training, or, if the Greek be preferred, in harmony and gymnastic. The lost incentives of early man's activities of body, which gave him his rude health, have to be created artificially. The organized physical training of the body of every child has for its objective a physiological purpose, a recreational aim, and a mental and moral intention. The physiological purpose must begin in childhood for all children, and the exercises must be so designed as to increase the growth, strength, and control of the body of each individual child. Secondly, physical exercises must be taught in order to increase and develop the physiological functioning of the body, and of the whole body and not only of the muscular system. A child of 5 or 6 must be dealt with differently from the growing boy or girl of 8 or 9, or the older child of 12 or 14. No cast-iron system will suffice, and the final goal of physical training is mental and spiritual.

To make effective arrangements for dealing with the physical education of five million children calls for organization. The subject must be in the time-table; the school teacher must be equipped; the teaching must be conducted in accordance with approved standards; it must be supervised by organizers; and must be regarded as part of the routine education in hygiene. Sir George Newman remarks: "No formal words can express the value of the work of the teachers, for their continuing and living interest and enthusiasm, and for the large amount of time and voluntary services, in and out of school, which they devote to this important branch of education." So great has been the demand for the revised syllabus of physical training, issued last year, that 150,000 copies have already been sold.

There are 182 junior technical schools preparing students for commercial and industrial employment. A recent opportunity for surveying the position of physical education in these schools has not disclosed a very bright picture. Only about half of them have suitable gymnasiums or halls, and a number of them have nowhere at all for physical exercises. This is particularly serious in such an institution, because the training and development of the body is of direct importance from the point of view of future occupation. It teaches precision of movement and economy of effort, and helps to cultivate the habit of assuming the best posture for the work in hand.

A number of reports from the physical training organizers in different districts are quoted, and give a vivid picture of the movement. There are now 169 organizers—four more than last year. Dancing is a vital form of bodily exercise which has not obtained an established place in the physical education of children. It teaches control and balance of mind and body, and aids in encouraging poise, ease, and lightness of movement. It arouses the living sense of rhythm, affords direct training of eye and ear, and develops the feeling of space and order. Also it gives scope for the imagination and creative powers of the child. With so much at stake it should be taught well and wisely. Child dancing should be a simple, free, and living thing, by means of which the energy and natural exuberance of the child's spirit have full play. Anything that savours of self-conscious posturing is harmful. The aim must be to teach dancing rather than dances. During the last two years there has been an exceptional extension of the facilities for swimming, a form of physical training which is of high physiological value, and also recreational and utilitarian.

The new physical training college for men at Leeds, which was opened in 1933 to meet a long-felt need, has established itself satisfactorily; thirty-seven students have completed the first year's course, most of them being men who have already had teaching experience. There has been a reawakening of interest in the teaching of hygiene, and increasing emphasis is laid upon instruction in the creation and establishment of habits of health. What the child hears or sees may be soon forgotten, but what it does as a habit is retained. The question of sex hygiene still calls forth divergent views, but certain authorities are providing it.

NURSERY AND OPEN-AIR SCHOOLS

The report emphasizes that the child under 5 years of age stands at the gate of the whole educational system, that he is the seed plot of everything—medical, physical, mental, and moral—that what happens to him is bound to have results; and that he is not yet being sufficiently provided for. Much has been done, but not yet enough. Large numbers of children are admitted to school every year requiring immediate medical treatment, although the percentage has declined from 23 in 1925 to 16 in 1933. The facts are known, and public interest has been drawn to them. There are now six services available for children under 5: maternity and child welfare centres (between 2,000 and 3,000); clinics for toddlers; 100 day nurseries; sixty-two nursery schools, with accommodation for 4,933 children; nursery classes; and emergency open-air nurseries. Nursery schools play an important part in persuading children to take food to which they are unaccustomed, and in securing suitable dietary, rest, sleep, and fresh air. The average length of stay in the school is two and a half years, and in this period many defects are remedied and prevented. The emergency open-air nurseries have been established in connexion with the Save the Children Fund, the aim being to erect inexpensive buildings in distressed areas, at the same time providing work for the unemployed men. Another invention of the school medical service is the open-air school, the value of which is not by any means fully represented by the fact that there are 146 in existence, because they have introduced the open-air principle into the elementary schools of the whole country.

MEDICAL INSPECTION AND TREATMENT

Since the school doctor can only visit two or three times a year, it is essential that the school nurse should be an intelligence officer and also a link between the medical officer and the home. Teachers are turning more and more to the school medical service to help them to solve their problems with individual children. Increasing co-operation with the family doctor is evidenced by the fact that numbers of children are referred by practitioners to school clinics for diagnosis and treatment. Effective co-operation, says the report, must depend rather on mutual good will than on formal administrative arrangement, but there are certain steps which local authorities can take to promote it. The school medical officer can send the general practitioner a short note when he refers a child to him, and the local authority can publish a small handbook setting forth what services are available in the area. One undesirable result of the increasing interest of the public in the health of the child is a tendency to parental over-anxiety, but the effective reassurance of an anxious parent is by no means a waste of time, and may have a far-reaching beneficial influence on the psychological development of the child. The modern tendency to seek medical advice early not only benefits the individual but also adds to the medical profession's knowledge of how to prevent end-results which may be difficult to cure. There are now 1,340 school medical officers, of whom 264 are whole-time and 370 are women. There are 992 specialists, of whom thirteen are employed whole-time, and 778 school dentists, 488 being whole-time. The total number of nurses is 5,585. The number of children inspected in specified age groups was 36.7 per cent. of those in average attendance, and this figure is raised to 61.3 per cent. when the children referred for some special reason are included. The table of defects requiring observation or treatment remains much the same as in previous years. There is a decrease in the number of children suffering from chronic tonsillitis and a slight increase in malnutrition. Schemes of medical treatment for secondary school children have not yet reached the same stage of completeness as those for elementary school children.

TREATMENT SCHEMES

During the year under review there was no significant increase in the scope of treatment schemes, but thirty-four authorities effected improvements by extending their existing provisions. The total number of clinics for minor ailments—eyes, teeth, and orthopaedic defects—has increased slightly, but those for operations on tonsils and adenoids and the x-ray treatment of ringworm have decreased. Many authorities make use of voluntary hospital provision for forms of treatment which require expensive apparatus or elaborate premises. Nearly all school medical officers report a steady improvement in cleanliness, and there has been an enormous reduction in the incidence of ringworm. The direct application of elastoplast for impetigo contagiosa is being tried in some centres, and is said to heal the sore more quickly than the older ointments, and at the same time to prevent spread of infection. Several local authorities have made arrangements to test the eyesight of children below the age of 8, and valuable results have been obtained despite the difficulties. Several squint clinics are doing excellent work. The audiometer is being used for testing hearing, but the report utters a warning that this instrument may give a somewhat exaggerated figure for the incidence of impaired hearing. Much valuable work is being done in a few districts under aural schemes of treatment, but this branch of work is much less common than, and its development has not reached the same degree as, the visual and orthopaedic schemes. A committee was appointed in January, 1934, to discuss the medical, educational, and social aspects of the problems attending children suffering from defects of hearing not amounting to total deafness. The committee has to consider the best means of ascertainment; otological standards for determining the need of special educational provision; cause, prevention, and treatment of defective hearing in

children; the value of electrical aids; and the best type of educational provision for those unfit for ordinary schools but not bad enough for deaf schools.

TONSILS, EYES, AND TEETH

The term "enlarged tonsils" has now been replaced by the words "chronic tonsillitis," the categories for defects of the nose and throat now being: chronic tonsillitis only, adenoids only, chronic tonsillitis with adenoids, and other conditions. The year 1933; therefore, was a transitional period, but the records are interesting in showing a transference to the fourth category of a number of cases of tonsillar hypertrophy which would have appeared in the first group in previous years. This was to be anticipated, but it is surprising to learn that there is a much greater relative decrease in the category of "adenoids only." The operations for tonsils and adenoids numbered 77,564, as against 95,875 in the preceding year and 110,239 in 1931. Early in the year it was decided to obtain an authoritative expression of opinion as to the best anaesthetic for these operations. The body of anaesthetists consulted deprecated the use of chloroform and of chloroform and ether mixtures.

A committee appointed in 1931 to inquire into the medical, educational, and social aspects of problems affecting blind children reported in July, 1934. Their report was reviewed at the time. The fundamental line of thought in it was to emphasize that partially blind children belong educationally and socially to the sighted world; the term "partially sighted" was suggested instead of partially blind. The committee formulated ophthalmic standards for defining these children, and the report strongly urges that all those responsible for blind children should most carefully review their charges periodically, in order to determine what type of treatment is most appropriate to them.

The report declares that of all the schemes provided by the local educational authorities the school dental service is the slowest in developing. During the year there was an increase of only eleven in the number of school dentists, bringing the total to 566. Since this means only one full-time dentist to 8,900 children, it is obvious that there is much to be done. During the year 3,303,983 children were inspected, and there was a slight increase over the preceding year in conservative work, with a corresponding decrease in extractions. A good deal of propaganda has been carried out by the Dental Board, but there is still great need of a wider appreciation among the whole population of the value of care of the teeth. Dental disease is said to be the most common of all physical defects among children.

ORTHOPAEDIC AND MENTAL WORK

A considerable proportion of children in the elementary schools show postural defects. The aim of an orthopaedic scheme is to ascertain the cripple at the earliest possible moment and to provide treatment, re-education, and after-care, and, where necessary, special vocational training. Any scheme, to be effective, must include children under 5, and the education, health, and infant welfare committees must co-operate. The interrelationship of the orthopaedic clinic, the infant welfare centre, the tuberculosis dispensary, and the orthopaedic hospital is of the utmost importance. Nor must the necessity for the co-operation of the parent and private practitioner be overlooked. To embark upon orthopaedic treatment without ensuring effective co-ordination of all concerned is, says Sir George Newman, to court disaster from the outset. The diseases chiefly responsible for crippling occur mainly before school age, and ascertainment must be pushed earlier and earlier. Comprehensive schemes have been approved in 233 areas, but there are still forty areas where no provision of any kind has been made for cripples, and in another forty-three areas there are only partial arrangements which are of very doubtful value.

The report gives a survey of the special schools for physically and mentally defective children, and of the work done in them.

INFECTION AND MORTALITY

The common infectious diseases—measles, whooping-cough, diphtheria, and scarlet fever—still occupy a prominent position among the principal causes of death in childhood. Measles and whooping-cough take their toll in the younger age groups and the other two in the older children. The death rate from tuberculosis continues to fall, but 1933 showed an increase in death from rheumatic fever and heart disease, an increase correlated with the prevalence of scarlet fever during 1933. This disease was 50 per cent. more common than in 1932, and 129,525 cases were notified. The total number of deaths, however, was well below the average. There was a serious outbreak of apparently simple sore throats in some districts, and this may well have been part of the scarlet fever wave.

THE INFANTS HOSPITAL EXTENSION

OPENING BY THE PRINCESS ROYAL

The Princess Royal, on December 11th, opened a new in-patients' block, nurses' home, and remodelled wards at the Infants Hospital, Vincent Square, Westminster. Her Royal Highness was received by the Mayor of Westminster and by Sir Gomer Berry and Dr. Eric Pritchard, respectively the chairman and the medical director of the hospital, and various members of the staff were presented. Brief speeches were made by the Chairman and Dr. Pritchard, and by Violet, Lady Melchett, after which the Princess declared the new sections open and made a round of inspection.

The new building, on an extension of the island site where the hospital has stood since 1907, overlooking the playing fields of Westminster School, will accommodate seventy infants and seven nursing mothers, and, with the thirty cots in the reconstructed old building, will bring the total accommodation to just 100 patients. The hospital, which takes children up to the age of 5 years only, claims that it is the largest of its kind in the British Empire. Only two years ago a new out-patient department was opened, containing a large waiting hall, a number of consulting rooms, departments for x-ray work, light treatment, massage and remedial exercises, a dispensary, and a theatre for minor operations, with, in the basement, isolation rooms for patients suffering from infectious complaints, pending their removal elsewhere.

OBSERVATION "WARDLETS" AND MILK LABORATORY

The ground floor of the new building is given up to administration. On the first floor there are seven small separate rooms for the accommodation of nursing mothers with their infants, also four separate wardlets, each containing one cot only, for observation purposes. Each of the next two floors contains five wards for four patients, and four additional ones for either one or two cases. On the fourth floor is a well-equipped operating theatre, with anaesthetic and sterilizing rooms, and on this floor, also, there is accommodation for a number of private patients in separate wardlets. Every possible arrangement is employed for ensuring light and ventilation and the avoidance of cross-infection. Open-air balconies, to which every ward and wardlet has direct access, extend along three sides of the hospital, and are large enough for all patients to be put in the sun or shade, according to the time of year. The separating partitions are all of glass to facilitate supervision and to provide the maximum of light. Every ward has its baby's bath, so that risk of change of temperature on passing to an outside bathroom is avoided, and each infant has its own locker with all toilet provisions and thermometer. The barrier system for the prevention of infection is carried out meticulously. The older part of the hospital building has been reconstructed to accommodate surgical cases, housed in two large and two small wards, providing a total of thirty cots. On the top floor is a fully equipped milk laboratory, with refrigerator and dietetic kitchen.

The new nurses' home provides for thirty-six nurses; the nursing staff in an infants' hospital of 100 cots has, of course, to be much larger than that, but others are still accommodated in the old home apart from the main building, where also lecture and demonstration rooms have been installed. The pathological and research laboratory, of surprising extent for a relatively small hospital, was designed by the founder of the hospital, Sir Robert Mond, more than twenty years ago, and so well and ambitiously was it planned that when the main institution had recently to be reconstructed in accordance with modern ideas no alterations were necessary. Last year nearly 6,000 investigations of one kind or another were carried out in this laboratory.

CLINIC FOR DEAF CHILDREN

One department of the reconstructed hospital is a clinic for deaf or partially deaf children, who are likely to go on to deaf-mutism unless some attempt is made to educate them. An amplifier enables those who have any sense of hearing to appreciate sound, and for others there is a special instrument which enables them to follow the voice by using the tips of their fingers. The decoration of the hospital has been well carried out on simple lines. The whole of the new buildings are heated by the plenum and ceiling-panel systems, with provision for emergency heating by gas and electric fires when required. All the floors of the wards are composed of teak blocks, while those of the consulting and treatment rooms are covered with rubber. The cost of the new buildings and reconstructions has been £150,000. In view of the considerable enlargement of the hospital's provision the consulting staff has been increased. The schedule of charges for private patients has not yet been worked out, but something like £1 a day was mentioned. It goes without saying that an infants' hospital is the most expensive of general hospitals to run.

Reports of Societies

MENINGITIS OF OTITIC ORIGIN

At a meeting of the Section of Otology of the Royal Society of Medicine on December 7th a discussion took place on meningitis of otitic origin. Mr. E. A. PETERS was in the chair.

Mr. T. B. LAYTON, in opening, limited himself to the cases of otitic meningitis which arose from the newly infected mastoid. He divided lumbar puncture into diagnostic, prognostic, and therapeutic. A diagnostic lumbar puncture was performed to distinguish an otitic from other forms of meningitis, a prognostic to determine the stage to which the disease had progressed, and a therapeutic as supplemental therapy, either for drainage of the theca, intermittent or continuous, or for the insertion of pharmacological substances into the theca. The essential treatment in every case was to remove the "factory" of organisms in the mastoid or other part of the temporal bone which was in contact with the dura mater. He proceeded to speak in detail of the treatment common to all stages. The mastoid was opened, and if a track of disease could be recognized leading down to the dura mater it was followed and the bone in contact with it removed widely from both middle and posterior fossae. Steps were then taken to fix the wound widely open, and the cavity was hosed with saline, anything up to a couple of gallons. The container was held high and the nozzle at some distance from the wound, so that a good stream played upon it, and it was then tightly packed. The operation did not save the patient's life, but it put him in such condition that the nurse, under medical guidance, had a chance of doing this. Mr. Layton then passed to a description of the three stages of otitic meningitis. The symptoms were bilateral and proceeded from above downwards. The first was rigidity of the neck. As soon as this symptom was found the treatment already described should be instituted. Every hour lost endangered the patient's life. Lumbar puncture, in his opinion, should

not be done at this stage. It resulted in delay, hurt and distressed the patient unnecessarily, and revealed nothing not already known. By disturbing the intrathecal circulation it might do harm. There were those who said that this first stage was not meningitis, but he begged that it might not be called meningism, for that word, by its origin and tradition, was associated with inactivity, and a term was needed which inferred immediate and vigorous treatment. "Meningeal irritation" would be better. Where rigidity of the neck only was present the great majority of patients should recover. Once any further symptom had arisen the case would not be safe "unless luck is with you, and you must not expect this to be so in more than alternate cases." By "luck" Mr. Layton explained that he meant the combination of unassessable factors. The second stage was that in which Kernig's sign was present in addition to rigidity of the neck. The state in which the sign could not be elicited but at the same time one could not feel sure of its absence formed the boundary zone between the first and second stages of meningitis. The boundary zone between the second and third stages was that in which the abdominal reflexes were lost. For many years he was uncertain whether Kernig's sign appeared before or after the loss of the abdominal reflexes, but now he felt certain that it always preceded. The two symptoms of neck rigidity and Kernig's sign, and their relation one to the other, were the only signs of clinical importance. If the patient's life was to be saved action must take place before anything else developed. Headache was due to the distension of the theca with fluid; he had not found it an early symptom, and would class it in the late second stage. In this second stage a prognostic lumbar puncture should be done, and from the appearance of the fluid a decision made as to whether the prognostic lumbar puncture should be converted into a therapeutic one. If the fluid was clear and the pressure not high this should not be done. If clear, but with an increase of pressure, sufficient should be removed to reduce it to normal. If cloudy, more should be drawn off, the exact amount depending upon whether the patient was under an anaesthetic or not. In the subsequent treatment at this stage he believed that if the fluid was clear the treatment should be that described in the first stage; if it was opalescent this should be supplemented by intermittent thecal drainage obtained by performing lumbar puncture twice or thrice daily for several days. The number and period should be determined by the characteristics of the fluid and the condition of the patient, with special reference to headache and rigidity of the back. In the late stage of otitic meningitis the patient lay on his side with the knees bent up, the back extended, and the head thrown back. A cry escaped him from time to time, owing to the severity of the headache. The lips were parted, the mouth dry, the tongue heavily furred, and the temperature steadily mounting. It was characteristic of the condition that the symptoms were exactly bilateral. In this stage of the case a spirit of defeatism had been acknowledged; nevertheless, he thought these cases should be attacked with vigour and determination, always remembering that a case should never be allowed to get to this stage if it could be helped. A prognostic lumbar puncture must be done. In the examination of the fluid he laid most stress upon two observations: the number of cells as indicated by the degree of opacity, and the presence of organisms. A distinction must be made between cases in which the haemolytic streptococcus could be grown *in vitro*, and those in which an organism, probably the haemolytic streptococcus, could be observed directly in a smear. The former was of pathological interest only, and of no clinical value; the fight was over before the report arrived. Intermittent thecal drainage was still a stand-by for the milder cases in this group. The insertion of any antiseptic drug was valueless. Whether intermittent thecal drainage would occasionally save a case he did not know; it was not to be relied on. He did not think Jenkins's operation of translabyrinthine drainage was applicable to these cases, except where the access of the disease to the meninges was across the labyrinth. Along two other lines of treatment they must work in the future: (1) to add to intermittent drainage of the

theca the replacement by a serum, specific or non-specific; and (2) to replace intermittent by continuous thecal drainage.

Mr. NORMAN A. JORY said that any pressure of the fluid above 200 mm. of mercury was to be regarded as pathological. Anything which raised the intracranial venous pressure and the pressure—in consequence—of the choroid plexus gave an increased filtration of the fluid. In meningitis several factors combined to raise this pressure. An increased cell count over 10 per c.mm. must be regarded as pathological. On the count alone a degenerating glioma of the brain could be confused with a cerebral abscess. In a series of thirty-nine cases of acute-septic lepto-meningitis seen at one hospital in ten years, thirty-six proved fatal. The majority of the cases were in children. There was acute or subacute trouble in the mastoid in twenty-nine cases; organisms were recovered from the cerebro-spinal fluid in twenty-one. In thirteen of the cases lumbar puncture proved sterile. Translabyrinthine drainage was carried out in only three cases. In three instances the labyrinth was found infected at the necropsy. In all the cases the chlorides were below 700 mg. per 100 c.cm. In serous meningitis the fluid was under increased tension, with increased protein, and it might be either clear or turbid.

Dr. C. P. SYMONDS said he considered that neck stiffness and Kernig's sign depended on irritation of the posterior root in the lumbar and posterior cervical regions; he did not regard them as signs which were inseparable from actual meningitis. He spoke of a case of tuberculous meningitis which came to necropsy and yet there had never been neck stiffness; the exudate was confined to the cisterna pontis. But one could not say that when neck stiffness and Kernig's sign were absent there was no meningitis; early, localized, or mild meningitis might exist without the presence of these signs. A diagnosis could be made only by an examination of the spinal fluid. There were three main modes of progression of infection from the middle ear to the meninges: (1) from infected vessels into the bone, these vessels being ultimately corrected with those in the subarachnoid space; (2) the path might be through the labyrinth, whose fluid communicated with the cerebro-spinal fluid; (3) through bone, dura, and arachnoid, with a reactive process on the part of the newly infected tissue. If the invasion was by means of infecting blood vessels there might be no premonition of meningitis. When the invasion was in the form of osteomyelitis, with progressive spread step by step, warning signs such as headache, vomiting, and increased temperature were very important. With regard to the risks associated with lumbar puncture, he had at one time stressed the danger of micro-organisms finding their way via the blood stream to the meninges, this being rendered easier by the puncture, but investigations in America did not support that fear. But he still felt that withdrawal of spinal fluid might lead to mechanical rupture of adhesions, and so to the diffusion of a meningitis which previously had been only local. One case he knew was that of a patient with extradural abscess who, following lumbar puncture, rapidly developed a diffuse meningitis. The danger was greatly lessened if not more than 2 c.cm. of fluid was removed and a very fine needle was used so as to withdraw it very slowly. He tried to have a report on the fluid within six hours of the puncture; the cell count was the important feature, and the quantitative estimate of the protein was quickly done. Helpful points in prognosis were the presence and nature of the micro-organisms found and the patient's general condition. As to the possibility of recovery of a case showing micro-organisms in the spinal fluid, Neumann published a series of fifty-nine cases of otitic meningitis, twenty-two of which recovered, six having had organisms in the fluid. He doubted the efficacy of serum, and his objection to its use intrathecally was that it provoked a marked reaction of the meninges of itself.

Mr. E. WATSON-WILLIAMS said that in these cases neck rigidity, without other signs, was not confined to early stages. In a series of twelve cases neck rigidity was of no great significance in prognosis, and it did not indicate

the stage of the case: five of the twelve cases not showing neck rigidity early, died, and of seven who had marked rigidity and head retraction, with Kernig's sign, one died. Two factors which had a direct bearing on the prognosis were: first, the presence of organisms in the fluid, a matter of grave prognosis, but not necessarily fatal; secondly, the interval between the onset and the date of operation. If a patient did not get well with 40 c.c.m. colloidal silver solution fifteen minutes before daily lumbar puncture, he thought there was a poor chance of his answering to more vigorous measures.

The PRESIDENT said there were two groups of cases: (1) those of infection owing to approximation—that is, in which streptococcal infection passed through all barriers and directly infected the meninges; (2) those owing the usual causes. He thought that the condition named by some "meningismus" was present in more cases than was generally recognized. Mr. SYDNEY SCOTT said that when comparing sets of statistics on this subject it was impossible to make a just comparison unless one could be sure that only cases showing micro-organisms in the fluid were included. Retraction of the head he regarded as a very important sign of meningitis, but he would not diagnose a case without other confirming signs, and lumbar puncture should be done. When a case of meningitis succumbed, it was because of either encephalitis or septicaemia. The so-called "lucky" cases, in which recovery ensued, were those in which the antibodies were potent and the infection relatively mild. Transthecal drainage had but a limited applicability. He related several difficult cases. Mr. HOLR DIGGLE showed how much the accepted treatment of otitic meningitis had varied in nine years. He considered that if a patient had headache, perhaps with a little vomiting, and he had a tender spot in the mastoid region, he would eliminate the sepsis, but saw no reason for disturbing the lumbar theca by reducing the pressure if there was a danger of spreading the infection. Cases had recovered which had no treatment other than repeated lumbar puncture. Mr. C. P. WILSON asked questions as to procedure, and Mr. LAYTON and Dr. SYMONDS replied.

PUERPERAL SEPSIS: SERUM TREATMENT

At a meeting of the Fever Group of the Society of Medical Officers of Health on November 30th, with Dr. H. S. BANKS, the president, in the chair, Dr. J. M. GREENWOOD, late assistant medical officer, Monsall Fever Hospital, Manchester, opened a discussion on "Puerperal Sepsis."

Dr. Greenwood based his remarks upon the number of patients admitted to Monsall Hospital, Manchester, during the twelve months, August 1st, 1933, to July 31st, 1934. During that period, he said, 196 women were discharged from the puerperal sepsis unit of the hospital, and these cases might be classified as follows: (1) sepsis following full-time labour, 112; (2) sepsis following abortion, sixty-two; (3) admitted as septic, but not considered to be so, twenty-two. General peritonitis was found in twelve and septicaemia in eleven cases. Anaerobic cultures were not made. Four of the former group had a septicaemia associated with the peritonitis. Normal labour had preceded admission in 53.3 per cent. of all patients, in 55.5 per cent. of those with peritonitis, and in 20 per cent. of those with septicaemia. The symptoms and signs of general peritonitis varied considerably from those enumerated in textbooks. They were chiefly as follows: gradual onset; anxious expression; tympanites; vomiting, 50 per cent.; diarrhoea, 33 per cent.; rigors, 75 per cent.; no pain, or rather severe pain; no rigidity of abdomen; average range of temperature, 100° to 103° F.; pulse between 120 and 140. Operation was performed in every case of doubt, and no abdomen was opened unnecessarily. Cases of peritonitis were not admitted much earlier than others; this was probably due to the difficulty in diagnosis. Cases of septicaemia, however, were admitted rather earlier. There were sixteen deaths in the total of 196 patients, giving a mortality of 8.1 per cent. Four of these patients died from causes other than puerperal sepsis, and twelve

from puerperal sepsis in 174 septic cases, giving a mortality of 6.7 per cent. It was found post-mortem that in all the patients who died from sepsis the uterine wall was infiltrated with white cells. One specimen was obtained by subtotal hysterectomy in a patient with peritonitis following a perforated uterus after abortion; a well-marked leucocytic barrier line could be seen microscopically. This patient recovered. Treatment was directed at preventing complications after the onset of puerperal sepsis. Glycerin irrigation of the uterine cavity was a routine measure, as well as other general procedures. It was shown by Philips in 1923,¹ Dr. Greenwood continued, that prior to the use of glycerin, when douching of the uterus was employed at Monsall Hospital, the complications present were about double those found after glycerin therapy was instituted. He also showed that the average duration of stay in hospital was forty-eight days, as compared with 26.2 days when glycerin was used. The duration of stay must vary with each individual medical officer, but in the present series all the patients were able to walk up and down a flight of stairs before discharge. The duration of stay was 25.4 days after full-time labours, and an average of 22.5 days after abortion. Glycerin irrigation of the uterus was employed in cases of septicaemia and peritonitis; intramuscular arsenic, given in the former, appeared to be of some value. Anti-scarlatinal antitoxin was only used in a few cases, such as puerperal scarlet fever. It was considered that the report of Benson and Rankin² on 114 cases of proved septicaemia by blood culture demonstrated that serum was of no value in the treatment of the condition. The treatment of peritonitis resolved itself into early diagnosis and laparotomy, but the results were very unsatisfactory. It was found that all the patients with a haemolytic streptococcal peritonitis died. Dr. Greenwood concluded by saying that attention was being drawn to the prevention of puerperal sepsis, and it was found in the report of the Ministry of Health³ that 50 per cent. of deaths might be prevented. Supposing this result were achieved, 50 per cent. of women would still require treatment. The treatment of puerperal septicaemia and peritonitis merited as much consideration as the prevention.

Dr. COLEBROOK spoke of the results of treatment by anti-streptococcal sera in cases admitted to Queen Charlotte's Hospital. They afforded no evidence, he said, that the serum had been useful, but rather suggested that in some cases it might have had a harmful effect. He thought there was need for careful investigation of this latter possibility, and that nothing was to be gained by the continued use of the sera now available.

Mr. WYATT said he regarded diarrhoea in cases of general peritonitis as almost a constant symptom; perhaps it had not evidenced itself in Dr. Greenwood's series, as the peritonitis had been present in some of the cases a day or two before admission, and it was undoubtedly an early symptom. The highest pulse in two of the patients with septicaemia who recovered was 116; this was very surprising, since in all cases with a haemolytic streptococcus in the blood a pulse rate in the neighbourhood of 140 was usual. Concerning Dr. Colebrook's report on the possible harmful action of serum, Mr. Wyatt said it was a pity the cases had not been analysed according to whether or no the patients had been given serum. He asked Dr. Colebrook if he had any idea whether blood grouping had been done in horses in the same way as in man, and whether that might have any bearing on the action of sera in general.

Dr. R. A. O'BRIEN said that serologists would be deeply interested in Dr. Colebrook's figures and deductions, but he did not think the collected figures from the whole country would bear out the latter's interpretation of his own series. Though the old style of anti-streptococcal serum showed no protective value in the laboratory, the modern concentrated streptococcus antitoxin used in scarlet fever would save the lives of rabbits given lethal doses of either filtrate or culture of haemolytic strepto-

³ Report of the Departmental Committee on Maternal Mortality and Morbidity, 1932, p. 14.

cocci, whether obtained from scarlet fever or puerperal patients. He did not agree that horse serum was lethal to mice, for he had seen many batches of serum tested by intravenous injection into mice of relatively large quantities. It was difficult to accept that horse serum was harmful to human beings, for the huge series of cases treated in America with anti-pneumococcus serum, either concentrated or unconcentrated, had never shown a higher mortality among the serum-treated than among the controls.

Professor JAMES YOUNG referred to the question, which Dr. Greenwood had raised, of the route of infection in cases of peritonitis. There could be no doubt, he said, that spread along the open veins of the uterine wall was a common mode of dissemination, and thence it was possible the peritoneum became involved. As against a spread by the Fallopian tubes he referred to cases of criminal abortion where acute peritonitis was present in the absence of any microscopical evidence of tubal infection. He regarded Dr. Colebrook's figures as of great interest, and agreed with him that they seemed to suggest that the employment of serum in puerperal sepsis might seriously aggravate the risk. The findings were of such clinical importance that they demanded a thorough investigation of the whole matter on large and comparable groups of patients.

Dr. SAGE SUTHERLAND gave a survey of the puerperal sepsis case mortality at Monsall Hospital during the period from 1910 to 1933 (twenty-four years); this showed a steadily increasing recovery rate. The highest death rate was 28.8 per cent. in 1920, and the lowest 7.9 per cent. in 1923. During the seven years ending 1933 the incidence of septicaemia among 1,130 cases of puerperal sepsis was 12.7 per cent., and was diagnosed as the cause of death in fifty-four cases, giving a mortality rate of 37.5 per cent. Peritonitis occurred in thirty-one cases in this series—incidence of 2.7 per cent. All these cases were fatal. During the last twelve months out of nine cases of puerperal peritonitis three patients recovered. This was attributed to operation at a much earlier period, and, as Dr. Greenwood pointed out in his paper, to the fact that in no case was the abdomen opened in error. Dr. Sutherland referred to minor septic infections unassociated with subjective symptoms as a possible source of morbidity resulting from the puerperium, the only sign leading to diagnosis in many cases being the objective symptom of subinvolution of the uterus, the absence of subjective symptoms being due to the insensitivity of the larger portion of the pelvic generative canal, sometimes spoken of as the "great silent area of the pelvis." In his opinion infection was more readily spread by the lymphatic drainage system than by the return blood circulation, and there was some analogy between puerperal infection and infection of the blood stream from a poisoned wound through the lymphatic system. Thrombophlebitis, he said, usually remained undiagnosed until the occurrence of cerebral or pulmonary embolism, and the absence of success in treatment was frequently due to the difficulty definitely of tracing the primary source of infection of the blood stream and lymphatic supply until the symptoms had progressed beyond the most favourable period for treatment.

Dr. H. STANLEY BANKS said it was becoming quite clear that neither the old anti-streptococcal serum nor the newer streptococcus antitoxin exerted any beneficial effect in puerperal septicaemia and peritonitis, which were the forms responsible for most of the mortality. Whether the antitoxin was of value as a prophylactic against these grave forms was, he thought, neither proved nor disproved. The other principal new factor in recent treatment was glycerin irrigation of the uterus. His own experience of the method was entirely favourable, provided correct technique was employed. The available evidence appeared to suggest that the substitution of glycerin treatment for former crude methods had had a favourable influence on the fall in mortality. In one particular form—namely, puerperal scarlet fever—where presumably the Dick toxin was a noxious agent, treatment by intravenous antitoxin was attended by strikingly favourable results.

He had frequently given hundreds of cubic centimetres of horse serum intravenously with apparently beneficial results, except perhaps in patients so ill as to be beyond the power of reaction. The suggestion that certain horses appeared to give a toxic serum was one that called urgently for investigation. In an extensive experience of the use of scarlet fever antitoxin intravenously, he found with all the makes of serum he had tried that batches were occasionally encountered which were entirely unsuitable for intravenous injection, owing to the severe immediate reactions they produced. None of the suggestions so far advanced by serum makers afforded a satisfactory explanation of this phenomenon.

GROWTH-RETARDING FUNCTION OF PARATHYROIDS

At a meeting of the Liverpool Medical Institution, held on November 29th, with the president, Dr. J. MURRAY BLIGH, in the chair, Dr. T. LLOYD HUGHES read a paper on "The Parathyroid Glands, particularly in Relation to their Growth-retarding Functions."

Dr. Hughes said that the work of Thompson and Robinson in 1931 had led to the investigation of the possible relationship between the parathyroid oxyphil cells and the growth-retarding hormone. Dr. Hughes then described the investigation he had made. The parathyroid glands were dissected out from 200 post-mortem cases, and were examined from the point of view of numerical, anatomical, and histological variations. The oxyphil cell content of all the glands in these cases was numerically computed according to a modification of a method used by Rasmussen in counting the oxyphil cells in the anterior lobe of the pituitary. In this way variations in the oxyphil cell content with age and various diseased conditions were identified and graphically represented. The oxyphil cell content of the parathyroid glands was found to increase with age in a more or less regular manner. The oxyphil cell content of the parathyroids was shown in cases of malignant disease to be reduced below the normal for the age period. This was considered to indicate an absence of growth-retarding hormone resulting in a tendency in the body to develop conditions of excessive growth should the necessary stimulus be forthcoming. The possibility was considered of the oxyphil cells being cells of special function related to the growth-retarding factor isolated from the parathyroids, and not degeneration products of the principal cells.

CLINICAL CASES

At a meeting of the North of England Obstetrical and Gynaecological Society at Sheffield on November 23rd, with the president, Professor DANIEL DOUGAL (Manchester), in the chair, Mr. J. E. STACEY (Sheffield) described some clinical cases. The first was an unusual abdominal cyst.

Mrs. T., a 4-para aged 47, complained of gradual abdominal enlargement for over two years, with vomiting after over-eating and dull pain in the upper abdomen for six months. She had had one attack of jaundice three years previously, and was severely constipated. A huge cystic mass filled the abdomen, the girth being fifty-four inches; on bimanual examination the cyst filled the pelvis, pushing the cervix behind the symphysis. A diagnosis of ovarian cyst was made and the abdomen opened by an incision eight inches long. Three pints of brownish fluid were free in the peritoneal cavity, and the abdomen was filled by a thick-walled cyst adherent to all the viscera but not to the parietes. Forty-six pints of brownish fluid containing cholesterol were aspirated. The cyst was opened through the transverse mesocolon, and an inspection of its posterior wall showed what appeared to be pancreas. Marsupialization was done, and the patient left hospital with the wound healed after draining five weeks. Analysis of the fluid proved that the cyst was pancreatic, lipase, trypsin, and amyllopsin all being found. Mr. Stacey had been unable to find so large a pancreatic cyst described in the literature.

The second case was that of a nullipara aged 39, married for thirteen years. She had had five weeks' daily haemorrhage with pain, following thirty-three days' amenorrhoea; her periods normally occurred every twenty-four days. This history and the presence of a tender mass felt behind the uterus, apparently in the pouch of Douglas, led to a diagnosis of ectopic gestation. On laparotomy the uterus was found to be two months pregnant an irregular mass, two inches by one inch by half an inch, was seen growing from the back of the lower segment and attached to the rectum. It was decided to remove it in order to prevent obstructed labour; during its extirpation the uterine cavity was opened and part of the cervix removed; hysterectomy with bilateral salpingo-oophorectomy was therefore done. Part of the mass was left adherent to the rectum. The uterus contained five fibroids, one being the size of a walnut and encroaching on the cavity; the foetus was two and a half centimetres long. Section of the tumour showed an adenomyoma of the recto-vaginal septum, with decidual reaction.

Mr. Stacey went on to report a series of five cases of epithelioma of the vulva, treated in the first instance with radium. At intervals varying from three months to two years after the radium treatment excision of the vulva with the diathermy knife had been done, owing to extension of the growth or severe local pain, or both. The radium dosage in specified cases was applied in the form of twenty-five needles, each of three milligrams, for seventy-two hours, to the ulcer and regional glands. Sections taken after the radical operation showed radium burns in two cases, and epithelioma was present in all. Mr. Stacey had been impressed for some time by the ineffectiveness of radium treatment for vulval carcinoma. He found that when the ulcer failed to heal extension was rapid, and radium burns caused such intense pain that local excision was soon demanded. He suggested that a judicious combination of radium and excision at the start, with the addition of deep x rays, was perhaps the solution of the problem.

The PRESIDENT described a case of malignant ovarian tumour, and Mr. ST. GEORGE WILSON (Liverpool) one of angular pregnancy.

CORK CLINICAL SOCIETY

At a meeting of the above society, on November 30th, Dr. R. C. CUMMINS reported a case of vertigo. After first dealing with the commonest causes of vertigo, the speaker outlined the clinical features of a recent case, the attacks being very severe and becoming progressively worse. He had come to the conclusion that the causal factor here was a septic focus in the form of low-grade infection around the teeth, though they were not badly diseased. Removal of the teeth resulted in a complete recovery. The point stressed by Dr. Cummins was that the teeth, as seen in this patient, were the most dangerous and yet the most difficult type of teeth to deal with, because they remained efficient for mastication and caused no pain or other obvious symptoms. They were grey-tinged, dull, but firmly set. A slight blue line was present at the gum margin, but no pus could be milked up. In such cases the individual is loath to agree to, and may even resent, removal. But painless low-grade inflammatory reaction was taking place round the roots, making them firmer, and extensive bacterial absorption into the circulation was certainly present. Dr. O'HEA CUSSEN then read a paper on speech defects. The communication dealt in turn with lispings, falsetto voice, stammering, and cleft-palate speech. Each defect and the method of treatment was illustrated so far as was practicable.

The executive committee of the Brussels Diplomatic Conference, 1935, has received a communication from the fifteenth International Red Cross Congress at Tokyo congratulating the Belgian Government on taking the initiative in calling a meeting aimed at the humanization of war and charging the Red Cross Society to give every assistance. In view of the importance of the Tokyo gathering, this action represents a valuable step forwards towards the realization of the objective of the International Committee of Military Medicine.

CORRESPONDENCE

London University and its Medical Schools

SIR,—The letter of Sir E. Graham-Little in the *Journal* of November 24th (p. 962) raises a point of great interest and importance to medical students and teachers in the University of London. It is, as he points out, a deplorable fact that only a relatively small percentage (56 per cent. in 1932, 59 per cent. in 1933) of the students of medicine of the University who have passed the Second M.B. (anatomy, physiology, biochemistry, and pharmacology) ultimately take the M.B., B.S. degrees, because, as Sir Ernest rightly points out, they are often, on account of economic stress, unable to stay the course.

Now it is probably true to say that practically every medical student of the University, though intending to proceed ultimately to the degree, first takes the qualification of the Conjoint Board (M.R.C.S., L.R.C.P.), which he can do at a somewhat earlier period than he can sit for the degree. This enables him to register and go out and earn some money as an assistant, or perhaps in a practice of his own. In almost every instance he intends to keep up his reading and come back in a year or so and take the Third or Final M.B., B.S. But here comes the difficulty. The Third or Final Examination comprises pathology, bacteriology, forensic medicine and public health, medicine, surgery, and midwifery. Though this can be passed in two groups, one of the groups is composed of surgery and midwifery (B.S.), the other of medicine, pathology, bacteriology, and forensic medicine, including public health and hygiene (M.B.), and failure in one subject of a group means failure in the group. There would be comparatively little difficulty in keeping up the three clinical subjects, and even improving his knowledge of them, for he is in touch with them in the course of his daily work. It is, however, utterly different in regard to pathology and forensic medicine. These are academic subjects with little relation to his daily experience in general practice, and if he is to keep up to examination standard he must do it by a pure "grind." Even that may be impossible, for there is no access to actual pathological material and specimens. Is it any wonder that many give up the struggle and never return to face the Final?

The remedy is, to my mind, simple. Let a third professional examination be instituted, comprising pathology, bacteriology, forensic medicine, and public health, and make it possible for this to be taken, say, at the end of the fourth year and before it is possible to sit for the Final Examination of the Conjoint Board. He would then, no doubt, take the Conjoint Board Examination as usual, but, having already passed in pathology and forensic medicine, would have little difficulty, even though he had gone into general practice, in getting up his three clinical subjects to the degree standard. At least the attempt would not be the hopeless struggle that it is so often at the present time.—I am, etc.,

University College Hospital Medical
School, Dec. 6th.

F. J. BROWNE.

SIR,—The important question raised by Sir Ernest Graham-Little (November 24th, p. 962) is one which in my opinion should receive careful consideration by the University of London. Two important reasons for this have been given by Professor Major Greenwood (December 5th, p. 1072), and need no amplification. There are many other points in its favour, of which I consider the following to be one.

By the time he has reached the Second Examination for medical degrees the student has attended the Univer-

sity for at least two years and two terms, and has passed examinations of a standard comparable with those for the intermediate science examination; or, alternatively, has actually passed the intermediate science examination at the end of his first year of study. The standard of examination at the Second Medical Examination is, in my experience, at least equal to that of the final general B.Sc. degree, and possibly somewhat higher. If it is objected that three whole years must be spent after matriculation in order to qualify the student for a degree, this could easily be remedied by the addition of a further term of work for those wishing to take the science degree. This additional term could be well spent in further study in either anatomy, physiology, chemistry, biochemistry, or pharmacology, and I would even suggest that the addition of general pathology might be considered. Some such curriculum and degree would have very many things to recommend it, and I have little doubt could, in principle, be made effective.—I am, etc.,

London, N.W.11, Dec. 7th.

C. LOVATT EVANS.

Uveo-parotid Tuberculosis

SIR,—It is very gratifying to learn that Dr. Tanner and Mr. McCurry have seen three cases of uveo-parotid tuberculosis since Dr. Thomson and I published our review of this condition in 1933.

An unfortunate state of affairs has arisen, however, with regard to their second case, and it is important that the error should be corrected. This case, which was originally under the care of Mr. R. S. Lawson in July, 1931, is the second case reported by Dr. Thomson and myself in the *Lancet* (October 6th, 1934, p. 743), and the photomicrographs reproduced in the *Journal* of last week are from the same sections as those (Fig. 4) published by us. As we pointed out, this patient had not been seen by us, but we recorded the notes kindly supplied by Mr. Lawson, who also sent us the sections prepared from the parotid biopsy. We communicated with this patient in the summer of 1933, when she said she was then normal in every way. There is no doubt that difficulty will arise in the future as a result of the conflicting statements made by Tanner and McCurry and Garland and Thomson about the same patient, as the former authors state that "tubercle bacilli were demonstrated" in the parotid, whereas we stated that "tubercle bacilli could not be found in spite of the most careful searching." This latter statement was based on the pathologist's report (supplied by Mr. Lawson) and on our own failure to see any bacilli in the sections which we borrowed. Perhaps we were in error, but in any case this fundamental point should be cleared up.

It is interesting to learn that this patient is now developing chronic pulmonary tuberculosis.—I am, etc.,

Leeds, Dec. 10th.

HUGH G. GARLAND.

SIR,—I have read with great interest the paper relating to the above condition in the *Journal* of December 8th, including the clinical accounts of three descriptive cases. Several points emerge from the discussion, principally in connexion with aetiology and symptomatology, which, in virtue of their important bearing on the subject-matter, would seem to be worthy of special attention. In passing, it is of interest to note that the disease is one which appears to have a definite affinity for the female sex. Such a statement is ably confirmed in appropriate literature, whilst the three cases described in the text substantiate it. The age incidence seems to favour the period from 20 to 40 years.

One of the most significant findings is that of the demonstration of the tubercle bacillus described in Case 2. Microscopical appearances and post-mortem changes have

continually shed grave suspicion on a tuberculous aetiology, but failure to isolate the specific organism has proved a thorn in the flesh to many exponents of this theory. A family history of tuberculosis is not by any means always conspicuous by its presence, though a story of discharging neck glands in youth is often obtainable from patients. Perhaps one of the most constant physical signs is that of enlargement at the root glands of the lungs, demonstrable in skiagrams, and it would appear from the post-mortem results of Souter's case, mentioned in the text, that tuberculous infection can be cited as the cause. With regard to the question raised in the discussion as to whether the prodromal symptoms are due to toxic absorption from such mediastinal adenitis, I am inclined to the belief that the latter is resultant rather than causative. During a recent investigation which I had occasion to make into cases of this malady and Mikulicz's disease, infection of the hilar glands was observed in both diseases. When one considers that little or no constitutional disturbance is witnessed in the latter condition it is difficult to blame mediastinal adenitis for promoting toxæmia in the former, since both maladies bear a striking resemblance to each other.

The conception of a tuberculous infection, gaining entrance by the nasopharynx, mouth, or tear duct, or indeed of familial origin, giving rise to uncomplicated salivary gland enlargement in its latent stage (as evidenced in Mikulicz's disease), and causing constitutional upset in its active stage (as evidenced in uveo-parotid fever), would seem to associate each malady more intimately, and meet the case to the aetiological and symptomatological satisfaction of both.—I am, etc.,

Alloa, Dec. 10th.

A. D. MACDONALD, M.D.

Treatment of Haemoptysis

Endotracheal Injections of Adrenaline

SIR,—In their note on pathology and treatment of haemoptysis, published in the *Journal* of October 27th (p. 762), Drs. H. V. Morlock and A. J. Scott Pinchin report to have used the introduction of adrenaline into the bronchial tree both by the nasal catheter and by the cricothyroid route; however, they do not seem to have been favourably impressed with the efficacy of that treatment. In connexion with these points I would like to state that for ten years the medical clinics under my direction have been using a very efficient method of staying haemorrhage from the lungs. Such method has been devised by a pupil of mine, Dr. Giuffrida, and traces its origin from the studies carried out by my school on a local reticulo-endothelial pulmonary chemotherapy. It consists of injections of adrenaline by the endotracheal superglottic route.

The technique of administration is very simple. A source of light is placed in front of the patient, who puts out his tongue. The operator, standing opposite, seizes the tongue between his left thumb and forefinger, while holding with his right hand a syringe filled with 3 c.cm. of the drug (1 c.cm. of 1 per 1,000 adrenaline diluted in 2 c.cm. of water) and fitted with a cannula of 2 mm. bore and 11 cm. length, bent—at a distance of 7 cm. from the cone—so as to form an angle of 110 degrees. The cannula is introduced by the tongue into the mouth as far as the epiglottis, and the patient is directed to breathe in deeply and slowly. The piston is then swiftly pushed down during an inspiration.

The administration of adrenaline often causes coughing, which generally is unlikely to become severe; moreover, coughing shows that the drug has not been swallowed, but has gone right home. The psychic trauma of haemoptysis abates the pharyngeal reflexivity in a remark-

able way, thus making the procedure easy; only a small proportion of highly excitable patients require their throat to be sprayed with a 4 per cent. novocain solution prior to injection with adrenaline. The good effects of this method are confirmed in about 90 per cent. of the cases. If necessity arises the administration of the drug may be repeated every twelve hours (or every eight hours in the worst cases) for two or three days.

Italian and foreign experience has amply borne out the value of such treatment, which is often little short of astonishing; as a matter of fact, it is not an uncommon occurrence for the next sputum subsequent to the injection to be no more blood-tinged. However, the popularity of the method is not, chiefly abroad, on a par with its efficacy, owing, I think, to the misconception that extreme knowledge and delicacy of technique are required. On the contrary, the method stands the test of simplicity.

Quite recently Dr. Pennetti has shown that haemoptysis may be controlled also by a mere endotracheal injection of water, and our contribution warrants such finding, especially in not severe cases. It appears, therefore, that there is a factor of reflex nature concerned too.—I am, etc.,

Sicily, Nov. 20th.

Prof. MAURIZIO ASCOLI,
Director of the Medical Clinic,
Royal University of Palermo.

Short-wave Diathermy

SIR,—I have read with much interest the recent correspondence in the *Journal* with reference to the uses of short-wave therapy, and in addition have received numerous brochures from the makers with the claims of short-wave therapy enumerated. Sinusitis, carbuncles, and neuralgia are three of the conditions which can be benefited. It may be fitting to indicate that many of us engaged in the practice of physical medicine have treated successfully over the years numerous patients suffering from these conditions by means of infra-red and ultra-violet irradiation. Cases of sinusitis require an average of eighteen treatments to cure the condition, provided free drainage can be established by the irradiation. This is indicated by a copious nasal discharge during the initial treatments. One has treated cases of all types, acute and chronic, and in every case not only have the symptoms abated, but the necessity for operation has been obviated. The results should, as far as possible, be verified by an ear, nose, and throat specialist, and by a radiographer. Infra-red rays act by producing a hyperaemia, and this is further enhanced by the application of focal ultra-violet irradiation. The nares and pharynx can be disinfected by the application of the bactericidal rays of the Kromayer lamp, and the external auditory meatus can be similarly treated. General irradiation from a suitable ultra-violet generator should also be administered. My own preference is for the titanium alloy arc. I very much doubt if these results can be improved upon by ultra-short-wave therapy, and if the latter is the method of choice general ultra-violet irradiation should also be given as an adjuvant in every case.

In a patient recently treated and referred to me by an ear, nose, and throat specialist every sinus was involved. His general condition precluded operation. As a result of treatment on the above lines symptoms of pain and tenderness have disappeared, chest symptoms have cleared up, and he has gained 14 lb. in weight in six weeks. This latter fact indicates the "passing" of a septic condition, as also does the amelioration of the secondary symptoms resulting from toxic absorption from infected sinuses.—I am, etc.,

W. ANNANDALE TROUP, M.C., M.D.

London, W.1, Dec. 7th.

SIR,—There is rapidly increasing evidence of the value of short-wave therapy; but if the development of this form of high-frequency currents is to be based upon a scientific rather than upon an empirical basis, the co-operation of the physicists and the biologists with the electrotherapists is urgently needed, and is, indeed, much overdue.

The high-frequency currents of quantity (diathermy) evolved from the high-frequency currents of tension (d'Arsonval), and now the high-frequency currents of resonance or syntony (short-wave therapy) have in turn evolved from the high-frequency currents of quantity. This process has occurred as the result of instrumental development involving most difficult and intricate electrical problems, for the solution of which the aid of the electrical physicist is absolutely essential. Though these three forms of high-frequency currents merge one into the other by imperceptible gradation, the characteristic clinical and biological action of the three is widely different. The electrotherapist requires the assistance of the biologist to reveal the fundamental nature of these differences. But it is not only in reference to the high-frequency currents that this associated investigation is required; there are very many problems of electrotherapy that would be much advanced by the co-operation of the biologist and the physicist with the electrotherapist.

Surely the investigation of these problems is worthy of the consideration of the Medical Research Council. Would it not be possible for the National Physical Laboratory or some other body to assist us by demonstrating the relative merits of spark-gap and valve machines for the generation of short-wave high-frequency currents, and also to show us, as the result of their investigations, how the physical properties of high-frequency currents alter as the frequency increases and the wave-length shortens?—I am, etc.,

Oxford, Dec. 9th.

W. J. TURRELL.

Transport of Cases with Back Injuries

SIR,—In your account (*Journal*, December 1st, p. 1012) of the discussion on this subject at the meeting of the British Orthopaedic Association you mention that I supported the recommendation of Mr. McMurray, but you do not give my reasons. May I state them now?

In the first place, it is necessary to get rid of several misconceptions which seemed to vitiate the discussion.

(1) That a man injured in a coal mine is carried away by his companions just as he is, without being first put on a stretcher. (2) That fractured spine of the character under discussion is always liable to be complicated by injury to the spinal cord. (3) That a fall of rock or coal always doubles a man up, causing exaggerated flexion of the spine, which should be treated by hyperextension. (4) That fractured spine is an injury by itself, and is not accompanied by other injuries to ribs or limbs or pelvis.

The true facts are: (1) That there is *always* a stretcher at the coal face, and that the man is *always* placed on it before being carried to the ambulance room. (2) That injury to the spinal cord does not occur in more than one in ten of the cases. (3) That whether the man is doubled up or not depends on which part of the back is struck. If it is struck high up between the shoulders the man is undoubtedly doubled up, forced flexion occurs, and the twelfth dorsal or first lumbar body gives way, causing kyphotic deformity. But if he is struck low down in the lumbar region instead of being doubled up he is hyperextended, producing fracture of the third or fourth lumbar body with displacement forwards, the treatment of which should be flexion, not extension. (4) That fractured spine is very commonly accompanied by other injuries.

I supported Mr. McMurray in condemning the prone position at the coal face because of the above facts, and because, even if certain cases may be benefited by it, a large number of complicated cases will be rendered much worse, and a correct decision as to which position should be adopted can only be come to after a careful x-ray examination. I submit that the best first-aid treatment is to clear the rock and coal away, lift the man on to the stretcher in the usual manner, carry him to the ambulance room, and get him off to hospital as quickly as possible.—I am, etc.,

North Staffordshire Royal
Infirmary, Dec. 6th.

PAUL BERNARD ROTH.

Obstetrics in India

SIR,—I have read with interest the article in your issue of December 8th (p. 1060) on obstetrics in India, by Dr. Rufus Thomas, and should like to congratulate him on the energy and vivid language with which he describes the conditions in Jammu, which I fully believe he has not exaggerated. At the same time I should like to make a few further remarks.

The conditions Dr. Thomas describes were once universal, and still prevail in many parts of India, but efforts made during the past fifty years, and especially during the past twenty, have done something to mitigate them. It was these conditions which led to women medical missionaries opening work in India, and which caused Lady Dufferin to organize her fund for providing medical aid by women in 1885. Women doctors were brought out from England, training of nurses and midwives was begun, and, later, Indian women were admitted to the medical schools and colleges. In 1903 Lady Curzon organized a fund for training indigenous dhais, and in 1921 Lady Chelmsford a similar fund for maternity and child welfare. All these charitable funds were far too small for the purpose. In 1914 the Government for the first time made a grant to the Dufferin Fund, which made it possible to open a small women's medical service, and placed the relief of women on a sounder footing, although still a very inadequate one. Since 1915 modern child welfare has made its appearance in India, and there is now an All-India Bureau of Maternity and Child Welfare in connexion with the Red Cross, and with a medical woman as director. Infant welfare centres are multiplying, and ante-natal work is getting known. Seven training schools for health visitors are established in different parts of the country. The workers trained in these have a midwife's as well as a health worker's training. The endeavour is to plant them out in different areas under local bodies or charitable organizations to help mothers and infants, and especially to teach the indigenous dhais and keep their work under supervision, because it is now recognized that it is hopeless to expect illiterate women to carry out what they have been taught in the way of cleanliness and antiseptic when there is no public opinion to require it, unless they can be kept under supervision.

It would, of course, be better to replace these dhais by midwives of a better class, trained, and at least partly educated. This is being done successfully in some parts of the country, but in other parts there are almost insuperable difficulties. Women in the more backward areas prefer the dhai, and will not employ the trained midwife. Midwives, after training, tend to gravitate to the large towns, where fees can be obtained, and it is difficult to get them to work in small towns and villages. Then the class of educated women to draw on is small. True, as Dr. Thomas suggests, there is the class of Hindu widow, but only a proportion of this class is allowed to work, and they are much in demand for teachers and

nurses, both of which are more popular professions than midwifery. It must not be forgotten, in reviewing the causes of maternal mortality in India, that a great part of it is due to disease as well as to bad attendance. Osteomalacia is rife in some parts of the country, and pernicious anaemia in pregnancy is a frequent cause of death. Premature birth leads to much infant mortality.

It cannot be stated too strongly that, in spite of the efforts made, conditions such as Dr. Thomas describes are still prevalent over large parts of British India and the Indian States. It is impossible in a letter of this nature to go further into the matter, but it does seem as if, in spite of energy, hard work, and enthusiasm of workers, too little has been accomplished. The Government has too much taken the attitude that childbirth is a domestic subject not to be interfered with. It has left the campaign too much to charitable organizations, whose funds were not enough to deal with one-fiftieth of the country. Indian local bodies have shown themselves slack and uninterested; Indian women have not until quite recently been represented on them, nor had they formerly knowledge as to what was needed. Government, lately, has shown more interest, but there is still the attitude, as expressed by one Government officer some years ago, "Women's work is, of course, very desirable, but it is a luxury"—so to be dispensed with when retrenchment is needed. Many instances could be given.

What is needed is a much larger vision on the part of the authorities—a realization that the present conditions of childbirth not only cause untold suffering to hundreds of thousands of women, but that they handicap the rising generation with weakness and poor physique at a time when India particularly needs strength—mental and physical—for its people.—I am, etc.,

Upper Norwood, Dec. 11th.

MARGARET I. BALFOUR.

Surgical Diathermy for Cervicitis

SIR,—Mr. J. C. Ainsworth-Davis's article (November 24th, p. 935) on surgical diathermy for cervicitis must have aroused interest in a subject which is rather backward in this country. Having failed to get satisfactory results myself with medical diathermy, I was impressed by the writings of Hyams on his treatment with surgical diathermy. This was one of my reasons for deciding to visit the U.S.A. in 1931, and for starting a clinic at Charing Cross Hospital for the treatment on my return. There is a good deal to learn in this method, and I did not consider I had sufficient experience after four years' work to bring the subject to any very general notice, though I have referred to it in post-graduate lectures and medical addresses.

The soundness of the method lies on its pathological basis. A purely surface infection of a mucous membrane composed of compound racemose branching glands is a pathological impossibility, and in the case of the cervix uteri, like that of other mucous membranes, the idea of a "surface infection" is giving way to a more rational view. In the cervix uteri there is (1) a surface infection which gives rise to discharge and its sequelae; (2) interstitial infection of the deeper tissues which reaches up to the level of the internal os itself, and which is responsible for the metastatic symptoms in joints, etc.—an infection under tension of the tissues. It is this which all superficial forms of treatment fail to eradicate, and likewise trachelorrhaphy or amputation. Another aspect of the pathology is the bearing of the cervical infection on puerperal infections. I think the argument is incontrovertible that a great deal of puerperal infection does arise from an opening up of this infection in the process of labour, but as a lymphatic, not a surface, spread. I think a distinction has to be made between these cases and the mere carrier of streptococci in the cervix and its environment, whether they are haemolytic streptococci or not. The latter, I believe,

are in labour entirely harmless to the subjects themselves provided there is no local trauma of tissues, and in such cases I have proved it is safe to perform even a bougie induction of premature labour.

In quite a different category is the woman who has an infection of her cervical tissues (and they are far from uncommon). This type of case I treat with a modified surgical diathermy as late as the thirty-sixth week of pregnancy, and do not allow them to have their labour in the ordinary labour wards, because they are a risk both to themselves and to other patients. I think it is a failure to recognize this principle in pathology that is one of the weakest points in ante-natal work as often carried out. Many of these women have developed a natural immunity to their infection, so that their labour may be attended by nothing more than a morbid puerperium, provided there is no *locus resistentie minoris* caused by local trauma in the delivery. But I do not know of any means of distinguishing them from those in which a general infection from the lower uterine segment and its attendant sequelae will occur, as was shown by Whitridge Williams long before many of us were born. In technique it is important to avoid, as far as possible, removal of tissues deeper than the mucous membrane (and for this reason the "coniser" is better than a loop), otherwise the early result will be serious haemorrhage and the late result stenosis of the canal.

My experience of cases I did four years ago leads me to believe that it is very necessary to adopt measures to keep the cervix dilated for a time after treatment, otherwise severe dysmenorrhoea may occur as a late sequel. Dr. Agnes Savill has called attention to another point, and that is coincident infection of the corpus. This I believe should be dealt with in the first place before the cervical condition is touched, and I adopt the extremely simple manoeuvre of intrauterine injection of glycerin and mercurochrome—a modification of Remington Hobbs's principle—if there is any clinical evidence of infection in the corporeal part of the membrane. In conclusion, I should like to take this opportunity of expressing my thanks to the council of the hospital for purchasing for me the very expensive plant, and to my colleagues on the staff of the hospital for the opportunity of enlarging my experience by the study of their cases.—I am, etc.,

London, W.1, Dec. 10th.

EVERARD WILLIAMS.

Autotransfusion in Ruptured Ectopic Gestation

SIR,—In the *Journal* of September 8th (p. 470) Dr. M. W. Renton recorded a case of traumatic rupture of the spleen in the treatment of which autotransfusion was used. Whilst agreeing heartily with him that this procedure is at times of great and life-saving value, I should like to point out that indications for its use are necessarily limited. Its employment is at present almost restricted to cases in which safe blood can be recovered from the peritoneal cavity, with the possible exception of blood aspirated from the pleural cavity in cases of trauma to the thorax—and then only if the blood is uncontaminated by alveolar air.

It is obvious that intraperitoneal blood in cases of damage to liver, kidneys, or intestinal canal is unsafe: even more so would be blood that had passed through the vagina in cases of ante-partum and post-partum haemorrhages—suggested by Dr. Renton as suitable for this procedure. Happier indications, however, are haemorrhages in conjunction with splenic damage, some gynaecological operations, and above all with ruptured ectopic pregnancies. For the treatment of the urgent secondary anaemia following ruptured extrauterine pregnancy the method has been extensively used with excellent results.

It permits of a minimum of delay (the transfusion being carried out concurrently with the operation), the technique is very simple, and the effect rapid and satisfactory. Still, it is necessary to bear in mind that disasters have been recorded, and that autotransfusion should not be made a routine procedure even in ruptured ectopic, but be employed only when indicated by the patient's condition.

As an example of its use in gynaecology, may I mention a case of extensive myomectomy with severe blood loss. This operation can be performed with little loss of blood by using either a Bonney's clamp or a diathermy knife, but if neither of these is available it is a wise precaution to preserve and citrate the blood for return to the systemic circulation if the patient's post-operative condition suggests the need.

It may be of interest to record that some years ago I made some inquiries into the state of the blood in cases of intraperitoneal bleeding from ectopic pregnancies. With the assistance of a haematologist information was obtained that indicated that: (1) Fluid blood removed from the peritoneal cavity is, before citration, in a sufficiently normal condition to be safely used for transfusion. (2) The same blood after citration undergoes a lysis amounting to about 5 per cent. of its haemoglobin content, and is still a safe fluid for transfusion purposes. (3) The results of repeated van den Bergh tests showed that there was no breakdown of the red corpuscles after their return to the systemic circulation.

Whilst thoroughly endorsing the value of autotransfusion, it is, I think, necessary to repeat that, since no transfusion, auto- or hetero-, is entirely free from risk, the procedure should be used only when definitely indicated, and not as the routine it is tending to become in cases of ruptured ectopic gestation.—I am, etc.,

J. B. DAWSON,

Professor of Obstetrics and Gynaecology,
University of Otago, New Zealand.

Dunedin, Oct. 18th.

Maternal Mortality

SIR,—The *Journal* issues of November 24th and December 1st contain matter of great interest to all who are concerned about the question of maternal mortality (and how many of us are not?). The divergence of opinion expressed only serves to increase that interest.

Mr. Aleck Bourne's plea for the abolition of the pelvimeter will not, I imagine, receive much support. It has already drawn a reply in the negative from Professor R. W. Johnstone. I always looked upon the use of the pelvimeter as the first step in my examination of the pelvis, but always with the realization that the information gained was not "accurate" in the strict sense of the word. At the same time, any marked departure from the normal served as a warning to me to observe greater care in making my internal digital estimation of the size and shape of the true pelvis. That the external measurements, as determined by the pelvimeter, were normal did not make me consider that internal examination was unnecessary. Both are surely necessary steps in the same attempt to assess the size of the pelvis, and as such are to be considered jointly in the light of the total information derived therefrom. In regard to the intertuberischial diameter, I would much prefer to rely upon that obtained by a pelvimeter than trust to the "knuckle test," if compelled to choose between them. I should be very shocked if I thought that such an operation as Caesarean section might be performed on the findings of external pelvimetry alone, nor can I think that internal examination, which takes such little time, but yields such valuable information, is as neglected as Mr. Bourne would seem to suggest. Dr. W. R. Mackenzie, in supporting Mr.

Bourne, goes to the other extreme, and condemns all pelvimetry, whether metallic or digital, external or internal, saving only that afforded by the roentgenogram. I can pay no higher tribute to the value of *x* rays than to say that from about 1923 I made it a practice, whenever possible, to have at least two radiographs, one at eight months, the other as near term as practicable. In many cases earlier radiographs were taken as well. It is impossible to exaggerate the value of such a procedure, affording as it does such a variety of information. But all this should be taken in conjunction with the knowledge gained by the other methods of pelvimetry, and should not displace them. I would go so far as to say that no ante-natal examination is complete without these two radiographs. Incidentally, may not the time come when a disgruntled husband will sue an obstetrician on the ground that he did not have an *x*-ray photograph taken? If such an action could succeed in the case of a fracture, why not in the case of a pregnancy? The possibilities are enormous.

In the *Journal* of December 1st (p. 1010), in your report of the meeting of the Royal Society of Medicine, which discussed ante-natal care and the maternal death rate, Dr. T. J. Hollins is reported as believing it possible "to tell with exact certainty the presentation, size of child, relative size of head and pelvis, and internal measurements of pelvis by the aid of *x* rays, and that *x* rays should be used in all cases of primiparae and in those cases of multiparae in which there had been trouble in a previous confinement." My own experience leads me to agree with him. Later in the same account Dr. A. J. Wrigley is reported as having "crossed swords with Dr. Hollins over the value of *x* rays in ante-natal examination. Radiology was of little help, and the radiologist himself admitted it." It would be interesting to know how many obstetricians would subscribe to this view. And does the radiologist himself admit it? How many have done so, and on what grounds? And is radiology taken advantage of in ante-natal clinics to the extent that it ought to be? I doubt it.

In the same report Professor F. J. Browne's scheme for a whole-time maternity service does not appear to have received the support it deserved. In my humble opinion it is the best solution to the problem of maternal mortality yet put forward. His statement that admission to hospital often means treatment by a house-surgeon, often without supervision, is no more than the bare fact. He might have gone further, and said that the house-surgeon often had no more experience than that gained in his "twenty cases" as midwifery clerk during his hospital training. How many times during the course of this training is a student taught how to put on forceps, with the living subject as the model?

Dr. G. W. Theobald is reported, on page 1011, as stating, "as for the toxæmias of pregnancy, there was not the slightest evidence that ante-natal care could affect the death rate." I must confess I do not understand this statement. Perhaps Dr. Theobald will kindly state what he understands by the term "toxæmia of pregnancy," and what conditions he would include under the term. Would he include "hepatic eclampsia" or "nephritic eclampsia," or the form of hyperemesis gravidarum which is accompanied by such urgent signs as jaundice, albuminuria, and great prostration, and followed, if untreated, by coma and death? In all these conditions are found (post mortem) changes in liver and kidneys, suggesting grave toxic influences. Has ante-natal care no part in the early discovery of such conditions, and has treatment no effect on their course and ultimate result? In Dr. Theobald's account of the obstetric methods at St. Mary Abbots Hospital (*Journal*, November 10th) he states that eighty patients were admitted into the ante-natal ward

because of foæmic symptoms, and that all the mothers save three went out with living infants. In his case records he gives details of a patient with eclampsia who died, the liver showing the classical lesions. This would appear to have been a case of "hepatic eclampsia." The tone of this case record seems to suggest regret that she did not come into hospital ten days before, for he says, "she did not come into hospital until ten days later, during the whole of which time she had been ill." Was this a case of toxæmic eclampsia? If so, would her admission ten days earlier have made any difference to the result, if we accept Dr. Theobald's contention that ante-natal care has no effect on the death rate? Personally, I do not accept it at all. It would be of interest to know how many obstetricians would agree with such a sweeping assertion.—I am, etc.,

RUFUS C. THOMAS, F.R.C.S. Ed., M.C.O.G.

Newton, Porthcawl, Dec. 5th.

SIR,—I think that the time is now opportune to quote some figures of a large maternity hospital. During the last few months both the medical and the lay papers have contained numerous references to the maternal mortality from childbirth, and, although statistics are not a true indication of an institution's worth, they are the only means of conveying to those outside the results of the work carried out in the hospital.

Admissions into the Leeds Maternity Hospital are divided into two types—namely "booked" and "emergency." The former class consists of all patients who have made at least two attendances at the ante-natal clinics, and thus may include many abnormal obstetrical conditions. During the year 1933 there were 1,757 such admissions, and only one mother died. (This patient was admitted with an empyema following an attack of influenzal bronchopneumonia.) The death rate of the hospital's own booked cases was thus 0.595 per 1,000 live births—nearly nine times less than that of the country as a whole. Of the emergency admissions twenty-three women died, and of these eight were admitted after delivery. In the preceding year the "booked" maternal mortality was 1.3. These figures, including as they do over 3,200 deliveries, are, I feel sure, an excellent example of the value of large maternity hospitals; they also indicate that where such an institution shows in its report a maternal death rate far in excess of the average figure it is entirely due to the emergency admissions.

Another interesting point discovered in the records of last year's deliveries is that no fewer than 1,807 out of 2,073 mothers were given a general anaesthetic for the actual delivery of the child, and that in 689 cases an attempt was made to make the whole of the labour painless.—I am, etc.,

DAVID W. CURRIE, F.R.C.S., M.C.O.G.,

Nov. 26th.

Registrar to the Leeds Maternity Hospital.

SIR,—The debate on the above subject still rages in the medical and public press, and the utmost confusion prevails. There seem to be two aspects to the problem: the one of a general survey of total results over a period of years, and the other the personal one based upon personal experience.

In the *Journal* of November 24th (p. 948) is a report of a meeting at which the subject for discussion was "Has Ante-natal Care reduced Maternal Mortality?" Dr. G. F. McCleary, after some juggling with numerators and denominators, etc., is reported to have said: "With all these allowances, however, the figure for maternal mortality is intolerably high." It is practically certain that widespread ante-natal supervision during the last fifteen

years or so has not reduced maternal mortality as a whole, and to a logical mind it has therefore failed in its purpose. Theoretically, ante-natal supervision is sound practice, and the unpleasant results of it must be due to one (or both) of two reasons. Ante-natal care has been incompetent and the forecast of labour inaccurate, or the treatment of some supposed abnormality discovered ante-natally has been unfortunate in its results—in other words, the treatment was worse than the disease. There can be no question that ante-natal care, and also the conduct of labour, require a high degree of manual dexterity and practical skill in estimation. I do not think it impertinent to ask: "Can any examination, even the M.C.O.G., decide the practical worth and ability of a candidate?" If the reply is that no examination attempts to estimate practical ability—and I am led to that conclusion—then there is no diploma which qualifies a person to undertake ante-natal care or midwifery on a large scale.

With regard to any labour *per vias naturales*, a question yet to be decided is whether it is safer in the patient's own home or in a hospital. It is significant how often the haemolytic streptococcus finds its way into hospital cases. It is amazing what can be successfully accomplished in a patient's home under very bad conditions and a paucity of facilities. Great care should be taken in apportioning blame on a fatal case which has been transferred from home to hospital. I think it is very doubtful if any confinement is ever conducted without the mother being "infected" to some degree, and I think it is prudent to ask whether it is better for her to be infected with the organisms of her own home, to which she has had some opportunity of acquiring immunity, or to be infected with the organisms of hospitals, probably of a more spartan type, to which she may have no immunity.

I believe the act of transference often weighs heavily against the patient, and I note in the *Journal* a recent discussion on placenta praevia. Without taking sides as to treatment, it is significant that W. J. Young describes a series of cases (twenty) treated at home without a fatality, and J. Stanley Coleman quotes three cases ending fatally but all transferred to hospital. When investigating personal experience it is very difficult to prove or disprove anything by statistics. I noted that E. Lawton Moss struck a bad patch with concealed accidental haemorrhage. A single "snag" can spoil the figures of a general practitioner covering a period of years. The statistics of Dr. G. W. Theobald and those mentioned by Lawton Moss are excellent, and yet their respective techniques are widely different. The suggestion that a record of a temperature of 98.4° F. in the puerperium is pathological rather staggers one, as most people look upon a temperature of 99° or so after delivery as quite physiological—or shall I say, provocatively, defensive.

Mr. Bourne suggests that the pelvimeter should be abolished, but surely, it is not the pelvimeter that is wrong; it is the conclusion that is drawn from its use that matters. I was taught twelve years ago that it should only be used as a guide. Does Mr. Bourne seriously believe that the decision to do a Caesarean section is ever made on the findings of a pelvimeter, and that alone? With regard to the value of an internal examination, "obstetric specialists" seem to contradict each other, as with several other ideas in obstetrics, and naturally the general practitioner has to make conclusions for himself. The whole matter boils down to the fact that obstetrics is not a science but an art. A doctor can only become a craftsman in this art in the usual way—experience. On the question of experience Dr. Theobald's suggestion is right, though, so far as I can see, my four years' hospital experience in midwifery is of little advantage to me in general practice.

To conclude, I suggest, in view of the diversity of opinions on ante-natal treatment and its efficacy, that all ante-natal clinics should be converted into albumin-testing centres, and let the emergencies be dealt with when they arise.—I am, etc.,

Wembley, Dec. 2nd.

J. SHIRLEY CALLCUTT.

SIR,—Is it not time that serious attention was given to the comparability of the maternal mortality statistics? Professor Johnstone in his letter (*Journal*, December 1st, p. 1014) suggests that another era of "national hysteria and panic" is upon us. It is universally agreed that crude death rates may mean nothing, yet (so far as I am aware) no serious attempt has been made to "correct" the maternal mortality rates for the purposes of comparison between one area and another. Amongst other factors crude death rates should be "corrected" for primiparity and for extreme multiparity. Furthermore, the steadily advancing age of child-bearing mothers and of primiparae especially ought to be regarded. Examination would show that there is a higher puerperal mortality among child-bearing women over 35 years of age.¹

I suggest that social changes of the last twenty years are such that we ought to expect a rising crude maternal mortality. If it is stationary, that indicates an improved obstetric service. If Sunderland shows better "crude" rates than Bournemouth, may it not be that the corrected or standardized rates for these areas would reverse the position? I imagine that primiparae and small families are as common in Bournemouth as the reverse is common in Sunderland. This is a matter of more than academic importance. It affects the morale of child-bearing women and the morale of the profession. Moreover, "blunderbuss" methods of seeking a cure are likely to be very costly and very futile. Consider, also, the effect of puerperal sepsis upon crude rates of maternal mortality. Sepsis is an infectious disease, and will not be greatly controlled by "clinics" *per se*. In some areas the maternal problem is sepsis. In that case "hospitalization" is dangerous. Puerperal sepsis rates rise and fall with the prevalence of certain streptococcal epidemics. This point may be checked statistically.

The whole matter is much too complex and too important to be dismissed lightly. Cannot a careful statistical inquiry into puerperal death rates be made and a serious effort to "standardize" them be instituted?—I am, etc.,

HOWARD E. COLLIER,

Department Industrial Hygiene and
Medicine, Birmingham University.

December 5th.

Anaesthesia in Maternity Cases

SIR,—Dr. Arthur Campbell's letter on the above subject in the *Journal* of December 1st (p. 1016) is very much to the point. For many years I used an almost precisely similar home-made apparatus. I usually started the anaesthesia, and later gave the bulb to the patient to compress by her own hand. Patients know at once when they feel the oncoming signs of uterine contraction, and by a few squeezes of the bulb procure for themselves the slight unconsciousness which tides them over their pains without in any way interfering with the progress of delivery. As soon as they have had the requisite amount of chloroform their hand automatically relaxes its hold. The practical answer to this method is that in over thirty years' experience I never had a death or a complication in any way attributable to chloroform.

What a simple and safe process this is compared with the cumbrous apparatus, even though it has been whittled

¹ "Social Changes and Maternal Mortality": H. E. Collier, *Journ. Obstet. and Gynaecol. British Empire*, 1930, xxvii, 27.

down to 15 lb. weight, that is now being brought into vogue! As Dr. Campbell says, if you begin with small doses and very gradually increase there is no danger at all. This method permits the accoucheur to give his whole attention to the perineum and the other management of delivery with only a mere glance at the patient. If she has not got enough she will very soon make it known, and if she has, her hand will be lying idly beside the uncompressed bulb.

No drug has yet been invented that will beat chloroform as a safe and efficient anaesthetic agent in midwifery, if properly administered in the way indicated by Dr. Campbell.—I am, etc.,

Edinburgh, Dec. 3rd.

G. D. G.

Medical Benevolence

SIR.—No one having questioned the fact that those lay men and women who are intimately associated with the administration of the affairs of the medical profession have a moral right—nay, duty—to give their support to the Royal Medical Benevolent Fund, it may be asked, How can this be accomplished?

It could be very successfully done by the formation of a lay associates' guild, open to those whose salaries range from £250 a year upwards. There are, I believe, some 2,000 men and women working in the hospitals, colleges, schools, and research institutes of this country who would, I am confident, be only too happy to be given an opportunity of assisting to lighten the burden of the doctor and his dependants, upon whom—such being the nature of his duties—tragic misfortune all too frequently falls. A graduated subscription from this source should produce at least £1,500 a year—a very useful addition to the revenues of the Royal Medical Benevolent Fund. Incidentally, it would mean to the subscribers only the smoking of one packet of cigarettes a week less for the men and a theatre seat or a bottle of perfume less once a month for the women.

To limit subscriptions to those who have taken the Hippocratic oath does not seem right in these days when there is so much distress about. Furthermore, the sister professions of law and theology have in recent years both opened their doors to outsiders.—I am, etc.,

London, N.W.3, Dec. 8th.

"FAIR PLAY."

Discoverer of Cortical Rhythm

SIR.—Some recent newspaper articles have given a sensational account of the investigations which we have made in Cambridge on the electrical changes taking place in the cerebral cortex. In these articles we are deeply concerned to find ourselves credited with the discovery of the rhythm which can be detected from the human brain by electrodes applied to the scalp. This is an important discovery, but it was made six or more years ago by Professor Hans Berger, director of the Psychiatric and Nerve Clinic at Jena, and has already formed the subject of eight papers by Professor Berger.

We have repeated and confirmed many of Berger's observations: our interpretation of the rhythm differs in some respects from his, but we wish to make it clear that our own work is of recent date and is in the main confirmatory, whereas Berger has already made a detailed study of the cortical rhythm in a very large number of cases, and has shown the effect of mental work, external stimuli, sleep, drugs, etc. We hope that a forthcoming paper by us, in *Brain*, will remove the impression that we are in any sense the discoverers of the Berger rhythm, and of its modification by mental processes.—We are, etc.,

E. D. ADRIAN.

Physiological Laboratory,
Cambridge, Dec. 3rd.

Obituary

LORD RIDDELL

Lord Riddell died on December 5th. The event has called forth an immediate volume of unqualified appreciation of his work and character, and a testimony of widespread affection such as rarely marks the passing of a public man. No doubt this manifestation is partly due to the fact that his was such an outstanding figure in the sphere of journalism and in the newspaper world. Lord Riddell's interests were, however, very varied, and none of them was superficial. Not least among them were those on the fringe of the profession of medicine—medical charities, medico-legal matters, and other subjects of a medico-sociological character. His loss will be severely felt, not merely by many members of the medical profession with whom he was on terms of individual friendship, but by numbers of others who appreciated very highly his sympathetic interest in their affairs, and who must now feel that a valuable influence and link between the profession and certain spheres of public life has been severed.

Born in 1865, Lord Riddell died in his seventieth year. It is during his last decade that his interest in these medical matters has been so definite, and that recognition of this interest has been so marked. Since 1925 he has been president of the Royal Free Hospital, and since 1930 the chairman of the London Voluntary Hospitals Committee. From 1930 to 1933 he was president of the Medico-Legal Society. In its Centenary year (1932) the British Medical Association elected him an honorary member, and about the same time he became an honorary Fellow of the British College of Obstetricians and Gynaecologists. In none of these spheres did he take his office as a sinecure, and to none of these honours was he indifferent or unappreciative. His interest was active and his work was hard as president or chairman. Especially will the Royal Free Hospital feel his removal. One evidence of his connexion with this institution was his short biography of Dame Louisa Aldrich-Blake. He is said to have himself given some £100,000 to the hospital, and it was through his influence that the late Mr. Eastman gave £220,000 for the foundation of the dental clinic associated with it. But beyond this it may be said to be his beneficent zeal and his organizing ability and business acumen which have raised the Royal Free Hospital to its present high position. He was really proud of his honorary membership and fellowship of medical associations and colleges, and used to declare (after dinner) that they brought him fame, especially as an obstetrician, and requests to take an active and responsible share in the practical daily work of his new profession. As a member of the British Medical Association he did not fail to wear his badge on appropriate occasions, and at least once he insisted on attending a meeting of the Division of which he was, by residence, a member.

There is no need to repeat here the details of Lord Riddell's achievements in other spheres. Without any of what are usually regarded as youthful advantages, his career was, almost from the beginning, an outstanding success, first as a solicitor, especially with regard to Private Bill legislation; then as a journalist and newspaper proprietor, notably in the case of the *Western Mail* and the *News of the World*; then as controller of a great publishing firm, George Newnes, Ltd.; then, both during the war, the peace negotiations, and the Washington Naval Conference, as Press liaison officer and publicity agent, performing a great national service. His work in these matters is recorded in a delightful and interesting

manner in his recent volumes the *War Diary* (1931), the *Diary of the Peace Conference and After* (1933), and *More Pages from My Diary*, dealing with the pre-war period and published this year.

Lord Riddell's was a most attractive personality—simple, shrewd, helpful, kindly. In conversation he was always interested and interesting, and became one of the most welcome after-dinner speakers. His baronetcy came to him most deservedly in 1918, and his peerage in 1920. He leaves a widow, but had no children.

ROBERT FLETCHER MOORSHEAD, M.B., B.S.

Medical Secretary, London Missionary Society

We regret to announce the death, at the age of 60, of Dr. R. F. Moorshead, who was for more than thirty years the medical secretary of the London Missionary Society. Born in Bristol in 1874, he obtained his medical education at the Bristol Medical School and at St. Bartholomew's Hospital. He graduated M.B., B.S. Durham in 1898, taking the conjoint diploma a year later, and the F.R.C.S. in 1903. We are grateful to a correspondent ("G. B. P.") for the following account of his missionary and other activities.

From the days of Livingstone the annals of medical mission work abroad have a roll of honour, increasing in length, of medical men and women. These, so well qualified to win high positions in their profession, devoted themselves and their talents to the outstanding needs of far distant races and peoples, by whom the blessings of modern medicine and surgery were almost unrealized, and whose lives still needed the moral and spiritual inspiration of the Christian faith. On such a roll Fletcher Moorshead's name should surely be placed, though the sphere of his life lay mainly in the home country. For over thirty years he spent his life on behalf of the Medical Mission Auxiliary of the Baptist Missionary Society; an auxiliary which, in association with the late Dr. Percy Lush and the late Sir Alfred Pearce Gould, he helped to found in 1902, and for the remarkable growth of which he was mainly responsible since that time. So striking has been the interest and support that Moorshead elicited throughout the Baptist community that there are now established in India, China, and Africa sixteen hospitals with 900 beds, and a staff of thirty European and eleven native qualified doctors, assisted by thirty-four European nurses and 234 native hospital assistants and nurses. Tremendously keen on his professional work, and hoping at one time to spend his life in the foreign field, he realized, shortly after qualification, the need of his Society's Home Base in the formation and development of its medical department. For this object he readily sacrificed his personal and medical ambitions, to assume the arduous, exacting, and meticulous work of medical secretary.

As already indicated, his success in this sphere has been widespread and permanent, and his life's labours and influence find a lasting record in the creation and development of hospital buildings and centres of healing in many lands. On behalf of his Society and work he visited India in 1905-6, and China in 1919-20, and many recall the inspiration which he left behind when making these tours. His writings mainly dealt with medical mission subjects. He was the author of *The Appeal of Medical Missions*; *The Way of the Doctor*; *Heal the Sick*; *25 Years of B.M. Missions*; and edited, in recent years, *Conquest by Healing*, a monthly journal. Latterly his health had given rise to anxiety, and he was expecting to retire in two years—after thirty-five years' service—but, following a recent strenuous round of public engagements in Scotland, he suddenly developed double pneumonia, and despite all remedial efforts he passed away,

after a week's illness, on December 4th, leaving a widow, with whom widespread sympathy will be felt.

Fletcher Moorshead's memory will be treasured, not merely for what he accomplished, but also for his personality. He never considered himself—generous to a fault when any effort or help was sought from him; of a friendly and sociable disposition, which secured for him friends wherever he went, he was also an effective public speaker in the cause so close to his heart. He has lived, and with success; he leaves a world strengthened by his presence, his ideals, and the memory of a life devoted to the highest ends.

ALEXANDER ARTHUR MACKEITH, M.B., C.M.

On December 5th the medical profession in Southampton lost one of its best-known and honoured members by the death, in his 69th year, and after a long illness, of Dr. A. A. MacKeith. Dr. MacKeith, who graduated M.B., C.M. at Glasgow in 1887, came of a family of doctors. He practised for some years in Exeter and Ilfracombe before he settled in 1900 in Southampton, where he conducted a successful practice for many years.

An energetic and practical man, he was always in the forefront of the most important affairs of the profession, both locally and nationally. He saw the importance of a strong, representative professional body, and devoted years of a busy life to the British Medical Association, which he served as a representative of the Southampton Division, and as president of the Southern Branch (1921-2). To his credit stands the inauguration of such important institutions as the Southampton Public Medical Service, one of the pioneer schemes and now a model for numerous similar services, and the Hospital Contributory Scheme in Southampton, for whose constitution and inception he was mainly responsible—he remained its vice-chairman until his death. He was chairman of the Committee of Management of the Free Eye Hospital for ten years, and remained on the committee till his death.

Dr. MacKeith was a surgeon major (T.), and was attached to the Heavy Brigade, R.G.A. During the war he was P.M.O. Troops, Southampton, and medical officer to the prisoner-of-war camps. It is characteristic of his energy that within a few hours of the outbreak of war he had organized and launched a medical war emergency committee, which arranged for the conduct of the practices of doctors on active service. His work in this respect was gratefully acknowledged by his fellow practitioners, who showed their recognition by presenting him with an illuminated address and a silver salver. He took a keen interest in the work of the St. John Ambulance Brigade and Association until his death. A man of logical mind, with a keen insight and the power to take the long view, MacKeith was a good and just negotiator, a man whose integrity was his most outstanding virtue, coupled with cautiousness and gentlemindedness, round which all other manly virtues fitly clustered—a friend and counsellor, whose loss is deeply felt by his patients, his colleagues, and his fellow citizens.

He leaves a widow and ten children, with whom the deepest sympathy is felt. Four of his sons are doctors, who, as they reached years of maturity, have achieved success in the profession.

THE LATE DR. STRICKLAND GOODALL

"A JUNIOR COLLEAGUE" writes: Dr. Strickland Goodall's early death must be largely due to the self-sacrificing devotion with which he worked unceasingly for the benefit of others. With all his being he gave of his best: to his profession, his patients, his colleagues, and to all and sundry, who never spared him in their anxiety to gain from him that help—for physical or mental

ills or ignorance—which was always so abundantly offered. His courage and indomitable will would not spare himself; his skill and knowledge (a generation in advance of his time), enthusiasm and sympathy made him continually and self-sacrificingly give all. We who have had the privilege of knowing him will always treasure a very blessed memory of this unassuming and most beloved physician. His contributions to medical knowledge are so well founded that they will stand the test of time. Doubtless there will also be raised some tangible memorial that shall spread farther and to future generations the benefits of his teaching.

We learn with great regret of the death, on December 5th, of Dr. EDWIN FITZGERALD O'CONNOR of Bessbrook, Co. Armagh. Born in 1889, the son of the Rev. D. Hamilton O'Connor, rector of Newbridge, Co. Kildare, he was an exhibitor of Trinity College, Dublin, and graduated B.A. in 1910 and M.B., B.Ch., B.A.O. in 1912. As an undergraduate he played hockey for his university and for Ireland. After holding house appointments in Victoria Central Hospital and Wallasey Dispensary he joined the R.A.M.C. in 1914, served with distinction in Gallipoli and France, and was awarded the Croix de Guerre by the French Government. After demobilization in 1920, he commenced practice in Bessbrook, and some two years later was appointed medical officer to Daisy Hill Hospital, Newry. Here he found the opportunity for the practice of surgery, to which he brought a natural aptitude and skill combined with a sane enthusiasm. During his all too short tenure of this office he made the hospital a surgical centre for a large district, and gained to an extraordinary extent the confidence and trust not only of his colleagues, but of the general public. Dr. O'Connor was a member of Portadown and West Down Division of the British Medical Association, and a Fellow of the Ulster Medical Society. He was an enthusiastic Freemason, and dearly loved a day with the Newry Harriers. He married in 1915 Miss Evelyn Morris of Ruabon, Denbighshire, who has nursed him with courage and devotion during a long and painful illness bravely borne. There are three daughters and one son of the marriage.

We regret to announce the death, on November 25th, in his seventy-sixth year, of Dr. P. F. STURRIDGE of Chippenham, Wilts. Dr. Sturridge was born in Jamaica, and came to school in England at the age of 14 years. He received his medical education at Middlesex Hospital, and was a contemporary of the late Sir Henry Morris, Dr. Sidney Coupland, and Sir John Bland-Sutton. He obtained his M.R.C.S.Eng. in 1881 and his L.R.C.P.Ed. in 1882, and was Prosecutor to the Royal College of Surgeons and house-physician to the Middlesex Hospital. Starting in general practice in Kendal about 1884, he remained there for nearly forty years. He specialized in surgery and ophthalmic work, and was on the staff of the county hospital. A skilful and safe surgeon, he had to tackle everything that came along—sometimes in the most out-of-the-way places. His skill with cataract operations gained him the reputation of a miracle-worker in some of the isolated hamlets among the Westmorland fells. His only contribution to medical literature was a book on the eyesight of school children, and he used to predict that electric light would put the whole nation in spectacles. He was surgeon to the North-Western Railway, and a keen lecturer and examiner to the St. John Ambulance Association. He had been a member of the British Medical Association for twenty-six years, and was the first secretary of the Kendal Division, an office he held for eleven years. During the war he was surgeon to the local war hospital. After the war he returned to Sutton Benger, near Chippenham, with a small practice, and was soon the centre of the Church and social life of the village. On the death of his wife, three years ago, he gave up his home, and spent his winters in Jamaica and his summers in Yorkshire and London. He is survived by a married daughter in Yorkshire and a son practising in London.

The Royal Society of Medicine has suffered an irreparable loss by the death, in the Brompton Hospital, on December 4th, of its esteemed librarian, Mr. H. E. POWELL, after a trying illness which lasted many months. Mr. Powell was respected and loved in a degree which few persons in his profession attain. He was a learned man, and on every occasion unstintingly placed his personal knowledge at the disposal of all workers in the great library over which he presided with such efficiency, and by his example he materially raised the standard of medical bibliography in this country. He was a man of peculiar modesty and self-effacement, disliking intensely to be in the limelight, but devoting his whole energies to the perfection of his library and to the interests of the Royal Society of Medicine, of which he was such a loyal servant. I knew Powell for twenty-seven years, first as assistant in the library then as chief librarian, and I cannot recall an instance in which we differed, either on a question of policy or practice. I have known no one more affectionately spoken of nor one whose illness aroused such sympathy from the most highly placed members of the medical profession. His life was uneventful. Hubert Edward Powell was born at Twickenham in 1881, the son of a business man well known in that town. He went to school at Malden, and early showed the habits of the student and scholar. He entered the Royal Society of Medicine as an unpaid library pupil and gradually mastered the intricacies of the business under Sir John Y. W. MacAlister, whom he ultimately succeeded as librarian in 1920. In the course of years Powell acquired a very wide knowledge of practical medical librarianship, and his help was daily sought by, and daily given to, medical authors, inexperienced or learned. Powell was a born librarian, and had all the instinct for a successful career in his chosen work. Outside his medical work he was a wide reader of history, and he had an extensive and critical knowledge of the early British dramatists. His scholarship gained his election to the Fellowship of the Society of Antiquaries. Powell was also a mechanician, and spent his lonely bachelor evenings in the harmless pursuit of horology, until he became an expert in the construction of complicated watches and clocks. Powell was a fine character. He asked for nothing, he expected little, he gained much; and he will long be remembered in medical circles as an unselfish man who never turned a deaf ear to a request and one who attained to a high position in his profession.

WILLIAM BULLOCK,
Honorary Librarian, Royal Society
of Medicine.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Faculty Board of Medicine has appointed Dr. G. S. Graham-Smith, Dr. A. N. Drury, and Mr. W. H. Bowen to be members of the M.D. Committee until September 30th, 1935.

UNIVERSITY OF LONDON

The following have been recognized as teachers of the University in the subjects indicated in parentheses:

University College: Dr. Archibald Durward and Mr. John Kirk (Anatomy).

St. Thomas's Hospital Medical School: Mr. Roland H. Beggon (Surgery).

London (R.F.H.) School of Medicine for Women: Mr. Claude W. Morris (Anaesthetics).

St. Mary's Hospital Medical School: Mr. Gerald L. M. McElligott (Venereal Diseases); Mr. William C. W. Nixon (Obstetrics and Gynaecology).

The degree of Ph.D. in pathology has been conferred on Mr. William A. Gray, F.R.C.S.

Professor W. Langdon Brown has been appointed governor of the Harpur Trust, Bedford.

At the celebration of Foundation Day, on November 22nd, the following degrees were conferred:

M.D. (*honoris causa*).—Sir Edwin Cooper Perry.

D.Sc. (*honoris causa*).—Professor Karl Pearson, F.R.S.

CONFERENCE FOR MEDICAL OFFICERS IN INDUSTRY OVER-SEAS

It has been felt for some time that sufficient opportunity has not been given to medical officers in industry over-seas to exchange views on the various problems peculiar to their particular industries and to the areas where they are practising. It is proposed to hold at the London School of Hygiene and Tropical Medicine an annual conference, lasting for two days, in order that medical officers in industry on leave from the Tropics may be able to meet their colleagues and discuss their problems. The main subject for discussion will be the prevention of disease—for example, control of malaria and epidemic diseases in the Tropics; water supplies; sewage and refuse disposal; housing; the keeping of records; and hygiene generally. It is considered that the contacts made at the annual conferences will not only be of value to medical officers attending, but will also establish contacts between these medical officers and the staff of the School. All medical officers practising on plantations, mines, railways, hydro-electric and construction schemes, and development companies generally will be welcomed. The conference each year will be held in July, and medical officers who would like to attend are invited to apply to the organizing secretary, Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examinations indicated:

FINAL M.B., CH.B.—Part I, including *Forensic Medicine and Toxicology*: Monica Hawkins, *B. Isserlin, J. S. W. Little, †N. R. Matheson, E. Philipp, L. A. Schnipelsky, E. Want, E. L. Ward. Part II: †Marion L. Tryon, R. D. Bodman, J. N. Heales, F. J. W. Lewis, A. J. Matheson, Mary G. Thomas. Group I only: H. James.

M.D.—J. C. Batt.

* Distinction in pathology.

† Distinction in materia medica, pharmacy, pharmacology, therapeutics, and forensic medicine and toxicology.

* Second-class honours.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following candidates have been approved at the examinations indicated:

FINAL MEDICAL EXAMINATION, PART II.—(*Medicine*): *H. D. O'Brien D. J. Bradley, Doris E. Morton, T. D. O'C. Donelan, C. J. Vaughan, H. M. Glover, H. A. Wells, J. Sorett, P. O'Brien, R. I. Shier, A. R. S. Jessop, F. J. B. Convery. (*Old Regulations*): C. O. Greer, H. S. J. van Niekerk. (*Surgery*): *H. D. O'Brien, Doris E. Morton, Mary E. Mansfield, Marie J. S. O'Toole, A. C. Pilkington, H. A. Wells, I. A. Walsh, Sheila K. Henderson, H. S. J. van Niekerk, J. F. Q. Conolly, T. D. O'C. Donelan, A. R. S. Jessop, J. F. Harbinson, P. O'Brien, C. O. Greer, D. J. O'Shaughnessy, S. M. Freedman. (*Midwifery*): J. N. P. Moore, J. T. Wellwood, M. Marmelstein, D. G. Walker, J. C. Gaffney, R. H. Pratt, J. R. Shapiro, L. W. McCaughey, J. R. McElroy, D. P. Burkitt, H. C. Bourke, R. L. Oakes, F. J. C. Loughran, R. C. O'Grady, G. W. M. Elliott, H. Pringle, E. S. Dorman, J. R. Kellert, Muriel E. Wallace, Maureen C. E. Gore-Grimes, R. A. Bond, P. X. O'Dwyer.

M.Ch.—J. E. Ellison.

* Passed on high marks.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS
OF GLASGOW

At the monthly meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, held on December 3rd, the following were admitted Fellows of the Faculty: John Glaister, M.D., Farquhar Grace, M.B., C.M., David Lamb, M.B., C.M., William Thompson Wotherspoon Paxton, M.B., Ch.B., Horace Minton Shelley, M.R.C.S., L.R.C.P., D.T.M. and H., Hans Stubbe, M.B., B.S.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At the monthly meeting, on December 7th, the following were admitted as Licentiates in Medicine and Midwifery of the College under the conjoint scheme with the Royal College of Surgeons in Ireland: G. F. Adye-Curran, J. H. Armstrong, Margaret Corbett, E. J. Crowe, A. J. Crummie, P. B. Cusack, P. O'D. Gallagher, N. B. May, J. C. McFeely, Margaret O'Connor, J. O'Leary, J. F. Sutcliffe.

The Captain Massy-Miles Prize, 1934, was not awarded, as there was no candidate eligible for such award.

The representative of the College on the General Medical Council reported on the recent proceedings of the Council.

The representative of the College on the Medical Registration Council of Saorstát Éireann reported on the recent proceedings of that Council.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The report of the Joint Select Committee on the Government of India was debated this week in both Houses of Parliament. In the House of Lords the Registration and Regulation of Osteopaths Bill was read a second time after a debate reported below.

In the House of Lords on December 5th Lord Merrivale presented the Matrimonial Causes (Procedure in Suits for Nullity) Bill and the Matrimonial Causes Amended Procedure Bill, which were read a first time. Lord Sankey, the Lord Chancellor, presented a Supreme Court of Judicature (Amendment) Bill, one of the objects of which is to provide for the hearing *in camera* of certain evidence in nullity cases.

Regulations for the relief of able-bodied unemployed, who are not entitled to unemployment insurance benefit under the Unemployment Act, and for their families were laid on the table and will be debated by the House of Commons next week. These regulations provide for exemption or partial exemption of sick pay, national health insurance benefit, maternity benefit, or wound and disability pensions as laid down by the Act. The allowances for children are graded according to the age of the child.

A Bill to confirm a Provisional Order relating to the Guisborough Joint Small-Pox Hospital District was read a first time in the House of Commons on December 11th.

On December 10th, in the House of Commons, Sir John Gilmour introduced the Metropolitan Police (Borrowing Powers) Bill. The measure extends the power of the Receiver for the metropolitan police district with respect to the borrowing of money for the provision of better accommodation for the metropolitan police force.

Registration of Osteopaths Bill

In the House of Lords, on December 11th, Viscount ELIABANK moved the second reading of the Registration and Regulation of Osteopaths Bill. The Bill, he said, was to secure the compilation of a register of osteopaths and to regulate the practice of this new system of therapeutics in this country. It also sought to impose on the practitioners of the system a prescribed standard of professional training and competence. Medical law as it now stood impeded the development of an independent system for the treatment of disease, such as osteopathy claimed to be. The prime object of the Bill was to remove the disabilities which attended the work of genuine osteopaths. Under the Bill a statutory board would be set up which would keep a register of qualified osteopaths and would supervise admission to the register. The Board would have power to prescribe a course of study which would qualify for the practice of osteopathy. The Bill contained nothing that would enable an osteopath to gain admission to the medical profession, and osteopaths did not ask to be admitted to the profession. They asked to be admitted to an osteopaths' register, and that only qualified osteopaths should be registered. He urged that the Bill should be read a second time and sent to a Select Committee.

The Medical Act and the Bill

LORD MOYNIHAN, in moving the rejection of the Bill, said that it involved the negation of all the principles embodied in the Act of 1858. That Act enabled every person to discriminate between those who had and those who had not passed through the medical curriculum, between the qualified and the unqualified practitioner. It received its inspiration from a desire for the protection of the public against certain dangerous people who had undergone no medical training in those fundamental sciences on which medicine was for ever based. The Bill would set aside all the defences erected for the protection of the public, and which had been shown to be necessary. If one particular theory of medicine were guaranteed recognition contrary to the Act of 1858 it would

not be long before other cults made appeals for recognition. If osteopaths were at last recognizing that a formal medical training was essential before they might successfully practise their art, there was nothing to prevent them from passing through the present medical curriculum. The Bill embodied an endeavour to destroy the unity of medicine and to force on the public, which was unaware of the danger, a spurious science which set aside the accumulated wisdom and expert practice of centuries. The Bill sought legislative authority for a theory of medicine which had in no country proved its validity.

Lord GAINFORD and Lord ERNLE supported the Bill, the latter remarking that at present any qualified medical practitioner who associated himself with an osteopath was placed under a ban. The Royal College of Physicians, therefore, stamped the osteopath as a quack or a charlatan almost indiscriminately.

A Question of Principle

Lord DAWSON OF PENN pointed out that the Bill raised an important question of principle. There were certain callings for which, by long custom or statute, a certain prescribed course of training was laid down. He would take three: the law, the master mariner, and medicine. The first course of training was preparatory and preliminary, for the purpose of securing that people entering those callings should have adequately trained minds before they were vocationally educated. Supposing a body of people said that it wanted to train persons for the Bar, and do it in its own way, without reference to the existing system, or another body said it had a suitable way of training captains of Atlantic liners, and asked for the same status as was given by the Board of Trade certificate, what would be the answer? He thought it would be an emphatic negative; and why should there be any difference in the case of medicine, which had a grave responsibility for human life? In the medical profession there was complete liberty of thought. Many doctors who had been trained for the medical profession practised osteopathy, and did so successfully. What the medical profession said was, that the osteopaths must go through the medical training, and then they would be free to do what they liked. There must be the background of preliminary, non-vocational training to make the trained mind, and it was only when the medical schools were satisfied with the basic training of the student that the latter were permitted to enter on the vocational part. During five years the medical student had to live laborious days, and the majority required further training afterwards. Diagnosis was the keystone of the arch of a medical training. There could be no giving way on the essential point, that knowledge of diagnosis must precede the power to direct and guide treatment. The Bill would merely give a short cut to people who wanted to acquire, through its provisions, the status of doctors. If that kind of training were to be allowed to displace the scientific training, which could only be built up by years of experience, if any short cut or backdoor entrance were allowed, the whole fabric of the efficiency of the healing art would be brought down from the level to which it had taken years to build up. Doctors were prepared to treat osteopaths as co-workers, but not to give them equality of status in the science of medicine, for which they had not had a proper training. For osteopathy to have the status of medicine without the training in pathology would be a public danger. Good as osteopathy was in the proper direction, it could be a perfect terror and a tragedy, as he himself knew. Manipulative treatment had a valuable place, but if an osteopath, as this Bill suggested, assumed the status of the highly trained doctor it would be very much against the public interest.

Lord AMPHILL said that Lord Moynihan had used language of exaggeration such as had never been heard in that House before. Midwives, dentists, and others had been registered, and no irreparable calamity had resulted. Lord MOYNIHAN replied that they had no objection to registration. Lord AMPHILL said that Lord Moynihan had been objecting all the time. The medical profession was the most jealous trade union in the world, and the General Medical Council had obstructed, resisted, and derided a great many advances in medical science. Lord Moynihan would have them believe that medical science to-day depended on some immutable principles laid down with all the force of a divine law. Every year, however, they heard of new practices which

were at first objected to by some medical men, but afterwards adopted. He hoped the House would not put itself into the false position of refusing to this profession the necessary protection, and also the necessary measure of protection to the public.

Issue of Death Certificates

Lord HEWART said that the Bill would allow an osteopath to issue death certificates. As a lawyer he was staggered by that proposal. The Bill went far beyond what any reasonable osteopath should properly desire.

Viscount GAGE, replying to the debate, suggested that they should compare the position of the ordinary member of the public to-day with what it would be under the Bill. There was nothing to-day to prevent an osteopath from treating a patient and receiving a fee for doing so. A patient might have a complaint with which an osteopath was specially competent to deal, but if he had something more deep-seated the osteopath might have no qualifications for diagnosing that. If the Bill became law the patient would be protected from the absolutely ignorant practitioner, but his complaint would still be diagnosed by somebody who possessed a good deal less than the minimum qualifications at present. That would be done under the blessing of the Ministry of Health, and if things went wrong the patient would have some grievance against the Ministry. What justification would the Ministry of Health have for putting the public in the dilemma of having to decide between two rival schools of medicine? If the House agreed to this Bill it would be countenancing the treatment of persons by partially qualified doctors.

The second reading was carried by 35 votes to 20, and the Bill was referred to a Select Committee, with full powers to call witnesses.

Health Conditions in Grenada

Replying to Mr. William John, on December 5th, Sir PHILIP CUNLIFFE-LISTER said health conditions in Grenada were, generally speaking, satisfactory. The latest reports available showed that the death rate of 13.8 per 1,000 in 1932 was the lowest on record. As regards tuberculosis, thirty-six new cases were notified in that year and forty-six deaths. The erection of a new and improved tuberculosis hospital was recommended recently by a medical commission appointed to report to the Governor of the Windward Islands on the medical services there. Sir Philip could trace no information concerning any malnutrition in the schools. As a result of school inspection 85 per cent. of the children were considered to be healthy. A Government grant of £100 to the Maternity and Child Welfare League in Grenada was deleted from the Grenada Estimates in 1933 owing to financial stringency, but in 1934 this grant, some portion of which was understood to be applied to milk distribution, was substantially restored. In accordance with the recommendations of the 1932 Poor Relief Commission, the poor asylum buildings were enlarged, a casual ward was provided in the vicinity of the Government hospital, and the nurses' quarters at the asylum and its sanitary arrangements had been improved. His approval was being given to the adoption, as from January 1st, 1935, of a simplified and more expeditious procedure for the granting of poor relief. In housing conditions there was still room for improvement.

Food and Health

Dr. J. B. ORR, director of the Rowett Institute, Aberdeen, addressed the Health and Housing Committee, at the House of Commons on December 5th, on human nutrition. Sir FRANCIS FREMANTLE took the chair. Dr. Orr said many believed that the full application of recently acquired knowledge of the effect of food on health would lead to a reduction in disease and an improvement in health and physique. Application of this new knowledge was hampered by the present world-wide unemployment and reduced purchasing power. As the latter fell total consumption decreased, and consumption moved to cheaper foodstuffs such as sugar, bread, and margarine, which satisfied hunger but were not adequate for health. There was evidence that malnutrition tended to increase in all large industrial countries, and measures were being taken to combat it. The United Kingdom had intensified measures to ensure that poverty due to unemployment did not result in deterioration of health. The number of children getting free meals at

school increased from 192,000 in 1928 to 399,000 in 1933. About three million children now took advantage of the scheme for cheap milk in schools. It was probable that further measures might be found necessary, especially in the depressed areas. Apart from the immediate economic depression there remained a long-range problem of how this new knowledge of nutrition was to be applied for the raising of the standard of health. Information was needed on the extent to which malnutrition existed, the extent to which it was due to inadequate diet, and the extent to which inadequate diet was due to poverty. If reliable information on these points were available it would be possible to evolve a national policy which would make for orderly progress, irrespective of whatever Government might be in power.

Several medical M.P.s joined in the subsequent discussion.

Maternity and Child Welfare

On December 5th Miss CAZALET asked the number of ante-natal clinics and the average attendance at each in Dewsbury, Rochdale, Huddersfield, Blackburn, Poplar, Putney, Wandsworth, Shoreditch, West Ham, and the Welsh counties, and the amount of hospital accommodation for maternity in each of these districts. Mr. SHAKESPEARE, in reply, furnished the following tabular statement relating to the year 1933. He explained that the figures did not include ante-natal clinics or maternity accommodation at voluntary institutions not subsidized by the local authority.

Local Authority	Number of Ante-natal Clinics	Average Number of Women per Clinic who Attended	Average Number of Attendances per Clinic	Number of Beds Provided at Maternity Hospitals and Homes
Dewsbury	2	212	623	13
Rochdale	1	516	2,463	51
Huddersfield	2	340	1,409	28
Blackburn	1	737	2,558	51
Poplar	4	282	964	35†
Wandsworth*	9	54	140	20
Shoreditch	3	182	527	15†
West Ham	9	2,181	5,718	141
Anglesey	—	—	—	2
Brecknockshire	—	—	—	7
Carmarvonshire	—	—	—	13
Cardiganshire	—	—	—	10
Carmarthenshire	1	67	238	6
Denbighshire	2	47	127	11
Flintshire	6	134	423	15
Glamorgan	35	76	193	53
Merionethshire	—	—	—	5
Monmouthshire	15	85	175	19
Montgomeryshire	—	—	—	13
Pembrokeshire	—	—	—	9
Radnorshire	—	—	—	3

* Separate figures for Putney (which is included in the metropolitan borough of Wandsworth) are not available.

† These beds are in hospitals provided by the London County Council.

In reply to Mrs. WARD, who asked, on December 5th, for figures of maternal mortality in the administrative areas of Cannock and Brownhills urban districts, and how the position compared with five years ago, Mr. SHAKESPEARE circulated the following:

	1923		1933	
	Deaths	Rate per 1,000 Live and Still Births	Deaths	Rate per 1,000 Live and Still Births
Cannock U.D.	3	3.75	2	3.63
Brownhills U.D.	2	4.50	1	2.93

Royal Commission on Durham University

The Royal Commission set up to inquire into Durham University and its constituent colleges is drafting its report, which it hopes to present early next year. This information was given to Mr. T. B. Martin by Mr. RAMSAY MACDONALD on December 6th.

Depressed Areas Bill

In committee of the House of Commons, on December 5th, to consider the money resolution attached to the Depressed Areas Bill, Dr. O'DONOVAN remarked that the migration of substantial numbers from these depressed areas, either voluntarily or by compulsion, gave rise to a biological problem. It affected the nerves, habits, and health of numbers who had been used to one environment. That matter should be considered closely.

The financial resolution passed through committee, and subsequently through the report stage. The committee stage of the Bill was begun by the House on December 6th, when Dr. ADDISON asked for a more exact definition of the relation between local authorities and the commissioners under the Bill. The committee stage was resumed on December 8th, when Dr. ADDISON pointed out that water supplies, drainage, and housing would be excluded from the activities of the commissioners. The report and third reading of the Bill were set down for December 13th.

Water Survey

Sir HILTON YOUNG announced in the House of Commons on December 7th that, after consultation with the Department of Scientific and Industrial Research and other Departments concerned and with their co-operation, Sir Godfrey Collins and he had decided that a comprehensive inland water survey should be undertaken for Great Britain. The information required would be obtained by the Departments from water undertakers, catchment boards, and other qualified bodies and persons. In cases where records were desirable but not now kept, measures would be undertaken to encourage the keeping of the necessary records. A water survey committee, composed of persons outside Government Departments, would be appointed to advise on the survey and on the progress of measures undertaken. In the constitution of the committee attention would be paid to the inclusion of both scientific and practical experience. It would be open to this committee to make recommendations on any further measures which it considered necessary for the purposes of the survey. He hoped to announce shortly the members of the committee.

Hospital Treatment in Workmen's Compensation Cases

Captain CROOKSHANK, on December 10th, informed Mr. Tinker that the Home Secretary was not aware of any increase in the number of cases that were taken to hospitals for treatment after accidents which came under the Workmen's Compensation Act. Proposals were considered some years ago, in correspondence with the British Hospitals Association, for requiring employers to pay for the cost of hospital treatment in workmen's compensation cases. On examination, however, it appeared that they would involve great practical difficulties, and that there were other considerations to be taken into account, including the possible effect on employers' voluntary subscriptions to the hospitals. The Home Secretary did not think that this question could usefully be taken up again except in connexion with a general review of the Acts.

Control of Infection by Aircraft in Sudan

Sir PHILIP CUNLIFFE-LISTER, replying to Sir Robert Hamilton, said he had received official information of a case of yellow fever that occurred in the Bahr-el-Ghazal Province of the Sudan in June last. Measures in excess of those obligatory under the International Sanitary Convention for aerial navigation were taken by the Government of the Anglo-Egyptian Sudan in co-operation with the Government of Uganda to stop the spread of infection to neighbouring territories. Aerial navigation from any aerodrome in the Bahr-el-Ghazal Province to such territories was prohibited, and aerodromes in the

Province were closed to all civil aircraft flying within the Sudan. Juba and Malakal were made and declared anti-malarial aerodromes, although there was no reason to believe that yellow fever existed in these districts. The sanitary staff at Wau in the Bahr-el-Ghazal Province was increased in order that every effort should be made to eliminate the mosquito vector. On arrival at any aerodrome in Mongalla Province aircraft were subjected to the measures prescribed under Article 47 of the International Sanitary Convention for aerial navigation. At the request of the Government of Uganda the Sudan Government agreed to subject all aircraft on departure from Juba to the measures prescribed under Article 43 of the Convention. No further special measures of protection on the part of the Governments of the East African territories under the control of the Colonial Office appeared to be necessary.

Conscientious Objections to Vaccination.—Mr. RALPH BEAUMONT asked Sir Hilton Young, on December 4th, the number of cases in which conscientious objection to vaccination of infants had taken place in each of the last ten years, and what percentage these figures bore to the birth rate in each of those years. Sir HILTON YOUNG gave particulars as follows:

			Number of Conscientious Objections	Percentage of Births Registered
1923	280,252	37.0
1924	271,176	37.2
1925	292,417	41.2
1926	224,122	40.9
1927	276,668	40.8
1928	280,815	42.5
1929	287,753	44.7
1930	235,792	45.6
1931	294,595	46.6
1932	291,015	47.4

Medical Services at Mexborough, Yorks.—Replying to Mr. Paling, on December 6th, Sir HILTON YOUNG said he had no information that the Montague Hospital, Mexborough, Yorkshire, had recently erected two medical wards by aid of grants from the Miners' Welfare Fund, but that these were not opened owing to the reduction of income through unemployment and bad trade in the five urban districts served by this hospital, or that, as Mr. Paling asserted, there were no medical wards at the present time and no adequate medical service. His sanction would not be required for the payment by the urban authorities, under the Public Health Act, of the product of a 1d. rate to provide a portion of the revenue required for opening the wards.

Medical News

The House of the British Medical Association, including the Library, will be closed for the Christmas holidays from 1 p.m. on Saturday, December 22nd, until 9 a.m. on Thursday, December 27th.

The House and Library of the Royal Society of Medicine will be closed from Saturday, December 22nd, to Thursday, December 27th, both days inclusive.

Sir Comyns Berkeley will open the extension of the Willesden Maternity Hospital at Honeypot Lane, Kingsbury, N.W.8, on Saturday, December 29th, at 3 p.m., with the mayor of the borough in the chair.

The next meeting of the Royal Microscopical Society will be held at B.M.A. House, Tavistock Square, W.C., on Wednesday, December 19th, at 5.30 p.m., when a paper will be read by Dr. John R. Baker, and Mr. J. H. Chivers will exhibit and describe some new types of Zeiss microscopical apparatus. Professor W. A. F. Balfour-Browne will deliver his presidential address before the Society on Wednesday, January 16th, 1935.

A joint meeting of the London Section and the Food Group of the Society of Chemical Industry will be held at Burlington House, Piccadilly, W., on Monday, January 7th, 1935, at 8 p.m., when Professor T. P. Hilditch will deliver the Jubilee Memorial Lecture on "The Fats: New Lines in an Old Chapter of Organic Chemistry."

Colonel Mervyn O'Gorman will read a short paper before the British Science Guild on "Bringing Science into the Road Traffic Problem," at the Royal Society of Arts, John Street, Adelphi, W.C., on Wednesday, December 19th, at 5 p.m. A discussion will follow. Admission tickets (for which there is no charge) are obtainable from the Guild at 6, John Street.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that a lecture-demonstration will be given at 11, Chandos Street, W., on December 18th, at 2.30 p.m. Further lecture-demonstrations, on general medicine, will be given on Fridays, at 4.30 p.m., beginning on January 11th. A series of pathological demonstrations, beginning on January 17th, will take place on Thursdays, at 3 p.m., at the Wellcome Museum of Medical Science. Clinical demonstrations will be given in 1935 on the second Saturday afternoon of each month, commencing on January 12th, at 3 p.m., at the National Hospital, Queen Square, W.C. A special series of surgical tutorial classes will be given on Tuesdays and Thursdays, at 8 p.m., at the National Temperance Hospital, beginning on January 15th. Other courses in the New Year include: cardiology, at the National Heart Hospital, January 14th to 26th; urology, at St. Peter's Hospital, January 21st to February 2nd; a week-end course on diseases of the heart and lungs, at the Royal Chest Hospital, on January 19th and 20th; and a course in manipulative surgery, at 11, Chandos Street, on four successive afternoons, at 5.15 p.m., from January 29th. Full details of all courses, etc., which, with the exception of the cardiology course, are open only to members and associates of the Fellowship, will be available shortly.

H.R.H. The Princess Royal paid a visit to the new Poole Sanatorium at Middlesbrough on December 6th. The sanatorium, which was presented to the borough by Colonel and Mrs. Gibson Poole, and was formally opened in June, 1932, has accommodation at present for thirty male adult patients and fifteen children. Under an extension scheme, it is proposed to make it the nucleus of a much larger institution, comprising 335 beds for the treatment of early and curable cases of tuberculosis from other North-East Coast local authorities. It is estimated that the extensions will cost £145,000.

The Minister of Health has approved the appointment of Dr. Thomas Williams Wade as medical member of the Welsh Board of Health, in succession to Dr. D. Llewelyn Williams, who retires from the public service on February 3rd, 1935, on attaining the age of 65. Dr. Wade has been employed as medical officer on the staff of the Welsh Board of Health since January, 1921.

The fifteenth annual dinner of the 14th Stationary Hospital was held on December 7th at the Trocadero Restaurant, with Colonel C. R. Evans, D.S.O., in the chair. The occasion was rendered unusually interesting by the number of reminiscences from various speakers relating to outstanding events in the hospital's history. It was very gratifying to find such a good attendance after so many years, and Colonel H. M. J. Perry, O.B.E., proposed a warm vote of thanks to Major H. L. Tidy for his organizing work, which had proved so consistently successful.

The issue of *Revue Médicale Française* for November is devoted to cancer.

The *Revue Sud-Américaine de Médecine et de Chirurgie*, published by Masson et Cie, Paris, will cease to appear at the end of 1934.

The second centenary of the Spanish National Academy of Medicine, founded in September, 1734, was celebrated in Madrid from December 10th to 15th.

We regret to learn as we go to press of the death of Dr. Theobald Smith, president of the Board of the Rockefeller Institute of Medical Research, whose original researches on diseases of animals and man were recognized by the Copley medal of the Royal Society and the Manson medal of the Royal Society of Tropical Medicine and Hygiene.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required; as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:
EDITOR OF THE BRITISH MEDICAL JOURNAL, Antiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: Bacillus, Dublin; telephone: 62530 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: Associate, Edinburgh; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Chemistry of Fehling's Reaction

Dr. J. M. MacPHAIL (Middlesbrough) writes: Can anyone suggest what is the nature of the reducing agent or agents found so often in the urine when equal quantities of urine and Fehling's solution are boiled together? It would seem that under normal conditions this mixture when boiled remains blue, and we know that as sugar gradually disappears from the urine a green reaction appears; but what is this green reaction that is present when no trace of sugar has ever been found in the urine? It is also found with urates and phosphates. Certain signs would suggest that its presence indicates severe disturbance of liver function, as it is found very often as a "pea-soupy" green with sediment twenty-four hours or more after a long anaesthesia and severe operation. In a few days this green becomes a grass green, but it may be three to four weeks before the "normal" blue of health returns. This green colour is also found when the liver is involved in chronic heart disease with dropsy and liver engorgement; in chronic alcoholism; in "chronic debility"; in cancers, etc. The only trouble seems to be that it is found too easily to be of definite distinguishing value. If it shows a defect in liver function, what are the reducing agents that get green into the urine? and is it not possible to evolve a liver test that may be put to the proof by a fairly ordinary analysis of the urine?

Aerophagy and Meteorism

Dr. LEONARD WILLIAMS (London, S.W.1), in reply to "Perplexed" (*Journal*, November 3rd, p. 843), wonders whether this really is a case of aerophagy, whether in fact the air has really been swallowed, or whether, as seems more probable, a portion of intestine, say, ascending and transverse colon, becomes atonically dilated owing to nervous influence or fatigue, and is promptly invaded by gas from the surrounding tissues. He writes: Surgeons have known flaccid stomachs and large intestines to balloon suddenly during an operation. And, seeing that Epsom salts and other drugs are known to withdraw fluid from the intestinal canal, there is surely nothing to prevent air from being withdrawn by the same route. If this patient's flatulence were really due to swallowed air it is unlikely that there would be a complaint of meteorism, because the gas in such cases seldom goes below the stomach; very often, indeed, it goes no further than the cardiac end of the oesophagus, and the complaint is of cardiac distress, because the wind cannot be eructated. The meteorism in this patient would probably be quickly relieved by oil of caput, and, as there is usually an element of spasm somewhere, belladonna ought to be useful.

Income Tax

Cessation of Employment Earnings

"E. M." was an unestablished medical officer under the L.C.C. On May 4th the earnings ceased, owing to a serious street accident. The original notice of assessment was based on the previous year's figures, but an amended statement was rendered, when the facts were explained. Now, however, a

demand for payment of tax on the original figures has been received.

It looks as if there was some lack of co-operation between the office of the inspector who amended the assessment and the collector whose duty it is to collect the tax. Probably the best thing to do is to send the collector's demand to the inspector's office, pointing out that it does not agree with the amended statement.

LETTERS, NOTES, ETC.

Psychology and Religion

Dr. A. J. BROCK (North Queensferry, Fife) writes: I have read in your issue of November 24th an abbreviated report of an address given by Dr. David Forsyth on psychology and religion. It is difficult, owing to the conciseness of the report, to be quite sure of his point of view, but he appears to class religion as belonging to "pleasure-thinking," and therefore to something hardly desirable. He tells us that a large part of the human energy "available for social enterprise" is at present "running to waste in the interests of religion," and this he wants diverted for the purposes of science, otherwise of "objective truth," which "best serves in subduing the forces of nature in the interests of the individual." Personally, while I agree that the main object of our psychical powers is to forward social enterprise and to help the individual, I think at the same time that Dr. Forsyth is a little too hard on religion. Will he, for example, answer me one or two things? He suggests that a child's idea of God is derived from its experience of its own father. But what happens if the child has never seen its father, or if the father is not very awe-inspiring—is, for example, a hen-pecked individual? And another question. How does Dr. Forsyth explain the common and almost instinctive belief of all children in fairies? Do these not correspond to anything in "reality," or are they perhaps only the child's brothers and sisters? Next, about the soul. According to your report of Dr. Forsyth's address, psychology "had observed that the idea [of soul] arose from the implicit belief of savages in the reality of their dreams." Well, now, will Dr. Forsyth tell me what he makes of the expression often heard in these days of bureaucracy and of mechanism in general, and from people who are not by any means savages, that they "cannot call their souls their own." Dr. Forsyth is anxious to advance the cause of the individual. So I put it to him: What is the use of individuals who have no individuality? Does he tell me there is no such thing as individuality, and that, like the soul, it is only the figment of a savage's dream? On the contrary, I suggest that one's soul or individuality is the most important thing about one. At the same time, it is certainly not recognized or recognizable by "science," whose sphere is nothing more than "objective truth." If I am right, then Dr. Forsyth, in his zeal for social enterprise and for the welfare of the individual, will have to pay more attention to a lot of what is often classed as "religion," and which he tends too airily to dismiss with abusive terms drawn from the armamentarium of current psychology, such as "masochism" and "sadism."

Diaries and Calendars

We have received from Messrs. John Walker and Co. (Farringdon House, Warwick Lane, E.C.4) a selection of diaries, calendars, and appointment books for 1935, many of which would be of service to busy medical men. The diaries are attractively bound, and are obtainable at a variety of prices from 1s. 9d.

Special Plate: Correction

We much regret that, owing to an unfortunate error at the engravers, the three radiographs illustrating the article "Mediastinal and Apical Empyema," by Dr. S. J. Hartfall and Mr. L. N. Pyrah, were reproduced in the wrong order on the special photogravure plate which appeared on December 8th. An examination of the reproductions, with their accompanying legends, shows that the photograph labelled Fig. 2 is really Fig. 1, that labelled Fig. 3 is really Fig. 2, while the one appearing as Fig. 1 should actually be Fig. 3.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 43, 44, 45, 46, 47, and 49 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 48 and 49. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 300.

WEIL'S DISEASE (LEPTOSPIROSIS)

A CLINICAL AND BACTERIOLOGICAL STUDY OF NINETEEN CASES
OCCURRING CHIEFLY AMONG FISH WORKERS

BY

L. S. P. DAVIDSON, B.A. CANTAB., M.D., F.R.C.P. ED.

R. M. CAMPBELL, M.A., M.B., CH.B.

(From the Department of Medicine, University of Aberdeen)

AND

H. J. RAE, M.C., M.A., M.B., CH.B., D.P.H.

J. SMITH, M.D., D.Sc., M.R.C.P., D.P.H.

(From the Department of Public Health, Aberdeen)

The occurrence in Minorca of an epidemic of jaundice was first described by Cleghorn in 1745. The publication by Weil in 1886 of an account of four cases of infectious jaundice led to the recognition of a symptom-complex of fever, jaundice, enlargement of the liver and spleen, the occurrence of haemorrhages, and, occasionally, febrile relapses under the designation of Weil's disease. Following the discovery of the *L. icterohaemorrhagiae* in the blood of a patient suffering from the Japanese form of the disease, and the proof of its specificity by Inada and Ido in 1915, the name "spirochaetosis icterohaemorrhagica" was suggested as a substitute for the many titles applied to this disease. Stokes and Ryle¹ in 1916 obtained bacteriological evidence of the existence of the disease among the British soldiers in Flanders; similar outbreaks were reported and confirmed among the German, French, and Italian troops on the Western Front.

The occurrence of spirochaetosis in the form of an acute febrile illness, without jaundice, was recognized.² In consequence it has been the practice of European workers to revert to the non-descriptive title of "Weil's disease," in preference to its synonyms laying emphasis on jaundice. Interest in the disease has increased in recent years in Holland, where in the past decade 452 cases have been observed, with a mortality of 10.2 per cent.³ Infection occurs by bathing and by accidental or suicidal immersion in the canals; a higher occupational incidence is reported among bargemen and workers in abattoirs and other rat-infested premises.

Leptospiral Infection in Britain

Potential sources of infection in Britain are known to exist, the carrier rate in rats varying from four out of 101 rats in London⁴ to thirty out of 100 in different parts of England.⁵ Buchanan⁶ found sixty-one infected rats out of a total of 166 from various parts of Scotland. In the light of these figures the reports of leptospiral infection in man are surprisingly few, and their authenticity is undoubted only in three outbreaks. Manson-Bahr⁷ in 1922 described a case in a seaman four days after immersion in the Thames, the *L. icterohaemorrhagiae* being isolated from the blood. An outbreak of epidemic jaundice in 1923, among miners in certain wet pits in East Lothian, was described by Gulland and Buchanan,⁸ the diagnosis in eighteen cases being based on the clinical features. Investigations by Buchanan resulted in proof

of the leptospiral origin of the East Lothian epidemic, a guinea-pig inoculated from the urine of a patient dying with typical post-mortem findings and showing the *L. icterohaemorrhagiae* in its tissues. A total of thirty-one cases in all was later reported on the combined clinical and bacteriological findings.⁶ The existence of the disease in Scotland among members of the community other than coal-miners, particularly those working in rat-infested areas—for example, near refuse dumps, piggeries, and breweries—was thus proved.

In May of this year the clinical diagnosis of a fatal case of Weil's disease, in a temporary sewer worker in London, was established by the recovery of the *L. icterohaemorrhagiae* from guinea-pigs inoculated with blood on the seventh day of the disease, and by the presence of a strongly positive sero-reaction with the typical "Weil" strain on the tenth day. Consequent inquiry by Hamilton Fairley,⁹ under whose charge the case had been, showed, on clinical and serological examination of ten persons, that a hitherto unrecognized and endemic focus of Weil's disease had existed for twelve and a half years among sewer workers in London. Other reports of isolated cases or localized outbreaks have been communicated on the clinical features. In some cases spirochaetes were stated to be present in the urine, but bacteriological proof of their identity with *L. icterohaemorrhagiae* was not produced. For a full discussion of the relevant literature the reader is referred to the papers by Hindle¹⁰ and by Taylor and Goyle.¹¹

Present Investigation

Workers in rat-infested premises, both in this country and in Holland, have been recognized as specially liable to the disease. The association of leptospiral infection with water workers in Holland and wetness of the mines in East Lothian is admitted. The object of the present paper, however, is to describe a current outbreak of Weil's disease among persons employed in the handling and cleaning of fish, and to indicate the circumstances rendering them liable to infection. So far as the present authors are aware, the peculiar incidence of the disease in this industrial group has not been reported previously.

In June, 1934, two patients (Cases 3 and 5 in Table I), suffering from an acute febrile disease associated with jaundice and nephritis, were admitted to the wards in the Aberdeen Royal Infirmary under the charge of the professor of medicine. A diagnosis of Weil's disease was made on the clinical features. Inoculation of the blood and urine into guinea-pigs gave negative results. (An

* Since this paper was submitted to the *British Medical Journal* four more cases of proved Weil's disease in fish workers have been investigated, making a total of twenty-three.

explanation of these failures is discussed later.) Sera collected on the twenty-first and thirty-second days of the disease, respectively, were dispatched to Amsterdam, and Professor Schüffner, who generously agreed to test sera in these and other suspected cases, reported positive agglutination reactions in titres of 1 in 30,000 with the classical "Weil" strain. As both these patients were fish workers inquiries were instituted; these showed clearly that several additional cases had occurred in this occupational group over a period beginning in April of this year. Infective jaundice being a notifiable disease in Scotland since February, 1924, it was decided to request the medical officer of health to circularize the medical practitioners of Aberdeen and its regional area for information as to "any cases of infectious jaundice which they may at present have, or in the past have had, under their care," and to investigate the working conditions of the fish trade.

As a result of the better recognition of the clinical manifestations of Weil's disease, other than icterus, during the past decade in Holland the proportion of mild cases unassociated with jaundice has risen from 13 to 60 per cent. of the total.³ Since information was requested from the Aberdeen practitioners about cases of infectious jaundice, we claim that a reliable index of the prevalence of leptospiral infection was not produced as a result of this inquiry.

We propose to divide the cases reported in this paper into two groups. Group I consists of a series of fifteen cases investigated between June and October, 1934, in which the diagnosis has been confirmed by bacteriological or serological methods. Points of particular interest in Group I are given in Table I. Group II comprises a series of four cases of great severity, diagnosed as Weil's disease from their clinical manifestations, but lacking bacteriological or serological confirmation. The value of serological tests is of recent establishment, and accordingly had not been undertaken in these cases.

Group I

In order to save space individual case histories are omitted, and the general picture of the disease as seen in these cases is presented and compared with the clinical features reported elsewhere. Of the fifteen cases in Table I, Cases 14 and 15 occurred in Edinburgh, the remaining thirteen in Aberdeen, and all have occurred during the present year. Twelve of the thirteen patients

were connected with the fish trade. Eleven were employed in cleaning, filleting, curing, or packing fish, and one in the transport of fish from the yards to the railway station. Of the remaining cases one was a farm labourer working in fields and ditches, another was a labourer at the zoological gardens, while a third was a labourer engaged in laying water-mains. Seven out of the twelve cases in fish workers occurred in April, May, and June, and the remaining five in September and October. Males were affected in eight, females in seven instances. The ages varied from 14 to 67 years, ten being under 25. Juvenile and adolescent labour, however, is preponderant in the fishyards. The incubation period is stated to range between the limits of four and nineteen days, with an average of 10.3 days.³ In view of the continuous exposure to sources of infection it was not possible to determine the incubation period in any of our cases.

Onset and Early Symptoms

The onset can be described as sudden in fourteen out of the fifteen cases, the illness developing acutely within twenty-four hours or less. All of these patients were confined to bed from the onset. Thirteen were admitted to hospital at periods varying from the second to the fourteenth day of the disease. Several of the following symptoms were present in the first four days of the illness: severe headache; weakness and marked prostration; muscular pains; shivering; anorexia, nausea, vomiting, and constipation; sore throat; abdominal pain; epistaxis and insomnia. Diarrhoea occurred at the onset in one case, and was followed by marked constipation. Meningeal symptoms with acute pain on moving the neck led in one case to suspicions of a cerebral condition. Abdominal tenderness was generalized or localized to the epigastrium, right hypochondrium, or right iliac region. The tongue was coated, moist in the early stages, and dry later. Muscular pains and a feeling of prostration were present in practically every case. Cases 9 and 10 were exceptional in this respect, although they had been diagnosed as influenza until the sero-reactions revealed their true nature. In the severe cases muscular pain was a very prominent symptom, affecting the back, loins, shoulder-girdle, neck, thighs, or calves, and lasting as long as seven days; acute tenderness of the muscles on pressure was associated. Joint pains were present in the most severe surviving case.

TABLE I

No.	Sex and Age	Occupation	Onset	Muscular Pains	Haemorrhages	Jaundice	Nephritis	Duration (Days)
1	Male, 17	Fish worker	Sudden	++	Haemoptysis; occult blood in stools	++	Albumin, casts	58
2	Female, 18	"	"	++	Epistaxis	+++ 70	Albumin, pus cells	77
3	Female, 16	"	"	++	Epistaxis. ? Haematemesis	++ 33	Albumin, casts, pus cells. 58	87
4	Male, 18	"	"	+	None	++ 50	Albumin, casts, pus cells	(16)
5	Male, 40	"	"	+++	Epistaxis; occult blood in stools	+++ 60	Albumin, casts, pus cells. 152	(57)
6	Female, 16	"	"	++	Epistaxis	None	Albumin, casts, pus cells, red blood cells. 52	(26)
7	Male, 22	"	"	++	Occult blood in stools	++ 25	Albumin, casts, pus cells, red blood cells. 145	(42)
8	Female, 14	"	"	++	? Haematemesis	++ 35	Albumin, casts, pus cells, red cells. 45	(43)
9	Female, 18	"	"	None	None	None	None	14
10	Female, 21	"	"	+	None	None	None	(25)
11	Female, 16	"	"	+	(None)	+++ 60	Albumin	20+
12	Male, 63	Fish carter	"	Not noted	Epistaxis; petechiae	+++	Anuria	9
13	Male, 39	Labourer: pipe layer	Gradual	Not noted	Not noted	None	Albumin, casts, pus cells, red cells. 23	(56)
14	Male, 39	"Zoo" labourer	Sudden	Not noted	Not noted	+ 23	Albumin, casts, blood. 51	112
15	Male, 67	Farm labourer	"	++	Petechiae; haematemesis; melena	+++ 52	Albumin, casts, blood	14

+ = Slight. ++ = Moderate. +++ = Severe. Figures in Columns 7 and 8 apply to icterus index in Murphy units and blood urea in mg. per 100 c.c.m. respectively. Figures in Column 9 indicate total days of incapacity from work; where convalescent period is not included, figures are enclosed in parentheses. Death occurred in Cases 12 and 15; the remainder recovered.

Stress is laid by authors in the East Indies and Holland on the flushed conjunctivae ("red eyes") due to dilatation of the episcleral capillaries. "Red eyes" was not noted in any of our cases, but its absence may be explained on the grounds that the patients were admitted to hospital on the average five days after the onset of acute symptoms. Herpes labialis was seen only in one case, and was not haemorrhagic. Haemorrhage from some situation was present in nine out of thirteen cases. Epistaxes were the most frequent, occurring in five instances. Nose-bleeding was slight in degree, occurred in the first four days, and was revealed only on direct inquiry. Severe haemorrhages of multiple origin are recorded in the two fatal cases of this group.

Fever was present in ten of the patients. Case 12 was collapsed, with a subnormal temperature, while Case 13 was admitted late in the disease. The temperature varied in its maximum height from 99° to 104° F., according as admission was late or early. The highest figures were recorded on the third, fourth, and fifth days. The duration of the primary fever was six to nine days. A secondary rise in temperature in six cases followed from four to eleven days after the termination of the primary fever, and lasted from five to twenty days; a maximum figure exceeding 100° was reached in four of these. Splenic and glandular enlargement was absent in all cases, but there was liver enlargement in one. A red, measles rash was seen on the legs of one patient on the tenth day of the disease, and disappeared within two days. Jaundice was detected in eleven out of the fifteen cases, being first seen on the fourth to the tenth day; in six of the cases it was present by the sixth day. Fluctuations in the jaundice were not observed. Save in two cases where jaundice persisted until the seventh week, icterus had disappeared by the third week.

Urinary Features

These seem to be worthy of emphasis. Albumin and casts were found in nine cases, albumin alone in three, and red blood cells in six. The urinary output was not markedly diminished, except in one fatal case with anuria. There was no associated puffiness of the face or other oedema. The association of jaundice and nephritis was found of great diagnostic value. Whether the azotaemia of Weil's disease is wholly dependent on impairment of renal function or in part at least on increased urea production is an undetermined problem.¹² Figures for blood urea values are available only in four cases before the tenth day of the disease (Cases 3, 5, 7, and 8). Raised values are present in these instances. Case 7 is of interest in that a urea content of 66 mg. per 100 c.cm. was recorded on the third day of the illness, later rising to the high level of 143 mg. per 100 c.cm. on the tenth day. These high degrees of nitrogen retention suggest that the association of a sudden onset, high fever, muscular pains, nephritis, and raised blood urea values in the absence of oedema or hypertension might be of considerable diagnostic service in the early stages of severe cases. A secondary rise in the blood urea content occurred during the period of secondary fever in two cases.

Course of the Disease

While the distressing subjective features of the onset, such as headache and muscular pains, disappeared within a week, and jaundice resolved on the average by the twenty-first day, the urinary findings took considerably longer to return to normal. Even in mild cases a trace of albumin was present six weeks after the onset, while in the severe cases albumin and casts in the centrifuged deposit were detected in the eighth week of the disease. In Cases 3 and 5 blood urea values fell to normal upper limits after six weeks. In six cases loss of hair, beginning

in the third week of the disease, was marked, and led to a state of partial baldness. It has been impossible to estimate the total period of disability except by the duration of stay in hospital. Convalescence thereafter was prolonged, since many of the patients felt unable to work owing to general weakness and tiredness, and complained of vague muscular pains for several weeks after discharge from hospital. There were two fatal cases in this group, death occurring on the ninth and fourteenth days.

Group II

Group II consists of the series of four fatal cases reported on clinical grounds. They extend over a period from 1929 to 1934. The several occupations of the patients were restaurateur, farm worker, market gardener, and fish carter. Three were males and one a female, and their ages were 64, 34, 34, and 24 respectively. A typical history of one of these cases is as follows. The patient was suddenly taken ill with severe muscular pains followed by sickness, vomiting, and haemoptysis, succeeded by jaundice on the fourth day. On the sixth day he was admitted to hospital moribund, when the findings and subsequent course were: severe jaundice, albuminuria slight, hyaline granular and epithelial casts in urine, blood urea 349 mg. per 100 c.cm., gradually increasing jaundice, repeated haemorrhages; finally, anuria, coma, and death on the ninth day. It is to be noted that one of the patients in these fatal cases was a fish carter. In another a history was obtained of fatal jaundice in two younger members of the family, aged 7 and 17 years respectively. Since the premises were rat-infested it was suspected that all three deaths had a common origin.

Bacteriological Investigations

It has been the experience of Dutch and other workers that *L. icterohaemorrhagiae* can best be recovered from human cases of infection by intraperitoneal inoculation of blood, urine, and tissue emulsions into young guinea-pigs rather than by direct cultural methods. In the present series blood samples from five cases and ten specimens of urine from six cases were inoculated into guinea-pigs, 1/2 to 1 c.cm. of blood and 5 c.cm. of urine being used. The results of these tests have, however, been vitiated by the fact that for the most part the cases were recognized a considerable period after the onset of the illness. To recover the organism from the blood it is necessary to obtain a specimen in the early stage of the disease—one to six days after the onset, while the patient is yet febrile. So with the urine the most favourable time for the demonstration of the organism is the period fourteen to twenty-one days after the onset. A most important point in connexion with the examination of urinary specimens is that guinea-pigs must be inoculated within one hour, otherwise the leptospira will have died off.

So far the organism has not been recovered from any blood specimens, but has been recovered from the urine of Case 8 and from emulsions of the tissues of one fatal case (12). The urine which contained the leptospira was obtained on the sixteenth day of the patient's illness, and a further specimen, obtained on the twenty-ninth day, failed to kill the guinea-pigs. It should also be pointed out that it is not necessary to wait for the death of the animals in order to obtain positive results. Two days after inoculation the febrile reaction in the infected guinea-pig begins, and if a small quantity of fluid is withdrawn from the peritoneum from day to day by puncturing the abdominal wall with a sharp pointed glass pipette, sufficient material will be obtained for examination by dark-ground illumination methods. If the peritoneal fluid shows a positive result blood may be obtained by heart puncture and cultured, several drops being added to four or five tubes of medium.

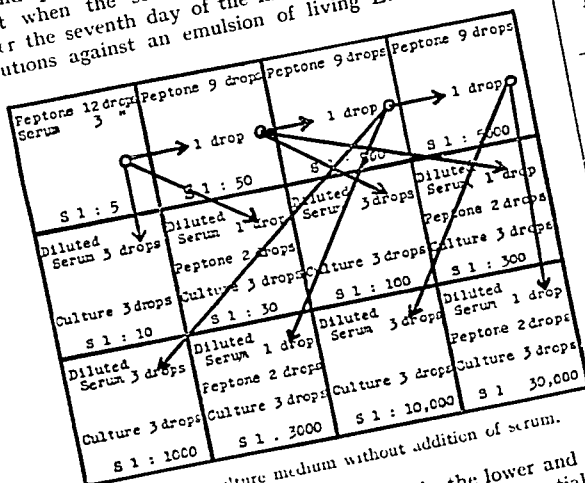

WEIL'S DISEASE

Cultural Methods

The culture medium used by the Dutch workers consists of the following: tap-water, 1,500 c.cm.; Witte's peptone, 0.15 gram; Ringer's solution, 300 c.cm.; and Sorensen's solution pH 7.2. The final reaction of this peptone medium should be between pH 6.8 and pH 7.2. Three c.cm. of the medium is placed in a small tube and sterilized. For use 0.3 c.cm. of fresh rabbit serum is added; the tubes are then heated at 56° C. for thirty minutes and incubated at 37° C. overnight. Certain rabbit sera seem to be somewhat inimical to the growth of leptospira, and, furthermore, guinea-pig serum filtered through an L5 Chamberland candle can be employed with success. Samples of horse serum have given less favourable results than rabbit or guinea-pig sera. The patient's blood can be cultured in this medium, and so also the urine if obtained free from other organisms. A point of practical interest is that since the leptospira may remain alive for days in clotted blood from human cases, the blood clot can be broken up and inoculated into guinea-pigs. To culture the leptospira the tubes are placed in an incubator at 32° C. and examined after three or four to seven days.

Sero-reactions

It is obvious that since only some 40 per cent. of cases show signs of jaundice, and since many cases recover after a febrile illness lasting four to seven days, it would be difficult to diagnose the disease on a clinical basis. If, however, the occupation of the patient is kept in mind, some indication of the possibility of a leptospiral infection should present itself. Schüffner and Mochtar¹³ showed that when the serum from human infections obtained after the seventh day of the illness was tested in various dilutions against an emulsion of living *L. icterohaemorrhagiae*.

Peptone = culture medium without addition of serum.

rhagiae, agglutination was obtained in the lower and lysis in the higher dilutions of the serum. This essential test is performed by setting up a series of dilutions of the serum in the cells of a sterile porcelain plate (painter's palette), or in small sterile test tubes 1 inch by half an inch. Figure 1 gives the details of Schüffner's method by which dilutions of the serum ranging from 1 in 5 to 1 in 15,000 can be obtained rapidly, and when three drops of the leptospiral emulsion (four days' growth at 32° C., and up to three days' growth at room temperature) are added to each the final serum dilutions range from 1 in 10 to 1 in 30,000. The tests are then incubated at 32° C. for three hours. The results are determined by examining a drop (obtained with a platinum loop from each dilution of the

serum) under the microscope by the dark-ground illumination method. For this purpose a most suitable optical equipment has been found to be the Leitz "dry" dark-ground condenser D 0.80 in conjunction with the achromatic objectives 3 (2/3 inch) and 6L (1/6 inch), the source of illumination being a 100 c.p. pointolite lamp. A $\times 20$ ocular can be used in conjunction with the 2/3 inch objective, and an $\times 8$ to $\times 10$ ocular with the 1/6 inch objective. A drop of the serum and living leptospiral emulsion is placed on a clean slide (0.9 mm. to 1.1 mm. in thickness, and examined first with the 2/3 inch objective and later with the 1/6 inch objective, no counterslip being interposed between the preparation and the objective.

TABLE II

Case No.	Day after Onset of illness on which blood was taken	Titre of Sero-reactions (aggl. and lysis) against:		
		<i>L. icterohaemorrhagiae</i> Weil	<i>L. canicola</i>	<i>L. icterohaemorrhagiae</i> Indian Strain
1	11th	1,000	300	30
2	65th	1,000	300	0
3	59th	32,000	300	300
4	61th	3,000	300	100
5	25th	20,000	300	100
6	29th	30,000	300	100
7	21st	10,000	100	0
8	9th	300	100	30
9	28th	3,000	100	0
10	8th	1,000	0	30
11	8th	1,000	100	0
12	8th	1,000	100	0
13	4th	300	0	0
14	32th	300	100	0
15	10th	1,000	100	0

By these methods agglutination and lysis are observable with ease and rapidity. The results of the sero-reactions are given in Table II, the sera being tested against the three living strains as used by the Dutch workers. It will be observed that the end titres of the reactions against *L. icterohaemorrhagiae* Weil are extremely high, the agglutination of the leptospira occurring in dilutions ranging from 1 in 10 to 1 in 300 or 1 in 1,000, and lysis occurring from 1 in 300 to 1 in 30,000, a typical result being:

	Serum Dilutions :							
	1 in 10	1 in 20	1 in 100	1 in 300	1 in 1,000	1 in 3,000	1 in 10,000	1 in 30,000
Agglutination	+++	+++	+++	++	++	++	++	++
Lysis	---	---	---	---	---	---	---	---

The reactions against *L. canicola* and *L. icterohaemorrhagiae* (Indian strain) are believed to be of the group type, *L. canicola* and *L. icterohaemorrhagiae* (Indian strain) being different serologically.¹⁴ If, however, formalized killed cultures are employed, then agglutination only is observable, the lytic action being inhibited. In one case, a fatal one, the serum failed to give any reaction on the sixth day of the illness, but when obtained two days later reacted to a titre of 1 in 1,000. The agglutinating and lytic action of the serum can be employed for the diagnosis of a recent infection, or an infection which has occurred many years previously.

Source of Infections

The industry which has grown up around the preparation of fish for human consumption cannot be said to be conducted entirely on up-to-date, hygienic principles. The patients in the present series have been employed, for the most part, in the handling of white fish. The girls are engaged as filleters and cleaners, and the men in the general handling and distribution of the raw material and offal. In this city some 250 different establishments, each employing perhaps five to six girls and two to three men, are constantly at work. These small businesses account for about 60 per cent. of the total, the remaining 40 per cent. being in the hands of larger firms, employing forty to 100 or more workers.

At the outset it may be said that for economic reasons the smaller businesses are less able to employ hygienic methods than the larger concerns, though this does not always follow. A visit to many of these establishments shows that the premises and equipment are often unsatisfactory. The fish are taken from the market in boxes; they are dumped in a corrugated iron shed in which at a wooden table five or six girls proceed to fillet and prepare the fish for sale to the retailer. The water for washing is obtained from the municipal supply, which is entirely satisfactory, but often, instead of being withdrawn from the tap, it is drawn from a tub placed underneath the tap. The latter source, the table, and the floor all rapidly become covered with slime and offal. In the evening the bulk of the dirt and offal is collected into barrels, which are not removed until the following morning. As the premises are often rudely constructed there is little protection against rats, which infest the whole area in which the business is conducted.

Some years ago one of us showed¹³ that 24 per cent. of rats, young and old, in the city harboured *L. icterohaemorrhagiae*. Recently, in July, 1934, when the disease was recognized, a visit was paid to some of the premises where the patients had been working. Six samples of water were obtained—four from floor washings and two from the tubs. To demonstrate the leptospira the technique of Applemann¹⁴ was employed. Young guinea-pigs were chosen, and the hair was depilated from the abdominal skin. The water samples to be examined were placed in buckets to a depth of two inches or so, and brought to a temperature of 32° C. The abdominal skin of the guinea-pig was then scarified, and two animals were placed in each bucket and allowed to remain there for one hour. The animals were then removed and replaced in their cages. In two instances guinea-pigs died on the tenth and eleventh day respectively after immersion in the water. Both animals showed the typical features of infection due to *L. icterohaemorrhagiae*, the organism being easily demonstrable by microscopical examination in preparations from the liver, and the disease was repeatedly reproduced in other animals by inoculation with liver emulsions.

More recently (October) six more samples have been similarly examined, with one positive result. The sample of water that produced this was obtained from the floor of the premises in which two cases of Weil's disease had occurred during the past summer. Probably the incidence and prevalence of *L. icterohaemorrhagiae* may be to some extent seasonal. Obviously, therefore, the opportunities for infection and the conditions for the survival and perhaps multiplication of *L. icterohaemorrhagiae* after being deposited by the rats are present. Persons employed in the trade have the skin on their hands frequently broken by their knives, and presumably infection occurs through the exposed flesh surfaces, or it may occur, as in Holland, by infection through the nasal mucosa and upper respiratory tract.

Discussion

In a subsequent paper it is proposed to deal with certain aspects concerning the aetiology, prevention, and treatment of Weil's disease. A short discussion regarding the importance of early diagnosis appears, however, to be desirable. Favourable results have been reported following the administration of specific antiserum in the early stages of the disease, and also in cases with commencing icterus. The best results, however, are obtained when serum is given within the first three days of the onset. Since jaundice does not appear regularly before the fifth day the clinical diagnosis depends on the recognition of such symptoms as abrupt febrile onset, muscular pain, "red eyes," and marked prostration. None of these symptoms, however, can be held to be specific for Weil's disease, since they may occur in many acute infections. This is particularly true of influenza and acute tonsillitis. A mistaken diagnosis of influenza had been made in several of our cases, and in none of the patients in Group I was Weil's disease suspected prior to our investigation. While it is true that the occurrence of a sudden acute fever in a sewer worker might suggest the possibility of leptospirosis, even in the pre-icteric stage, the problem is entirely different in workers connected with fish-curing and cleaning. For every case of Weil's disease occurring among the thousands of fish workers in Aberdeen there must be hundreds of cases of acute febrile illness of other origin with symptoms similar to those mentioned above. Weil's disease in the early stages might be suspected on the following additional grounds: a leucocytosis with a shift to the left in the polymorph series, latent icterus with a direct or biphasic van den Bergh reaction, acute nephritis unassociated with oedema or hypertension but indicated by slight albuminuria, the presence of granular and cell casts in the urine, and a raised urea or non-protein-nitrogen content in the blood. The tests required to obtain the above data, as well as guinea-pig inoculation with blood, would be impossible in view of the numbers concerned; hence it appears to us that the clinical diagnosis in the early stage, before jaundice occurs, presents almost insuperable difficulties to the practitioner in Aberdeen. Accordingly the full benefits of specific serum treatment are unlikely to be realized.

In view of the practical difficulties connected with guinea-pig inoculation of blood and urine, the sero-reaction will remain the chief method by which the diagnosis will finally be confirmed. Since a positive sero-reaction does not occur before the seventh day of the disease the information obtained is of little value in regard to treatment. It is reassuring to know that Professor Schüffner's investigations indicate that this reaction in Weil's disease is as specific as the Widal reaction in enteric fever. Our own experience is in keeping with this, since sera from 180 cases other than those of Weil's disease have been examined, and in no instance has the reaction been obtained even in a dilution of 1 in 10.

Conclusions

1. Nineteen cases of Weil's disease are reported, in fifteen of which the clinical diagnosis was confirmed by bacteriological or serological tests.
2. Thirteen of the patients were employed in the handling and cleaning of fish.
3. These findings show for the first time that workers among fish must be included in the occupational groups especially liable to Weil's disease.

It is necessary for us to express our indebtedness to Professor W. Schüffner, Director of the Tropical Disease Department of the Royal Dutch Colonial Institute at Amsterdam, for assistance in the serological diagnosis of the first cases, and for his

permission for one of us (J. S.) to visit him and to study the work carried out in connexion with the bacteriological and serological diagnosis of Weil's disease; to Major H. C. Brown of the Wellcome Bureau, for carrying out confirmatory adhesion tests; and also to the following physicians for allowing us access to the clinical material and records: Dr. W. F. Croll (Cases 1 and 7); Dr. A. G. Anderson (Cases 6 and 13); Dr. A. W. Hendry (two cases in Group II); and Drs. Edwin Matthew and J. D. S. Cameron (Cases 14 and 15).

AN ACCOUNT OF WEIL'S DISEASE IN QUEENSLAND

BY

J. GRAHAME DREW, M.A., M.B., B.Ch.CANTAB.,
D.P.H.

STATE MEDICAL OFFICER, DEPARTMENT OF PUBLIC HEALTH, QUEENSLAND

On July 7th, 1934, reference was made in the *Journal* (pp. 10 and 14) to the occurrence of Weil's disease in England. The arrival of that issue of the *Journal* in Brisbane coincided with an outbreak of the disease in Queensland. It is considered that a short review of the occurrence might be of value.

In February of this year the medical officer of health for the shire of Hinchinbrook (Dr. G. C. Morrissey) reported to the Department that during the past six months about thirty patients came under his notice displaying symptoms of a disease new to the district. The centre of this district is Ingham, a small town in one of the sugar-cane areas, situated in lat. 18° 8' S., a few miles from the coast, with an annual average rainfall of over sixty inches. The population is predominantly Italian.

Symptoms

The symptoms noted were as follows. The illness began as in influenza, with "shivers," frontal or temporal headache, generalized pains, and prostration, which was marked during the acute period and for a considerable time during convalescence. An early sign was the deep congestion of the conjunctivae. The symptoms varied in intensity. Some patients developed herpes of the lips, frequently haemorrhagic in character. Over 50 per cent. complained of upper abdominal pain of variable severity; the pulse was slow, but quickened as heart failure supervened. The temperature, initially of the febrile type, fell in a few days (six days) to normal, and in severe cases jaundice then appeared, with epistaxis and petechial haemorrhages.

The prostration became very pronounced, the spleen was enlarged and tender, and the urine was scanty and con-

tained blood. The tongue became brown, almost black, and dry. Vomiting of black vomitus tended to be persistent. In two cases there were terminal convulsions of moderate severity, preceded by delirium. One interesting feature of aetiological value was that most of the patients had enlarged axillary glands, and the hands showed evidence of old cuts and septic abrasions caused by the patient's occupation. The inguinal glands were enlarged also, but not so markedly as the former. During the occurrence of these cases the district had been experiencing exceptionally heavy and continuous rain.

Shortly after receiving this report the disease waned, but the shire council was instructed to set in motion an intensive campaign of rat destruction, as the district was heavily infested with these rodents. The Commonwealth Health Laboratory at Townsville was asked to assist by the examination of rats with the object of isolating the causative organism. The disease continued to be non-evident until the beginning of July, when it broke out again with renewed intensity. Up to the period of writing, when a further lull is in evidence, there have been 136 cases with seven deaths, and of the former a very large percentage of the patients were so seriously ill that recovery appeared doubtful. The treatment in all cases was purely symptomatic.

With the recrudescence of the disease Dr. T. J. Cotter of the Townsville Commonwealth Health Laboratory proceeded to Ingham, where he inoculated guinea-pigs direct with blood and urine taken from two patients, in accordance with the methods used by Fletcher of Malaya. Urine and emulsions of faeces from rats were also directly inoculated, but in all the results were negative.

Post-mortem Findings

Post-mortem findings reported by Dr. Cotter in one case were as follows:

"Well-developed muscular male, with marked icterus and generalized scattered skin petechiae. The liver was moderately enlarged, smooth, and congested, and finely streaked with bile. The gall-bladder was distended, with thickened walls, and contained thick dark green bile. The mucous membrane of the cystic duct appeared to be swollen. The spleen was enlarged, being about two and a half times the normal size. It was deep red in colour and very friable, tearing on removal; there was haemorrhage into the pulp. Renal system: a horse-shoe kidney was found with lower ends united across the vertebral column, the union consisting of kidney tissue, with ureters passing anteriorly. The kidney was swollen, soft, and engorged, with scattered subcapsular haemorrhages. The surface was smooth, and the capsule peeled off easily. The cortex was congested, and occasional haemorrhages were present. The pelvis and calices showed petechial haemorrhages on the mucous membrane. The heart was not dilated, and showed nothing abnormal macroscopically. There was hypostatic congestion of the bases of the lung. The bowel appeared normal."

Later, a post-mortem examination of an infected guinea-pig showed multiple small haemorrhages in all the viscera, with "butterfly" patches in the lungs.

At this time, further north, a large number of cases of "coastal fever" were occurring. This is an indeterminate fever, the cause of which is unknown, but which is probably due to a virus of the Rickettsia type conveyed in the bite of an insect. As the *L. icterohaemorrhagiae* had not been isolated in the cases at Ingham the occurrence of these cases of "coastal fever" tended to complicate the position, which became more pronounced as all the laboratory tests proved to be negative (Widal against Rawlings and Cairns strains, Weil-Felix reaction, blood examination for malarial parasites, and agglutination tests for *Br. abortus*). In addition, influenza was also present, further complicating the outbreak.

Preventive Measures Adopted

Notwithstanding these results, Drs. Morrissey and Leckie of Ingham stood to their diagnosis of Weil's disease, and the following measures, from the public health point of view, were advised: (1) an immediate supply of antiserum to be obtained by quickest route from abroad; (2) protective measures for cane-cutters—frequent disinfection of hands and feet in biniodide solution and the wearing of footwear (it is the custom among these men to work bare-footed in the cane-fields); (3) investigation of water supplies, which in the main are drawn from shallow wells; (4) closer sanitary inspection of quarters, etc.; (5) conference of various bodies interested to intensify the rat destruction campaign; (6) a research worker to be maintained in the fields.

Dr. Sawers of the School of Public Health and Tropical Medicine, Sydney, was then sent north. On August 15th Dr. Cotter was successful in isolating the *L. icterohaemorrhagiae*, thus confirming Dr. Morrissey's clinical diagnosis. Dr. Sawers corroborated this finding, and later isolated the leptospira from urine taken from rats in the Ingham district. Subsequent examinations have shown that a very high percentage of the rats are so infected there.

As the position at Ingham was fast approaching that of an industrial crisis, owing to the dread of the disease, the Commissioner of Public Health (Dr. J. Coffey) proceeded to the district to advise on preventive measures, which were embodied in the following pamphlet:

1. Avoid eating food in the fields unless the hands are thoroughly cleansed previously.
2. Avoid drinking water in the fields unless it has been boiled.
3. Avoid rolling and smoking cigarettes in the field.
4. Avoid using water lying in the field for washing hands or face; such water is liable to be infected.
5. Avoid walking through or in wet places.
6. Feet should be protected by wearing boots.
7. All cuts and abrasions should be washed immediately in a perchloride of mercury solution, one tablet to one pint of clear water.
8. All cuts and abrasions, after the above preliminary treatment, should be covered with adhesive plaster or other suitable covering.
9. All food in the barracks and elsewhere must always be protected from rats.

Remarks

From a close analysis of the situation it would appear that the disease has been introduced into the district from over-seas, as Dr. Morrissey, who has been at Ingham for twelve years, is positive that he had never seen a case in the district until October, 1933. As Weil's disease, was very prevalent in Italy during the war, and as the population of Ingham in the main is Italian, the theory that the disease has been conveyed by human carrier is highly probable; less likely is the theory that it may have been introduced direct by infected rats of foreign origin.

By plotting on a map of the district the places where the cases originated there is demonstrated a distinct tendency for infection to occur in farms in low-lying areas along the course of streams which have been shown also to be heavily infested with rats. The probable association of the disease with the rainfall is also interesting, since cases generally occur about ten days after rain. The cane-cutters work in all weathers, and it would appear that the moist conditions existing in the fields after rain have a benign influence on the life of the leptospira. After a prolonged spell of dry weather, on the other hand, the outbreak ceases. It may be, too, that the germ is left on the cane itself by infected rats, which destroy cane to about the extent of 10 per cent. In grasping the cane

preparatory to cutting, the hands become injured with abrasions, and it is possible that the leptospirae gain direct entry into the system in this manner, as witness the enlarged axillary glands in the cane-cutters suffering from the disease.

Firing the cane has been recommended as a temporary measure. By this action the cane and upper surface of the soil are sterilized, and the lower leaves, which are the principal cause of injury to the cutters' arms, are removed. Unfortunately, this action is rendered impossible during the most dangerous period, as the cane is too damp. The main problem which will tax the resources of the State, however, will be to eradicate the rat down to the irreducible minimum.

In the compilation of this review I am indebted to Dr. John Coffey, Commissioner of Public Health; Dr. F. McCallum, Chief Quarantine Officer (General); Dr. T. J. Cotter; Dr. W. Sawers of the Commonwealth Health Service; and Drs. Morrissey, Leckie, and Piscitelli of Ingham.

MODERN SANATORIUM TREATMENT*

BY

A. SALUSBURY MACNALT, M.D., F.R.C.P.,
D.P.H.

SENIOR MEDICAL OFFICER FOR TUBERCULOSIS, MINISTRY OF HEALTH

Treatments, like diseases, come and go. So strange, indeed, is custom in this respect that the elderly practitioner sometimes rubs his eyes in astonishment on finding that his old-fashioned therapy has come round again as the newest popular form of treatment. Many forms of treatment suffer from misapplication. For a time they are discarded in favour of some newer method, instead of inquiry being made as to the reasons for their apparent failure, and as to whether their rational application cannot be utilized to embrace the new departure.

There is a tendency now among some to disparage sanatorium treatment and to regard collapse therapy as the only form of treatment of pulmonary tuberculosis. It is true that artificial pneumothorax, together with other surgical measures such as phrenic evulsion and thoracoplasty, has revolutionized the treatment of chronic pulmonary tuberculosis within the last decade. This holds especially for the intermediate case and the case which has proceeded to cavity formation. Formerly, in many instances, treatment of these types could only be palliative, and was often disheartening. It is now active, and frequently successful. But this success in selected cases does not imply, as some Continental authorities urge, that in all cases of chronic pulmonary tuberculosis an artificial pneumothorax should be induced and surgical methods employed if pneumothorax is impossible. Such an attitude ignores not only the tried and proved methods of sanatorium treatment, but fails to take cognizance of the many cases of pulmonary tuberculosis in which artificial pneumothorax is contraindicated. To this important question Dr. F. Heaf has recently drawn attention.¹

The term "sanatorium treatment" is a loose one and has been applied to the treatment in a residential institution of all forms of pulmonary tuberculosis. Unfortunately, sanatorium treatment in the true sense has been adversely affected by this lack of clear definition. To the modern physician dealing with tuberculosis the words have a special and limited meaning: they apply to institutional treatment given to a tuberculous patient who is ambulant and afebrile—that is to say, the sanatorium patient is a selected case. Lack of appreciation of this fact has led

* Read in the Section of Public Health at the Annual Meeting of the British Medical Association, Birmingham, 1934.

to sanatoria being filled with unsuitable patients who were by no means fitted to undergo ambulant treatment. The unfavourable results given by these patients have cast reflections upon sanatorium treatment. Yet it was not the sanatorium system which was faulty, but its method of use. Furthermore, an appreciable proportion of these unfavourable cases by prior treatment might have been rendered suitable for sanatorium treatment.

Classification and Selection of Patients

The residential institutions in a tuberculosis scheme for the treatment of the consumptive comprise: (a) the hospital with observation wards; (b) the sanatorium; (c) the hospital or home for advanced cases.

The best form of institution is a combined one—the hospital sanatorium—which includes an observation block, a nursing or hospital block, and sanatorium pavilions. A certain preliminary selection of patients for institutional treatment is done by the tuberculosis officer in consultation with the patient's medical attendant.

From clinical examination and experience the tuberculosis officer will mark certain patients as in need of hospital treatment, others as suitable for sanatorium treatment forthwith.

But in practically every case it is desirable that the patient should be admitted to the observation ward and put to bed for a fortnight or so. During this time he will be under intensive observation by the resident medical officer. His temperature can be charted at four-hourly intervals; the influence of rest upon it can be studied; the sputum can be examined bacteriologically and measured; the pulse rate can be charted; the psychology of the patient can be taken into account; he can be x-rayed, and so forth. If his temperature while he is in bed remains normal the effect upon it of getting him up or of gentle exercise can be tested.

At the end of the period of observation a decision can be made as to the form of treatment which is applicable to the present needs of the individual patient. The ambulant afebrile patient may be transferred to the sanatorium section. Other patients may be regarded as likely to obtain arrest of their disease and to be suitable for sanatorium treatment after an initial course of hospital treatment; another group of patients will be selected for artificial pneumothorax, phrenic evulsion, or some other form of operative treatment. Such treatment is preferably given in the hospital or surgical block of the institution, after which the patient may be found eligible for transference to the sanatorium section. A fourth group will include those patients obviously needing hospital treatment, but in which doubt is felt as to whether they will ever attain that degree of quiescence of their disease which will make them fit subjects for sanatorium treatment.

Finally, there are the advanced febrile cases in which the disease has progressed so far that only palliative treatment is indicated. When the home conditions are good and provision can be made for isolation a certain number of these patients may be advised or permitted to take their discharge, but the majority require hospital treatment either in the hospital block of the combined institution or in a special hospital or home for advanced cases. This treatment is not only in the interests of the individual patient who thus has his last days of life made comfortable by medical and nursing care, but inasmuch as he is likely to be a source of massive infection the segregation of this patient from his family is a valuable measure from the public health standpoint.

Hospital Treatment

In hospital treatment the criterion of temperature is all-important. Bearing this in mind, it follows that as a result of institutional observation the greater proportion

of patients will require a period of hospital treatment, for the early afebrile case of pulmonary tuberculosis is comparatively rare. In most early cases the disease begins with fever, and fever is also indicative of active disease in intermediate and later stages. The chief feature of the treatment in hospital is rest in bed, which should be absolute not only in name but in practice. Incidentally, the value of absolute vocal rest for patients suffering from tuberculous laryngitis cannot be over-emphasized.

In a favourable case, after the temperature curve under the influence of absolute rest remains normal and the pulse rate is steady, neither being disturbed by the patient being allowed up all day; when, concurrently, the physical signs in the chest are inactive and non-progressive and the general nutrition and physique are good, the patient is fit to be transferred to the sanatorium. But if after a month or six weeks' hospital treatment the physician finds that his patient continues febrile he must consider future treatment in relation, as always, to the individual case. For example:

(a) In a unilateral case or one chiefly unilateral he will consider the advisability of artificial pneumothorax or some other form of collapse therapy.

(b) In others he may wish to try the effect of sanocrysin or some other form of gold-salt therapy.

(c) Another case may present features of regression. The temperature is hectic, or, more ominous still, of the inverse type, being higher in the morning than in the evening. The physical signs are bilateral and are advancing. The sputum is copious, and emaciation and prostration are marked. One can only hope here to relieve the patient by attention to special symptoms, and the strict regime of absolute rest can be relaxed.

(d) Other febrile patients the physician may consider as unsuitable for collapse therapy, but inasmuch as they show general improvement as regards nutrition and the spread of disease he may advise longer treatment under absolute rest.

(e) Then there are certain chronic cases of pulmonary tuberculosis which respond to hospital treatment, but are obviously unsuitable for strict sanatorium treatment. Under this category may be grouped certain of the tuberculous asthmatics, the emphysematous, those with tuberculous laryngitis in a certain proportion of cases, those prone to complications, such as pleurisy, bronchial catarrh, bronchitis, and gastro-intestinal disorders.

A proportion of cases of this kind may live for years with tubercle bacilli in their sputum. From time to time their resisting power breaks down, and they require institutional treatment or are ordered rest at home in bed under appropriate conditions; they become afebrile, and with due precautions may resume an active life, but clinical experience teaches one that under any undue strain or climatic exposure, or intercurrent infection—for example, influenza—the chronic disease is liable to exacerbate. Such patients need medical supervision throughout the course of their lives, but they only require, as a rule, limited periods of hospital treatment.

Sanatorium Treatment

It will be seen from what has been said that the average tuberculous patient only qualifies for sanatorium treatment after a period of observation followed by hospital treatment. The early ambulant afebrile patient who is found on observation immediately suitable for the sanatorium is the exception and not the rule.

It is not intended in this paper to discuss the details of sanatorium treatment. Its essentials are that the patient should reside in a healthy situation, where he can obtain plenty of fresh air, be under close medical supervision, and adhere to a specified regime of life, including an adequate but not excessive diet. Graduated exercise and some form of occupational therapy are an integral part of the treatment. The rate at which the exercise is in-

creased and the hours of work are extended depends upon the progress of the lesion, and the patient's disposition, weight, and appetite. The utmost care must be taken in controlling graded exercises and work. If the patient's temperature rises to 99° F. or over he should be kept in bed on "absolute rest" until his temperature is persistently normal. For a limited period the patient may rest in the sanatorium ward, but whenever his temperature remains febrile for more than a few days he must no longer be regarded as a sanatorium patient. He needs transference to the hospital or nursing block of the sanatorium to undergo treatment by "absolute rest," after which, under favourable circumstances, he may re-enter the sanatorium. This alternation between hospital and sanatorium treatment is in great part the secret of successful institutional treatment of pulmonary tuberculosis. It is best done in the combined hospital-sanatorium.

As to the duration of sanatorium treatment, this depends upon the response of the individual. Some patients require longer, others shorter periods. If possible the patient should be retained in the sanatorium until his disease is quiescent and he is in a fit condition to resume an occupation. In patients falling short of this standard their sanatorium residence should have educated them in a way of life which may enable them in the future to obtain quiescence or to prolong their days.

Conclusion

An attempt has been made in this paper to indicate the principles of modern sanatorium treatment, including the selection of patients for such treatment. In brief these principles comprise:

1. The diagnosis of pulmonary tuberculosis at the early stage.
2. A proper selection of patients for sanatorium treatment.
3. Full co-ordination between the tuberculosis officer and the medical superintendent of the sanatorium.
4. Observation and hospital treatment, including collapse therapy.
5. Correct co-ordination of hospital and sanatorium treatment.
6. Study and treatment of the individual patient by the medical superintendent of the sanatorium.
7. A proper sanatorium regime.
8. Prolonged duration of stay in the sanatorium.

To these principles should be added the maintenance of the ex-sanatorium patient in whom the disease has become quiescent under medical supervision for at least five years, the injunction to seek medical advice at the first symptom of renewed ill-health, residence in a village settlement, or, if this is impracticable, suitable after-care provision by the local authority.

The sanatoria of the more progressive authorities in this country obtain favourable results by the practice of these principles. If they were generally practised throughout the country we should hear less about the failure of sanatorium treatment.

An international post-graduate course on diseases of infants and children, with special reference to their treatment, will be held in Vienna from February 11th to 24th. A prominent feature of this course will be the clinical demonstrations and the exhibition of radiological, electrocardiographical, and other apparatus used in diagnosis and special therapy. The fee is 50 Austrian schillings, and further information is obtainable from the secretary of these international classes, Dr. A. Kronfeld, Porzellangasse 22, Vienna IX.

SEPTICAEMIA FOLLOWING TONSILLECTOMY

A RECORD OF CASES

BY

BRANFORD MORGAN, M.D., M.R.C.P.Ed. and Lond.

HONORARY ASSISTANT PHYSICIAN, NORFOLK AND NORWICH HOSPITAL,
AND JENNY LIND HOSPITAL FOR CHILDREN, NORWICH

In recent years there have been at least two interesting papers^{1, 2} showing the result of investigation into the post-operative complications following the removal of tonsils and adenoids. Clinical notes of a series of cases may therefore not be out of place.

This article makes no attempt to deal with the statistical aspect, but merely records a number of cases that resulted in certain serious sequelae. They occurred at a time when children undergoing this operation were kept in hospital for twenty-four hours. The patients were admitted on the morning of operation and discharged the following day. The total mortality during these years was 0.7 per cent. All the cases reported were operated upon by, or under the direct supervision of, the surgeons in charge of the ear, nose, and throat departments, and no patient was discharged under twenty-four hours after removal of the tonsils. All were examined immediately prior to operation by the house-surgeon.

Eleven cases of severe illness, with seven deaths, are herein recorded, all of which can be directly attributed to the operation. Streptococcal blood infection would appear to be the principal cause of the illness. In seven of the cases a streptococcal blood infection was proved by the presence of the organism either in the blood or in the pus from pyaemic abscesses, while in Cases 8, 9, 10, and 11, the probability of a streptococcal septicaemia is strong.

Although among a large number of operations the incidence of serious complications may be considered small, yet the occurrence of such accidents in connexion with what is looked upon as a minor operation is disquieting, and calls for a critical survey of method and management. Following on this unfortunate experience it is impossible to resist the obvious implications and deductions. It is significant that patients operated upon in private practice, either in their own homes or in nursing homes, seldom develop severe complications. Many of the hospital patients come from poor, overcrowded, and unhealthy environments. Their physical condition cannot therefore be considered satisfactory to undergo an operation, and their homes are certainly not suitable for their after-care. Whenever possible such cases should be taken into hospital or sent to a convalescent home for a few days prior to the operation.

As there can be little doubt that the chief source of danger is the presence of a virulent strain of streptococci in the upper respiratory passages or tonsils, it is a self-evident precaution to avoid operating upon those who have recently had, or been in contact with, infections of this nature. In this connexion it is as well to remember that the surgeon or the staff assisting him may be the source of infection, and that anyone in the throes of "a cold" should be excluded from taking part in the operation.

Since these cases occurred the period of detention in hospital has been increased to three days during the summer months and five during the winter months; complications have been greatly reduced and the mortality practically wiped out. Considerations of hospital finance and the length of the waiting list should not be entertained at the expense of the safety of the operation.

It is difficult, when one realises the vast number of patients referred for operation, to resist a sense of doubt

as to its necessity or even advisability in all cases. The beneficial results following the removal of tonsils and adenoids in selected cases are undoubtedly most striking, but operation is to be advised with deliberation after careful and, if necessary, repeated examination.

Case Records

Case 1.—A male, aged 8 years, had tonsils and adenoids removed, guillotine method, on March 4th, 1932. The temperature, which on March 5th was 99.8° , rose gradually to a maximum of 104.4° on March 13th. The throat was fairly clean; there were a few enlarged and tender cervical glands. On March 11th painful (Osler's) node was noted on right wrist, and on the same day a blood culture grew streptococci. Painful nodes were noted on the right foot and left upper arm on March 12th, similar nodes developing subsequently during the next day on the left hand and right knee. On March 14th there was fluid effusion into the left knee-joint, which cleared up without surgical measures. Three days later a fluctuating swelling appeared on the fourth finger of the left hand, and pus aspirated from this contained streptococci. The temperature then gradually settled, although it was never normal, until a sharp rise occurred on March 24th, which continued until March 27th, when a large abscess in the deep tissues below the left scapula was aspirated; this also contained streptococci. Gradual improvement followed, until the patient was discharged to a convalescent home. Anti-streptococcal (anti-scarlet) serum was administered daily throughout the illness, and blood transfusion was performed when it was at its height.

A case of streptococcal septicaemia with pyaemic abscesses, and recovery.

Case 2.—A female, aged 4 years, had tonsils and adenoids removed, guillotine method, on March 9th, 1932. The temperature was 100.4° on March 10th, reaching 102.4° on the third day, and remaining up until death took place, one week after operation. There was consolidation at the base of the right lung with generalized bronchitis. Blood culture grew streptococci.

A case of streptococcal septicaemia with bronchopneumonia and rapidly fatal termination.

Case 3.—A female, aged $7\frac{1}{2}$ years, whose tonsils and adenoids were removed, guillotine method, on July 1st, 1931, was detained in hospital for six days owing to slight pyrexia. She remained well for one week after discharge, but was put to bed at home on account of lassitude and feverishness. A slight swelling of the left knee was noticed on July 22nd, which gradually increased, the child becoming extremely ill. On August 8th she was readmitted, looking very pale, with tonsillar fossae clean, and temperature 105.2° . The left knee was swollen, tender, and flexed at 90° , and on exploration contained turbid fluid, from which streptococci were isolated in pure culture. On August 12th the right hip-joint was extremely painful, and on aspiration turbid fluid was obtained which contained streptococci. The temperature continued to range from 100° to 103° until death, on August 14th. Blood culture was not carried out.

A case of streptococcal septicaemia with pyaemic abscesses, and death.

Case 4.—In this case, that of a female aged 26 years, the tonsils and adenoids were removed by dissection method on October 16th, 1931. She was discharged on October 19th and remained well until October 23rd, when she complained of severe pain in the left ear, accompanied by fever of 105° . Owing to persistence of pain in the ear and pyrexia, the left mastoid was opened; no pus was found, and the lateral sinus was healthy. On October 27th right pleural effusion developed, blood-stained fluid being withdrawn on exploration, which on culture grew streptococci. Blood culture was sterile (one only). The pyrexia continued, and on November 26th thrombophlebitis of right femoral vein occurred. By the end of December the fever had subsided, and the signs of fluid in the right chest had disappeared. The patient was discharged well, except for slight oedema of the right foot.

A case of streptococcal septicaemia, streptococcal pleural effusion, with recovery.

Case 5.—A male, aged 5 years, whose tonsils and adenoids were removed, guillotine method, on September 16th, 1931, was discharged from hospital the following day apparently well. He was readmitted six days afterwards with a history of severe abdominal pain, vomiting, and diarrhoea for three days. On admission he was very ill, with sunken eyes and alae nasi working. The temperature was 102° , pulse rate 152, and respirations 32. The throat was clean, except for a slough still present on the right tonsil. There was generalized tenderness and rigidity over the abdomen, the signs being especially marked in the left iliac fossa. There was pneumonic consolidation over the lower lobes of both right and left lungs. It was decided that the abdominal signs were probably due to the pneumonia, but on the following day, the abdominal tenderness and rigidity persisting, laparotomy was performed under gas and oxygen anaesthesia, serous fluid with flaky pus escaping. This fluid contained streptococci on culture; blood culture was sterile. The child died two days after operation.

A case of streptococcal septicaemia, with bronchopneumonia, streptococcal peritonitis, and death.

Case 6.—A male, aged 9 years, had tonsils and adenoids removed, guillotine method, on August 8th, 1931. On the following day the child had a temperature of 100° , and was therefore detained in hospital. On the second day after operation the temperature was 102° , pulse rate 140, and respirations 22. The throat was satisfactory, and a few rhonchi were present in the lungs. The child was acutely ill and drowsy. The temperature ranged from 100° to 104° until the fourth day after operation, when it gradually subsided. A blood culture grew a few feeble colonies of streptococci.

A case of streptococcal septicaemia, with recovery.

Case 7.—A female, aged 3 years, was admitted to hospital for an indefinite febrile condition, supposed to be due to a recent tonsillitis. Ten days after admission, on June 8th, 1932, tonsils and adenoids were removed, guillotine method. Twelve hours after operation the temperature rose to 100.4° , and so continued. On June 12th there was pain with redness and swelling just below the left knee, maximum tenderness being over the head of the fibula. When the left fibula was explored on June 14th about 5 c.cm. of pus was evacuated; this contained streptococci. Blood culture was negative. The child made an uneventful recovery.

A case of streptococcal septicaemia, with streptococcal osteomyelitis of fibula.

Case 8.—The tonsils and adenoids of a female, aged 2 years and 9 months, were removed, guillotine method, on February 15th, 1932, on account of persistent nasal discharge. On February 19th the child was discharged from hospital apparently well. She was readmitted on February 24th with a temperature of 104° , pulse rate 148, and looking extremely ill and pale. No abnormal physical signs, except some post-nasal discharge and enlarged cervical glands, could be found. In spite of a blood transfusion the child died on the day following admission. Unfortunately, a blood culture was not attempted, but the clinical picture and progress of the case is highly suggestive of a septicaemia, probably streptococcal.

Case 9.—The tonsils and adenoids of a male, aged 2 years, were removed for unilateral nasal discharge, guillotine method, on May 15th, 1931. The child was discharged from hospital after twenty-four hours apparently well. Two days after operation he developed cough and dyspnoea, and became increasingly ill. He was readmitted to hospital the next day, with a temperature of 99.4° , pulse rate 160, and respirations 56; there was extreme cyanosis, and coarse rales could be heard all over both lungs. Death took place five hours after admission.

The signs in this child were suggestive of an acute streptococcal bronchopneumonia. However, the possibility of inhalation pneumonia cannot be denied, although I have not met with such in my experience of a very large number of tonsillectomies in children. Unfortunately, no post-mortem was obtained.

Case 10.—A male, aged 5 years, had tonsils and adenoids removed, guillotine method, on January 23rd, 1931. He was discharged from hospital after twenty-four hours apparently

well. Three days after operation there was a sudden onset of severe vomiting and diarrhoea. The child's condition rapidly became worse, and unconsciousness supervened the following day. On readmission (five days after operation) the temperature was 103°⁰, pulse rate 160, and respirations 32. The patient was very drowsy, but could be roused; his colour was good. There were scattered rhonchi throughout both lungs, a patch of tubular breathing, and crepitations at left base. The temperature remained at 103°⁰ to 104°⁰; delirium and unconsciousness supervened, death taking place two days after admission—that is, one week after tonsillectomy. No blood culture or post-mortem was performed, but the clinical picture was one of septicaemia.

Case 11.—A female, aged 9 years, had tonsils and adenoids removed, guillotine method, on October 7th, 1931. She was discharged from hospital after twenty-four hours apparently well. On arrival home she was seen by the family doctor, found her not at all well, with a temperature of 101°⁰. Child continued very ill; the throat was dirty, and the temperature ranged from 101°⁰ to 103°⁰. On October 10th there was severe epistaxis. The following day the patient was very ill; her expression was anxious, and her breath offensive. There was sordes on the lips and teeth, and the throat was very dirty and sloughy. The cervical glands were enlarged and tender, and blood oozed from the nasopharynx. She was admitted to a nursing home, when the temperature was 102°⁰, pulse rate 144, and respirations 28. A throat swab showed the presence of streptococci and staphylococci. In the morning of October 12th the patient's condition slightly improved, but in the evening there was another severe epistaxis, and she became semi-conscious. A post-nasal plug was introduced to control haemorrhage, and anti-streptococcal serum was given. The child died that evening. No blood culture was obtained.

Although the post-nasal haemorrhage was probably contributory, the fatal result in this case, in view of the high pyrexia and general picture, was considered to be due to septicaemia.

I desire to express my thanks to my colleagues in charge of the ear, nose, and throat departments for allowing me to see and record these cases.

M. Gundel and F. Müller-Voigt (*Deut. med. Woch.*, November 2nd, 1934, p. 1664) give an account of a hurricane campaign of diphtheria immunization in the town of Duisburg-Hamborn. With a population of 440,000 it has suffered more and more from diphtheria since 1928. In that year there were 1,438 cases and 112 deaths. In 1933 the cases rose to 2,090 and the deaths to 126. In 1934, up to September, there were as many as 2,214 cases and 160 deaths. Artificial immunization of the children seemed, therefore, urgently indicated, and within the space of six days first injections were given to 23,000 of the 38,562 children between the ages of 1 and 5, and to 57,034 of the 64,450 school children between the ages of 6 and 14. The material used was formol-toxoid and toxin-antitoxin, and the immunization was effected by three injections. In the absence of legislative measures wherewith to enforce this undertaking, the authors achieved rapid, wholesale immunization of the town's juvenile population by means of systematic educational propaganda and a well-organized campaign, which required the co-operation of more than a hundred doctors and over 3,000 other workers, about 1,700 of whom were school teachers. The propaganda included articles in the Press, and addresses. It was found much easier to deal with the school child than with the pre-school child, as the former could be shepherded by their teachers, whereas the latter required extraction from their homes, a process which could not be achieved by simply inserting notices in the Press. The rate at which the school children were inoculated, after some practice had been acquired, was 140 to 150 per hour; the rate was considerably slower for the pre-school children.

ACUTE IODISM FOLLOWING LIPIODOL BRONCHOGRAPHY

BY

J. G. SCADDING, M.D., M.R.C.P.
RESIDENT MEDICAL OFFICER, BROMPTON HOSPITAL

The use of lipiodol for bronchography has now become so much a part of the routine investigation of non-tuberculous chest diseases that the occurrence of any severe complication appears worthy of record.

Lipiodol consists of poppy-seed oil in which 40 per cent. of iodine is held in chemical combination with the unsaturated fats. The possibility of the production of toxic symptoms in patients with an idiosyncrasy for iodine is obvious. However, severe symptoms from this cause appear to be rare, owing to the close chemical combination in which the iodine is held. Sicard and Forestier¹ state that they have encountered only transient iodism of benign type. A report² of the Council of the American Medical Association on the dangers of the injection of iodized oils makes no mention of the possibility of dangerous toxic symptoms. Firth³ describes a personal experience of troublesome but not serious symptoms from iodine sensitivity following endotracheal introduction of chloridized peanut oil; in addition to coryza, lachrymation, and an urticarial rash, he had a transient parotitis and severe frontal headache, all passing off within a week. Carmichael⁴ records two considerably more severe cases after lipiodol, characterized by vomiting, diarrhoea, conjunctivitis, and a haemorrhagic, urticarial, and bullous rash. Both cases improved rapidly within a week. O'Donovan⁵ reports a case in which death occurred six weeks after lipiodol injection, accelerated by the aggravation of a previously existing papulo-pustular rash.

The two cases described in this communication, one of which proved fatal, occurred recently at the Brompton Hospital. Over 2,900 lipiodol examinations have been performed at this hospital without a previous serious accident from iodine sensitivity. A transient coryza with lachrymation and possibly a mild urticarial or erythematous rash, all passing off within a few days, have been observed not infrequently. In a few cases more severe rashes—appearing rather later, up to a week or ten days after the injection—have occurred. These tend to be of an acute and irritant urticarial type. Headaches have followed the injection in rare instances, and in one case frontal headache was severe enough to cause suspicion of acute glaucoma. I have been unable to find any previous record in the literature of a fatality directly due to acute iodism consequent on the diagnostic use of lipiodol.

Case I

A man, aged 46, was admitted to the Brompton Hospital in August, 1933. He was referred from a sanatorium, where doubt about the original diagnosis of pulmonary tuberculosis had arisen on account of atypical x-ray appearances and persistently negative sputum examinations. The differential diagnosis appeared to rest between chronic lung abscess and neoplasm. His general condition was poor, and he had lost 3 st. in weight.

On August 22nd I introduced 20 c.cm. of lipiodol by the subcuticoid route. The film taken after this showed a good outline of the bronchi, with a probable chronic bronchiectatic abscess of the right upper lobe; there was no lipiodol in the stomach. Six hours later he had developed marked coryza, with nose-bleeding, salivation, and injection of the conjunctivae. The following day he was obviously weaker; the pulse was rapid and of poor volume, and the temperature was rising; the nose-bleeding continued. Scattered petechiae had appeared, especially on the dorsum of the hands and

forehead; the conjunctivae had become grossly oedematous, and haemorrhages had occurred into them; the tongue was swollen, and there was a large submucous haemorrhage in it. The submaxillary glands had become very swollen and tense.

On the next day, August 24th, all the symptoms were more severe; the blood pressure was reduced to 85/60. An urticarial element was evident in the rash, which had become more widespread; subcutaneous haemorrhages were seen over the pressure points, especially the right elbow and the sacrum. There was marked dyspnoea, and scattered moist rales were audible over both lungs. There was great difficulty in swallowing on account of the grossly swollen tongue, but no evidence of oedema of the glottis sufficient to cause obstruction. Bleeding from the nose and gums continued; the patient was unable to open the oedematous and haemorrhagic eyelids. He ultimately died, from exhaustion and pulmonary oedema, fifty-four hours after the lipidol injection.

The treatment in this case consisted of the administration of a saline purge at the onset of symptoms; adrenaline locally to the swollen tongue and fauces failed to reduce the oedema; atropine was given to check excessive bronchial secretion; and sodium thiosulphate, 0.5 gram intravenously, produced no improvement.

Post-mortem Examination.—This was performed by Sir Bernard Spilsbury, and the following is a summary of the relevant pathological changes. External appearances: numerous large petechiae in skin of face, with larger haemorrhages in skin of upper eyelids and in conjunctivae. Numerous petechiae in skin of hands and feet, a few on rest of limbs and trunk. A group of large haemorrhages with ulceration over back of right elbow and over sacrum. Raised red nodule over trachea; no septic change found on incision. Heart: pericardial cavity obliterated by fine old adhesions. Extensive haemorrhages into visceral pericardium, chiefly over left ventricle. Heart somewhat enlarged and dilated. Small haemorrhages in myocardium, and one in endocardium. Microscopically, slight fatty degeneration and some brown atrophy of the muscle. Air passages congested, large petechiae in mucosa of trachea, becoming confluent in larynx. Oedema of ary-epiglottidean folds, especially on right side. Lungs: very dense adhesions over upper part of right lung; marked bronchiectasis, with fibrosis of upper half of right upper lobe, with a large cavity in lower part of lobe. Lower parts of both lungs congested and oedematous. Liver: small haemorrhages into substance. Kidneys: cloudy swelling and congestion. Intestines: haemorrhages in mucous membrane of middle third of small intestine. Tongue: haemorrhage in left side of tip, forming a small nodule. Submaxillary glands: enlarged, with haemorrhages beneath capsule and between lobules.

Case II

The patient, a woman aged 59, had been attending the hospital for some years. In 1930 a lipidol examination was performed, and showed bilateral basal cylindrical bronchiectasis. She had been treated on frequent occasions with medicines containing potassium iodide, though the dosage did not exceed 15 grains daily; neither the lipidol nor the iodide had caused toxic symptoms. A second lipidol examination was performed on June 29th, 1934, 20 c cm. being introduced by the crico-thyroid route, the patient subsequently returning home. The x-ray film showed more advanced bilateral bronchiectasis.

She was admitted to hospital on the following evening, June 30th, acute symptoms having appeared about six hours after the injection. On admission she had an urticarial rash with large purpuric patches over both olecranon, and just below the knees. There was gross painful swelling of both forearms, round both elbows, and behind the knees, the appearances resembling those of cellulitis. The face was puffy, the conjunctivae grossly swollen, with purpuric patches in them and in the eyelids. There were a few purpuric spots on the tongue, and one on the upper lip. The chest was full of bubbling rales and rhonchi; cough was difficult. There was some dysphagia.

On July 2nd all symptoms were more severe. The brawny swellings on the forearms were extremely painful. The patient was unable to swallow even fluids, but there was no respiratory

obstruction in the larynx; adrenaline locally failed to reduce the swelling sufficiently to render swallowing possible. The pulse was of very poor volume. The urinary output was scanty, and there was a cloud of albuminuria; the patient was rapidly becoming weaker.

It was thought that the lack of circulating fluid owing to deficient intake and to withdrawal of fluid into the oedematous tissues was the chief cause of the asthenia; 25 oz. of hypertonic (1.8 per cent.) saline with 5 per cent. glucose was therefore given intravenously. In spite of a rigor, very definite improvement followed within a few hours; the patient was able to swallow fluids freely, and the pulse became stronger. During the next few days steady improvement continued. The brawny oedema of the limbs persisted for a week, and the purpuric areas on the elbows, knees, eyelids, and upper lip ulcerated and healed under scabs. A purulent infection of the oedematous conjunctivae occurred, but cleared up without complications. The patient was not fit to leave her bed for four weeks, but eventually made a good recovery.

Discussion

There can be no doubt that the toxic symptoms in these two cases were due to hypersensitivity to iodine. The fact that the second patient had already had a lipidol injection, and had been treated with potassium iodide medicinally without ill effect, shows that testing for sensitivity by a dose of potassium iodide is of little value. It also suggests the possibility of the symptoms having been due to an abnormal sensitivity to the poppy-seed oil component of the lipidol. This appears to be negated by the close similarity of the symptoms to those known to be produced by iodine sensitivity. A case presenting very similar symptoms, though without the haemorrhagic rash, after a single dose of 25 grains of potassium iodide, has been reported by Snell and Savin.⁶ There can be no question of impurities in the lipidol, as in both cases it was perfectly clear, and other injections with the same batch gave rise to no ill effects.

The accidental introduction of lipidol into the stomach is generally considered to be a necessary antecedent of toxic symptoms. In neither of these cases was there lipidol in the stomach when the x-ray film was taken, but it is possible that, in spite of instructions to the contrary, the patients swallowed some after coughing it up. Sicard and Forestier,⁷ however, have shown that, judging the rate of absorption of lipidol by the rate of elimination of iodine in the urine, the rates of absorption from the lungs and from the gut do not differ so much as might be expected. For instance, they found that if lipidol is administered in capsules by the mouth 34 per cent. of the iodine is excreted by the kidneys within five days; if introduced into the bronchi, 20 to 23 per cent. is thus excreted.

It appears, therefore, that the greatest care in testing for sensitivity to iodine and in avoiding the introduction of lipidol into the alimentary tract will not always prevent the occurrence of serious symptoms from iodism after the diagnostic use of lipidol. It is suggested that in the fortunately rare event of such symptoms being severe, the use of intravenous hypertonic saline is a theoretically rational and practically useful measure.

I am indebted to Mr. Tudor Edwards and Dr. A. L. Punch for permission to report these cases, and to Sir Bernard Spilsbury for allowing me to use his post-mortem record.

Clinical Memoranda

A NOTE ON DRUG ADDICTION TREATMENT.

When his particular method finds a place in the text-books its author may believe that later developments should be published, even though the field covered is of restricted general interest. Addiction is rare in England, but abroad the demand for a reliable treatment is ever more insistent. It may be worth while, therefore, to describe a radical improvement and simplification of the "painless method" associated with my name, whereby the process of medical withdrawal can be carried out successfully by any careful practitioner.

First, as to rationale. Drugs of the atropine group have been employed in countless systems, but always previously in massive doses to produce delirium and confusion, under cover of which the patient is separated from his drug. All such methods constitute a serious shock to the frequently debilitated addict, with the result that convalescence is delayed and the final issue imperilled. A very different use of atropine has great advantages and no such dangers.

Atropine shows two distinct and, in some respects, opposite effects, as it is given in minute or in ordinary doses. With the latter, of course, vagal depression is constant, but such small amounts as 1/1000 to 1/500 grain occasion vagal stimulation. I have shown that this primary vago-stimulant action of small doses continues when tolerance to atropine is established. Thus a patient who has received frequent minute doses for a week will show a slowed pulse when the dose becomes 1/100 grain. This fact is used in my simplified process of withdrawal.

The morphinist or other addict is one who has become accustomed to preserve vagal preponderance and sympathetic depression by means of his drug. Less than his normal supply means sympathetic overaction, while deprivation ushers in a series of sympathetic explosions which may even endanger life. On the other hand, frequent minute doses of atropine secure for him the steady vagal tone which means a smooth passage to recovery.

The process is very simple in practice. Atropine 1/100 grain is dissolved in saline with the day's supply of morphine, "half a drachm" to be injected every two hours while the patient is awake." Obviously sleep is a measure of the patient's comfort, and the more he sleeps the fewer the doses needed. The amount of drug actually used forms the maximum for the day following, and the process is continued until less than 1/4 grain is taken in the twenty-four hours. Atropine is increased so slowly that ocular symptoms are not produced, and luminal administered in large and increasing amounts. The method is automatic and self-regulating, and the test of success is a slightly slower-than-normal heart beat, which is quite invariable with proper dosage.

The conception of the addict as sustaining by his drug an artificial vagal preponderance, and needing to have it continually sustained throughout withdrawal, is also useful when convalescence is considered. He will be safe from unpleasant sensation so long as his threshold of fatigue is not exceeded, but if he oversteps the mark sympathicotonia immediately is manifest. His physical and mental powers will rapidly improve, but their exercise must be most carefully watched, especially in the early stages, and, indeed, it may be doubted whether a completely normal day's work should be undertaken for several months.

Painless withdrawal, anxious consideration of problems of fatigue, and adequate psychological treatment are the three factors without which constant success is impossible. The neglect of one, and often of all, has made the usual prognosis in addiction unduly gloomy.

London.

G. LAUGHTON SCOTT, M.R.C.S.

RETROPERITONEAL SARCOMATOSIS

The following case should be of interest by reason of its rarity and the difficulty in diagnosis.

A woman, aged 47, was seen in the out-patient department of the Southport Infirmary on June 4th, 1934, when she complained of generalized abdominal pain and weakness. She said that she had been ill for about a month, but had rapidly become worse during the past few days, and had noticed that her abdomen was rather larger than usual. She had not vomited, her bowels were acting normally, she complained of no urinary symptoms, and the menstrual history was normal. Her past history revealed that a Caesarean section had been performed twelve years previously; she had been troubled by chronic kidney disease, resulting in albuminuria of pregnancy.

On examination she looked extremely thin, pale, and generally very ill, and gave the impression of a typical malignant cachexia. The temperature was 97°, pulse 124, and respirations 24. The tongue was dry, though not coated. There was nothing of note in the chest; the abdomen was distended, and a hard, irregular swelling was felt in the left iliac region, though it was difficult to discover anything definite on account of some free fluid. There was slight tenderness and rigidity on palpation in the left iliac fossa. The liver was apparently normal, the spleen could not be palpated, and the kidneys presented nothing abnormal. Digital pelvic examination proved negative. The urine was examined, and was found to contain albumin and pus. There was general swelling of the left lower limb.

The patient was seen by a physician, and a laparotomy was advised. She was admitted to hospital for this purpose on June 6th. The urine was subjected to a pathological examination, but no additional information was gained. The urinary tract was x-rayed, but nothing abnormal was found. The patient's condition, however, became rapidly worse. The skin was moist, and she perspired a great deal, the tongue remaining dryish. The abdomen became very much more distended, pain increased, and she vomited bile-stained fluid. Very little urine was passed during the last two or three days of the illness. The patient died suddenly on June 15th, without a diagnosis having been arrived at.

POST-MORTEM FINDINGS

On opening the abdomen a large quantity of dark, straw-coloured, apparently infected free ascitic fluid came away, and then a very unfamiliar picture presented itself. The omentum was pale, rather vascular, nodular, and fixed down to the sigmoid flexure, where there was a focus of active inflammation, due to diverticulitis. The intestines were pale, shrunken, atrophic, coated with lymph, and studded here and there with small, pale nodules. The stomach and duodenum appeared normal. There was no sign of any growth in the intestinal tract. The liver was pale in colour and normal in size, and the spleen was normal. The pelvic organs were very atrophic, and studded with the same type of nodules as the intestines. Kidneys were normal in size, but there was a pyelitis affecting each pelvis. There was a very hard extensive mass, which appeared regular on the surface, situated behind the mesenteric attachment of the intestines, extending along the vertebral column on each side, and spreading upwards towards the upper regions of the abdomen.

Sections were cut of the liver, omentum, and of a piece taken from the retroperitoneal mass, and microscopical examination revealed the liver to be in a state of toxic hepatitis, with fatty degeneration of the hepatic cells. Pieces of the thickened omental and retroperitoneal tissues showed a generalized sarcomatosis of the large round-celled variety.

One can conclude that this was a case of primary retroperitoneal sarcomatosis, possibly of lymphoid origin, and that the omentum and other parts of the abdominal cavity were affected by secondary sarcomatous deposits. The rapidity with which death took place, following a comparatively short illness, probably bears out these facts.

I should be very interested to hear other views on the subject, and of any other cases of a similar nature which have occurred recently.

HENRY F. G. IRWIN, B.A., M.B., B.Ch.,
Senior House-Surgeon, Southport Infirmary.

Reviews

CHILD GUIDANCE CLINICS

There are now more than two hundred child guidance clinics in the United States of America, and during the last few years their number in this country has been increasing. The name is not altogether a good one, and there are several clinics here which have never used it. The Institute of Medical Psychology in London, for instance, where one-third of the patients are children, had been doing work such as that carried out in the best American clinics for years, but has deliberately avoided the name. There are many medical men and others who still seem to have no clear idea of the work done at such clinics, and, indeed, the clinics themselves vary a good deal in character, and are conducted under diverse auspices. Those who wish to know more about their nature and activities will value a book recently published by the Commonwealth Fund, by Dr. G. S. STEVENSON and Mr. GEDDES SMITH, entitled *Child Guidance Clinics: A Quarter Century of Development*.¹ The book deals entirely with the American situation, and is based solely on American experience. This is reasonable, as the main pioneer efforts were made in that country, and it is by the help of the Commonwealth Fund that a considerable part of the work in England has been made possible. There are, however, beginning to be shown some divergencies of view and of method as the common type becomes adapted to the needs and conditions of this country.

The type is essentially an organized co-operation. The psychiatrist (in the wider American acceptance of the term), the psychologist, and the trained social worker are the essential members of the team, but with them should be associated the paediatrician, the teacher, the family doctor, and, of course, wherever possible, the parent. It offers, probably, the best example of that team-work which the modern wider outlook of medicine is rendering more and more imperative. The psychiatrist or psychotherapist should always be the leader of the team, but the exact relationship between each member and the others will vary somewhat in different clinics; and it is important to remember that "the co-operative situation demands not only participation in the study of a case but continued team-work in treatment." The children whose emotional state or difficult behaviour has led to their reference to the clinic must definitely be regarded as patients; but "diagnosis in a child guidance clinic is not a pigeon-holing word or phrase, but a reconstruction of the case." The patients come from various sources, some from the recommendation of the family doctor, some from schools, from children's courts, or from hospitals of the ordinary type; and the methods of the clinic may well vary within limits in accordance with the proportion of children coming through each of these channels. Not infrequently it is found that "treatment of the mother is an almost invariable concomitant of treatment of the child," but this should not be undertaken at the clinic unless it is the most promising way of solving the emotional difficulties of the child, and always in direct relationship thereto. In all clinics a play-centre is almost essential both for diagnosis and for treatment; for "in the use of playthings and play situations young children often reveal emotional problems which they would be unlikely to put into words," and unfettered play, or play which is not obviously directed or controlled, is frequently a valuable means of treatment.

¹ *Child Guidance Clinics: A Quarter Century of Development*. By George S. Stevenson, M.D., and Geddes Smith. New York: The Commonwealth Fund; London: H. Milford, Oxford University Press, 1934. (Pp. 186. 6s. 6d. net.)

The usual course of clinical activity, though developing on this pattern, is not yet fixed, but is proving of great service to individuals and must be regarded as definitely preventive in relation to delinquency and mental disease. The best clinics, moreover, are much more than therapeutic agencies; their educational activities, both for the medical practitioner and for the social worker, have greatly extended, and the opportunities for research which they afford are very valuable, though at present scarcely used.

BRONCHOSCOPY, OESOPHAGOSCOPY, AND GASTROSCOPY

The call for a third edition of *Bronchoscopy, Esophagoscopy and Gastroscopy*² has given Dr. CHEVALIER JACKSON the opportunity for bringing this well-known book up to date in some particulars. The chief direction in which this is required is due to the extension of endoscopic diagnosis and treatment, and some fresh coloured plates in the famous style of Dr. Jackson, showing views of the bronchi and oesophagus, even surpass the old familiar ones in vividness of colouring and artistic merit. The possibility of removing small pins from the periphery of the lung is described here, as also very fully in the recently published *Foreign Body in the Air and Food Passages, Roentgenologically Considered*. The word "possibility" is used, because it may be doubted if Dr. Jackson has laid quite enough emphasis on the fact that the number of bronchoscopists competent both by training and equipment to attempt such removals must be, and always will be, very small.

Reading the book again, it is impossible not to gain the impression that many of the problems which are of daily, or at least of frequent, occurrence in the author's bronchoscopic clinic are seldom encountered in this country, even in large clinics, and that the conditions of practice must be different in many ways. It is, however, a book with which any practitioner who claims to be a specialist in laryngology must be absolutely familiar, for in this volume the whole subject is brought to its essentials. To gain historical perspective it should be read in conjunction with the old *Peroral Endoscopy and Laryngeal Surgery*, if that is available. Dr. Jackson himself says that the bronchoscopist is likely to see things narrowly through a small tube metaphorically as well as actually, and for that the historical perspective is the proper correction.

PHYSIOLOGICAL CHEMISTRY

Turning over the first few pages of his book, which Professor McCLENDON entitles *Manual of Biochemistry*,³ one becomes immediately aware that it is no ordinary textbook on biochemistry, and that it is therefore advisable to go at once to the preface for a better idea of its scope than is conveyed in the title. The book represents in the words of the author "a condensation and rewriting of mimeographed material with considerable additions." It is essentially a catalogue of facts, the arrangement of which, so as to accommodate all his data, has obviously presented the author with considerable difficulty. Almost every conceivable subject or substance connected with animal or plant biochemistry receives mention, some at length, such as the vitamins and hormones, while others

² *Bronchoscopy, Esophagoscopy, and Gastroscopy: A Manual of Peroral Endoscopy and Laryngeal Surgery*. By Chevalier Jackson, M.D., Sc.D., LL.D., F.A.C.S., and Chevalier L. Jackson, A.B., M.D., M.Sc., F.A.C.S. Third edition, rev. Philadelphia and London: W. B. Saunders Company, 1934. (Pp. 485; 207 figures, 15 coloured plates. 37s. 6d. net.)

³ *A Manual of Biochemistry*. By J. F. McClelland. New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1934. (Pp. 381; 33 figures. 31s. net.)

are dismissed in a sentence, coupled with a single reference to the literature. This volume is certainly a storehouse of information. Little-known points of interest are jotted down concerning most substances, and many more data appear regarding the inorganic elements than can be found in any other biochemical work. Laboratory methods in condensed form find a place near the end, but those selected are not always the most recently published modifications of the authors quoted. Lastly, there is a table, printed on tinted paper, in which data concerning a thousand substances of biochemical interest are recorded. A great deal of labour must have been expended in the compilation of this work, but since access to the literature is rendered so comparatively easy nowadays, through the existence of comprehensive and efficient systems of indexing, one is left wondering in the end whether it has been quite worth while.

In preparing his *Introduction to Physiological Chemistry** Professor MEYER BODANSKY had as his chief aim the provision of a small textbook which would be sufficiently comprehensive to cover the whole field, and at the same time would aid the student to correlate biochemistry with its allied sciences. The first edition, which appeared in 1927, met with a warm welcome, and the fact that the volume under review represents the third edition provides further testimony to the skill and success with which the author has carried out his purpose. It is an attractively written book, and manages to convey in full measure to the mind of the student the fascination of a subject which has made amazing strides in recent times. Though called an introduction, its standard goes beyond the elementary, and the student is constantly referred to original sources for fuller discussions of the particular topic under consideration. It is indeed exceedingly well documented with a judicious selection of references. The present edition brings the material right up to date. Recent advances have not been merely tacked on, but the sections to which they apply have been rewritten so as to bring out the true relationship of the latest discoveries to the basic work which has preceded them, and to indicate their place on a frontier ever being extended into the unknown. Professor Bodansky is equally authoritative whether dealing, on the one hand, with the foundations built upon pure organic and physical chemistry, or, on the other, with the clinical applications of the science. It would be difficult to improve upon the manner in which he accomplishes his task within the compass of 662 pages.

THE PROBLEM OF MYOPIA

As is implied by its name, *Stretching of the Eye (Myopia) and its Treatment*,* Professor GRUNERT's monograph is a reversion to an old view of a baffling problem. The author dismisses the highly significant work of Steiger, holding that Steiger's biomathematical approach leads to therapeutic nihilism, and that its clinical value is therefore limited. Harking back to the fallacies which gave a limping justification for the use of both full correction and under-correction, atropine and eserine, and almost every other conceivable mode of treatment, the author urges that myopia is the result of the yielding of the sclerotic induced by changes in the intraocular pressure during childhood. Arguing from the fact that the posterior segment of the eye consolidates at a later period than the anterior segment, he further holds that myopia is the

result of a persistent infantilism of the sclerotic, this being sometimes hereditarily determined, but generally the consequence of an abnormality of the ciliary muscle. On this basis he advocates the use of pilocarpine in an attempt to bring the ciliary muscle to a normal state, and thus to put the eye into a position of fending for itself against the progression of myopia. So successful does he consider his results that he regards the treatment of myopia as one of the most grateful tasks in medicine. To illustrate his thesis he gives a number of case reports. To the reviewer these case reports are indeed convincing—that is to say they confirm his belief that a method which will render the treatment of myopia a "grateful task" is still to come, and that ingenuity spent in resurrecting old views on myopia is a waste of labour.

JOHNSTONE'S MIDWIFERY

The short interval that has elapsed since the previous edition of Professor R. W. JOHNSTONE's *Textbook of Midwifery* indicates that its enlargement and resetting have increased its already wide appeal. Careful revision has been a feature of past editions, and is again prominent in this issue,* including minor alterations and some of major importance. Among the former are changes in the chapter on menstruation required to meet the constant flux of opinion on the biochemical aspects, the inclusion of recent work on the changes in the foetal circulation at and after birth, and on the treatment of puerperal haemorrhages. The use of the forceps in the delivery of the after-coming head is advocated more strongly than before on account of the lessened risk of brachial palsy.

Alterations of principle include the adoption of the terminology approved by the Anatomical Society of Great Britain, and the separation from the section on the physiology of the puerperium of the portions dealing with the newborn child, which have been made into a new section. In it are three chapters giving a succinct account of the physiology and management of the infant, its diseases and birth injuries, and the methods of artificial feeding. The additional space and greater prominence thus given to this part of the subject serve to bring it into its due perspective. We have a little grumble, however, because part of the physiology of the breast is left in its former position, and the most has not been made of the valuable lessons in the direct application of physiology to clinical practice that a somewhat fuller study of mammary function can furnish.

By bringing into apposition the physiological and the pathological this new section follows a suggestion put forward in our review of the previous edition, but the author states in his preface that although he has pondered over the advice to do likewise throughout the book he prefers his original plan. There can be no argument about his decision, for every teacher must have full liberty to teach his lesson in the way he thinks best, and Professor Johnstone doubtless feels that an arrangement suitable for a short section is not equally suitable for the lengthier ones. But he will perhaps accept, in theory at any rate, the view that in training students the closer that ordered function can be contrasted with the disordered the easier it becomes to stress the importance of promoting the normal and the early detection of the passage into disordered function.

Our high opinion of the excellent instruction, scientific and practical, of Professor Johnstone's textbook is enhanced by its latest edition.

* *Die Dehnung des Auges (Myopie) und ihre Behandlung*. By Professor Dr. Karl Grunert. München: J. F. Lehmann, 1934. (Pp. 161. M. 7; Lwd., M. 8.50.)

* *A Textbook of Midwifery for Students and Practitioners*. By R. W. Johnstone, M.D., F.R.C.S.Ed., F.C.O.G. Seventh edition. London: A. and C. Black, Ltd. 1934. (Pp. 463; 277 figures. 18s. net.)

THE MEDICAL DIRECTORY, 1935

Once again we welcome a new edition of the *Medical Directory*—the ninety-first annual issue—for 1935.* The title-page is now in a handier position near the front cover, and the list of contents appears in bolder and more legible type, occupying two pages instead of one. So far as can be judged from preliminary glances through this substantial volume of nearly 2,400 pages, which will be our desk companion for the next twelve months, every compliment we have paid the *Medical Directory* in former years is fully earned again. No reference book surpasses it in accuracy and finish. The numerical summary of the medical profession shows that the names now number 57,128, being 649 more than the total for 1934. The largest increases are again in the geographical sections devoted to London and the Provinces of England. The entries under "Abroad" have grown to over 10,000, and Scotland shows an increase of thirty-two names. On the other hand, in Wales there has been a decrease of six; the Services have dropped by sixteen, and Ireland by 104. The section on "British Health Resorts: Spas, Seaside, and Inland," edited by Dr. Fortescue Fox, is now the official handbook of the British Health Resorts Association, and no longer appears as part of this volume. The twenty-sixth edition will be published early next year, and a copy will be sent gratis to every subscriber to the *Medical Directory*. The "Late List" of new names, changes of addresses, etc., appears at pages 2210 to 2213.

Notes on Books

Since the second edition in 1926 Dr. HALLS DALLY's handbook on *High Blood Pressure: Its Variations and Control*^b has been largely rewritten, and now provides an up-to-date and readable review, with special reference to practice and treatment. A good account is given of the clinical methods of estimating blood pressure, in which the precautions necessary to avoid fallacies such as errors in the systolic pressure are described, and the author's graphic method of representation on squared paper of various grades of arterial pressure is illustrated. This is followed by a well-illustrated chapter on the numerous sphygmomanometers available, among which the Baumanometer ("kompak" model) is recommended as meeting the requirements of most general practitioners on the grounds of accuracy, simplicity, permanence, portability, and strength of construction. In a discussion on the mean pressure the author concludes that there is not any good reason for attributing to it the great importance that the French school under the influence of Pachon and Vaquez have done. The causes and clinical picture of raised blood pressure are systematically considered, and much attention is paid to the numerous methods of treatment. Of the organotherapeutic substances liver extract, at one time advocated, has failed to produce any lasting benefit; but in selected cases the author has had encouraging results with vagotonine and, on the whole, satisfactory improvement with acetylcholine. Bismuth subnitrate, which gives off minute quantities of nitrite ions continuously in the intestine, is recommended in patients free from advanced arteriosclerosis.

Professor H. KLEINSCHMIDT has revised his well-known "Therapeutic Vade-mecum for Paediatric Practice" for a seventh edition, and in doing so has incorporated up-to-date methods and modifications in feeding, medicaments, and physical methods. In the dietetic section Professor Kleinschmidt's own predilections are apparent, and an appendix describes the special preparations required.

Preparations and Appliances

A TONSIL GUILLOTINE

Mr. ARTHUR MILLER, F.R.C.S. (London, W.1), writes:

The guillotine is still extensively used for the enucleation of tonsils in children. When this is done under a prolonged general anaesthesia the expert will succeed in removing the whole tonsil, conserving both anterior and posterior pillars, no matter what type of guillotine is used. Unfortunately, tonsillectomies are still performed by the short-anaesthetic method, owing to circumstances beyond the surgeon's control. He is then called upon to perform the acrobatic feat of enucleating both tonsils and adenoids in a fraction of a minute, and leaving both anterior and posterior pillars intact and unblemished. It is then that the type of guillotine used plays an important part in the efficient removal of the tonsils. The guillotine illustrated here has been used by me for some considerable time, and, it is claimed, overcomes the difficulties mentioned. The features of the instrument are as follows:

1. The fenestra is oval, and is of sufficient length to permit the longitudinal diameter of the tonsil being engaged without undue squeezing. (Any pressure required is produced by the transverse diameter of the ring with or without adjust-

ment of the blade.) This fact makes it very difficult for the upper or lower poles to escape from the ring the moment the blade is pushed home, a not uncommon occurrence when small-sized guillotines are used, particularly when enucleating flat or non-pedunculated tonsils.

2. The size of the fenestra can be regulated by the action of the screw (B). This does away with the necessity of employing different blades. The appearance of the tonsil on simple inspection is deceiving, and its actual size is often only appreciated after its dislocation from its bed, it is obviously an advantage to be able to adjust the size of the fenestra with the guillotine actually in the patient's mouth.

3. The bevelled edge of the blade prevents the anterior pillar from being drawn into the slot of the head when the blade is driven home. It is a common experience (except when using the reversed guillotine) to find the anterior pillar damaged in spite of correct application of the guillotine, particularly when dealing with flat or non-pedunculated tonsils. This is, in my opinion, due to the anterior pillar being dragged towards or into the slot of the head, where the actual damage often takes place. The bevelled blade peels the anterior pillar off the tonsil, folding the former, as it were, on itself.

4. The action of the guillotine is particularly smooth, as all the joints are of the ball-and-socket type. It is easily taken to pieces for cleaning purposes.

Messrs. Mayer and Phelps of New Cavendish Street, W.1, are the makers of this instrument.

GRAPE JUICE

Key Brand Grape Juice is a product of the Co-operative Wine Growers' Association of South Africa. After prolonged research a process has been discovered by which grape juice can be preserved without pasteurization, and its full natural qualities thus retained. The product is reported upon favourably by South African physicians. A bottle of reputed quart size, which contains the juice of 8 lb. of grapes, costs only 2s. This grape juice therefore provides the nutritive properties of grapes at a very low cost, and should be very popular.

KING EDWARD'S HOSPITAL FUND

ANNUAL DISTRIBUTION

The Prince of Wales, presiding at the annual distribution meeting of King Edward's Hospital Fund for London at the House of Lords on December 11th, read a message from the King expressing delight at hearing that the Fund would again distribute £320,000. His Majesty added that this result was a great tribute to those who supported the Fund, as well as to those who were managing its affairs.

His Royal Highness explained that this distribution was made up of £20,000 in special grants towards the pensions scheme, and an ordinary distribution of £300,000, the third successive occasion on which this figure had been reached. In 1932, when the amount had first been granted, the financial crisis had been expected to inflict serious difficulties on the hospitals. On the whole these difficulties had been successfully surmounted, but only by a great effort. More than two million pounds a year had been subscribed in London alone in voluntary gifts towards maintenance, building, and endowment, while patients had contributed last year £1,200,000, of which £365,000 had come through the Hospital Saving Association. Except in the pay wards, the patients' contributions were also voluntary, and those who could not afford to make any payment were treated free. It had, however, to be remembered that the surplus was only a small margin of income over expenditure, and there were not many hospitals which had such a surplus year after year. The expenditure was constantly increasing, because the hospitals were compelled to keep up with advances in methods of treatment, and so incurred added responsibilities in the form of extensions, improvements, and the maintenance of additional beds. In spite of the aggregate margin on the right side, there were still several hospitals with deficits, despite strenuous efforts to make both ends meet. All these reasons for continuous regular support of the hospitals were reflected in the King's Fund distribution. The grand total had been retained undiminished, but rather larger grants had been made to schemes of extension and improvement, and to hospitals which had failed to balance their expenditures. The Prince noted with pleasure that several more hospitals had adopted the waking hour of 6 o'clock for their patients, as recommended by a special committee of the King's Fund. Those which still had an earlier hour represented only 15 per cent. of all the patients in London, including those in some of the special hospitals, where earlier hours might be necessary. The question was not as easy as many people had thought, but it was hoped that the difficulties at some of these institutions might yet be overcome.

THE PROBLEM OF ROAD ACCIDENTS

The problem of road accidents continued to inflict serious embarrassment by necessitating the occupation of beds which were urgently needed for other purposes, and by entailing heavy charges on the hospital funds, which had been contributed for these other purposes. The latest amendment to the Road Traffic Acts dealt with emergency treatment rendered either by a private practitioner or by a hospital. The Parliamentary Committee of the Fund, in conjunction with the British Hospitals Association, was at present trying to discover how the partial provision that had been made by Parliament worked out in practice; it was then intended to prepare a statement of the arguments for and against the various alternative methods which had been suggested for making more complete provision. In this way it was hoped to discover how far agreement could be reached as regards the best form of remedy, since there was already general agreement that a remedy was needed. The Prince recalled the steps taken by the King's Fund in the last few years, especially in connexion with the transfer of accident patients from a hospital where there was no room to another where accommodation was available, and by the making of special grants towards the provision of beds for accident

cases out of money accruing from the Wells legacies. But the number of road accidents had increased to such an extent that sometimes, especially in outlying hospitals near the great highways, they might overflow all the accident beds, and enforce the sending elsewhere of urgent local cases of the kind for which the hospital was primarily intended.

PAY-BEDS AND OUT-PATIENTS

The Parliamentary Committee of the Fund was also co-operating with the British Hospitals Association with a view to obtaining general agreement as regards the provision of pay-beds for members of the middle and professional classes who could not otherwise obtain necessary treatment. Some hospitals, owing to the wording of their original trusts, could not legally make such provision, and the question was how best could be conferred upon all hospitals the powers now possessed by so many, while yet preserving their original objects, or, as the King's Fund Committee put it, "with due safeguards for the maintenance and extension of the ordinary beds." The Out-patient Arrangements Committee proposed to issue shortly for discussion by the hospitals a preliminary draft of a memorandum on time-saving methods at the dispensary stage where patients were supplied with medicines. This committee was also associated with the Management Committee's report on district nurses, in which it was suggested that the King's Fund, so soon as it was in a position to provide an additional £2,000 a year for the purpose, should make extra grants to enable hospitals to pay district nursing associations to look after patients in their own homes who did not require to see a medical practitioner on every occasion when they came up to the hospital for fresh supplies of medicine. This scheme would help financially in the extension of district nursing work, and would relieve some of the pressure on out-patient departments. It was decided to start it as from January 1st, 1935. The large number of recent hospital building schemes which had been appearing in such quick succession was partly the result of arrears which had accumulated during the war and the subsequent depression, and partly the sign of financial recovery. These extensions would all involve larger maintenance expenditure, and would require increased incomes.

THE YEAR'S FINANCES

Sir Edward Peacock, the honorary treasurer, said that it now seemed likely that the income for the year would be sufficient to cover the distribution. Legacies for 1934 amounted to more than £75,000; in each of the past seven years they had exceeded £58,000. A full year's income had come into the accounts from recent generous contributions to capital, notably the reversion of £136,000 under the will of the late Lord Mount-Stephen, and the gift of freehold property known as the William and Francis Radford Endowment. Lord Marshall, honorary treasurer of the League of Mercy, said that certain sources of hitherto substantial income had declined during the year, but that as the result of a special effort the league was again allotting £20,000 to the King's Fund. This made a total of £544,034 since 1899, of which £267,000 had been given since the Prince of Wales had become president of the league in 1919. At the same time the league was distributing £6,238 to extra-metropolitan hospitals, making a total since the league was founded of £167,998, and a grand total distribution of £712,032.

On December 7th an inaugural meeting of the London and Home Counties Branch of the Association of Special Libraries and Information Bureaux was held at Chatham House. Mr. H. H. Johnson was elected chairman and Miss Evelyn Atkinson honorary secretary. It was decided that the next meeting of the branch should take place at the new premises of the Royal Institute of British Architects in Portland Place towards the end of January. Further particulars may be obtained from the secretary of the association, 16, Russell Square, W.C.1.

British Medical Journal

SATURDAY, DECEMBER 22nd, 1934

RECENT RESEARCH IN BLACKWATER FEVER

Haemoglobinaemia in blackwater fever has in the past constituted a fundamental problem, not the least enigmatical aspect of which has been the small quantity of blood pigment quantitatively demonstrable. The occasional incidence of methaemoglobin has been noted by a few observers, and Ross in his recent monograph recorded it in twelve out of eighteen cases; Yorke and his colleagues found it in the plasma of two of their five cases, simultaneously demonstrating its absence from the corpuscles. Recently Fairley and Bromfield have made quantitative investigations on haemoglobinaemia in both malaria and blackwater fever, using a spectroscopic method similar to that described by Bloem. Multiple observations were recorded throughout the course of both these diseases, and, by collecting, oxalating, and centrifuging the blood in all stages under paraffin, the risk of artificial plasmolysis was reduced to a determined minimum.

In Part I of these studies¹ the blood pigments of the plasma in syphilitics experimentally infected with malaria, as well as in thirty-two natural infections of the latter disease acquired abroad, receive consideration. The conclusion reached is that blood destruction in malaria is mainly an intracellular phenomenon unaccompanied by demonstrable haemoglobinaemia, but generally associated with hyperbilirubinaemia, which varies in individual cases from 0.5 to 5.5 van den Bergh units (indirect reaction). Part II² deals with serial observations on the plasma of blackwater fever cases. Oxyhaemoglobin and methaemoglobin were invariably present, but when the corpuscles were washed free of plasma and lysed no methaemoglobin was liberated. Quantitative investigations revealed the unexpected fact that in both fatal and non-fatal cases methaemoglobin constituted the major portion of the total blood pigment, and that the oxyhaemoglobin content of the plasma decreased progressively as the methaemoglobin increased. In the three fatal cases of the series the maximal quantity of blood pigment estimated as the sum total of oxyhaemoglobin and methaemoglobin amounted to 3.6, 4.6, and 5.1 per cent.—a concentration regarded as sufficient to explain the phenomena of blackwater fever in terms of an intravascular haemolysis. Finally, it is pointed out that where methaemoglobin results from the action of drugs it has an intracorporeal location, and in the absence of corporeal haemolysis fails to appear in the urine; in this respect it differs fundamentally from

the methaemoglobinaemia of blackwater fever, where the methaemoglobin arises from oxyhaemoglobin only after its escape from the corpuscle.

In Part III³ the naked-eye characteristics of the plasma in blackwater fever are discussed: three derivatives of haemoglobin are mainly concerned—namely, oxyhaemoglobin, which imparts a red; methaemoglobin, which produces a brown; and bilirubin, which results in a bright yellow coloration. A mixture of these pigments is the rule, and the resultant colour (which is generally darkish or brownish red) depends on their relative and absolute concentrations in the plasma. Bilirubin, like the other pigments, is subject to considerable fluctuations, and varied from 7 to 88.5 van den Bergh units (indirect reaction) in individual patients. One case of blackwater fever complicated by *B. coli* cystitis proved of great interest; here the blood was chocolate-coloured and the plasma light brown. Only a small quantity of oxyhaemoglobin (0.28 per cent.) was found in the plasma, which, however, contained another pigment resembling methaemoglobin on ordinary spectroscopic examination, but differing from it in not being reduced by Stokes's reagent or ammonium sulphide; it also differed from sulphaemoglobin. It failed to appear in the urine throughout the course of the illness (though both oxyhaemoglobin and typical methaemoglobin reacting with Stokes's reagent did so) and was never found in the corpuscles, though it was demonstrated in the plasma over a period of ten days. Samples of the pigment were sent for investigation to Professor Keilin, who reported as follows: "A peculiar haemoglobin derivative with a normal prosthetic group in which the globin portion of the molecule was undoubtedly modified; the spectrum had the general appearance of methaemoglobin with the bands shifted about 60 Ångström units towards the short-wave end of the spectrum. Although it did not reduce with Stokes's reagent, the compound contained trivalent iron: it was easily reduced with sodium hyposulphite, and gave a typical haemochromogen (globinprotohaemochromogen). Apart from its spectroscopic resemblance to haemoglobin and its trivalent iron, it had no properties of methaemoglobin when tested with alkali, H_2O_2 , H_2S , azide, etc." This new pigment, the final report on which will be awaited with much interest, appears to be some modification of methaemoglobin in which the globin portion of the molecule has undergone an irreversible change.

The intensity and duration of haemolysis also received consideration. Sometimes it remained unabated until death, the patient dying of toxæmia and renal failure at a time when the red cell count was still falling, the haemobilirubin rising, and the degree of haemoglobinuria well sustained. In others a study of the secretory rate of oxyhaemoglobin and methaemoglobin in the urine confirmed the essentially fluctuating nature of the haemoglobinuria, and supported the view that several haemolytic crises, rather than one isolated

¹ Fairley, N. H., and Bromfield, R. J.: *Trans. Roy. Soc. Trop. Med. and Hyg.*, 1933, xxviii, 377.
² *Ibid.*, 1934, xxviii, 289.

³ *Ibid.*, 1934, xxviii, 367.

haemolysis, characterized blood destruction in these cases. Such fluctuations in haemolysis would not be anticipated were the haemolytic agent either a haemolysin or a drug given at the commencement of the illness, and as a result of these and other considerations Fairley and Bromfield put forward a new hypothesis regarding blackwater fever. In their opinion the haemolytic substance arises in chronic malignant tertian malaria from some cellular metabolic breakdown which is precipitated by quinine, plasmoquine, and possibly other factors such as chill, while its mode of action is, first, to lyse the corpuscles, and, secondly, to convert the liberated oxyhaemoglobin into methaemoglobin or the modified pigment described in their paper.

WEIL'S DISEASE

Evidence is steadily accumulating that leptospirosis, or Weil's disease, has a much greater incidence and a wider geographical distribution than was formerly recognized, and a progressively increasing number of sporadic cases of jaundice which have an occupational relationship that brings them in contact with water or slime contaminated by rats are being attributed to this cause. The infective organism, *Leptospira icterohaemorrhagiae*, which is known to be located in the kidneys of these rodents in most if not all countries where surveys have been made, reaches the exterior by way of the urine, and it is from this source that man is directly or indirectly infected.

In the October *Bulletin* of the Office International d'Hygiène Publique¹ the incidence of Weil's disease in their respective countries is reviewed in a series of articles by workers from Japan, the United States, France, Germany, and Sweden. In Japan, where Professor Inada originally isolated *L. icterohaemorrhagiae*, Weil's disease remains prevalent. Dr. M. Tsurumi points out that it may appear in epidemic or endemic form in river and swampy country or in coastal areas, but rarely in country which is high and dry. Coal miners in Japan are not infrequently affected by the disease. Its incidence varies in different years and different localities, and the total cases for 1933 equalled 1,636; the mortality rate was only 4.6 per cent. In the province of Ibaraki, however, the mortality during the last six years has varied between 16.9 and 29.9 per cent. In Toyama the public health authorities had been much impressed with the prophylactic value of two inoculations of a vaccine prepared from cultures of *L. icterohaemorrhagiae*, and in 1925 as many as 10,617 persons received such treatment; no troublesome reactions ensued. Mlle B. Erber presents a report of the agglutination reaction as carried out at the Pasteur Institute, Paris, on sera from suspected cases of Weil's disease. From 1932 to 1933 the laboratory received 1,232 specimens, of which 286, or 23.1 per cent., were positive. Of 1,048 specimens collected in Paris itself 215, or 20.5 per cent., were positive, and of 184 examinations undertaken for the Department of the

Seine seventy-one, or 38.6 per cent. Contact with water from rat-infested areas was the main source of infection, and certain occupations definitely involved the risk of contracting the disease. In Germany, Dr. Reiter states, occasional cases of Weil's disease have been encountered in bathers and sewer workers, and in 1933 Kister gave an account of a series of twenty-one cases from Hamburg with four deaths. Uhlenhuth and Zimmermann observed that white as well as grey rats could act as vectors. According to Dr. Olin the disease is uncommon in Sweden. It was found that 6 per cent. of rats in Stockholm harboured *L. icterohaemorrhagiae*. The report of the American delegate, Dr. H. S. Cumming, indicated that cases of infectious jaundice were rarely attributable to *L. icterohaemorrhagiae*, only ten cases having been recorded in Canada and the United States in which this organism had been demonstrated. Schüffner, who has done such outstanding work on this disease in Holland, found that during the past ten years 452 cases had occurred there, with forty-six deaths, the mortality rate being 10.2 per cent. Bathing in public baths and "water accidents," involving immersion in canals where rats abounded proved a common source of infection.

In the *British Medical Journal* of July 7th (p. 10) Hamilton Fairley described a hitherto unrecognized focus of infection among the sewer workers of London, and, by means of a clinical inquiry and serological tests undertaken by Professor Schüffner, was able to show that the disease had been endemic for at least twelve and a half years. It was discovered that labourers engaged in repairing and rebuilding old sewers were particularly affected; among other duties their work consisted in chiselling away and removing old brickwork covered with sewer slime, and this not infrequently led to abrasions of the skin of the hands and the arms. Infected rats have long been known to abound in London sewers, and contact with resulting infected slime was regarded as the source of the disease. Buchanan (1927), in an outbreak of Weil's disease among miners in East Lothian, had previously observed that the fungal slime lining the coal pits contained leptospirae pathogenic to guinea-pigs.

In our present issue two new outbreaks are described. From Aberdeen Professor Davidson and his colleagues report a series of nineteen cases of Weil's disease chiefly among fish workers. The symptomatology was typical, and the clinical diagnosis was confirmed by means of agglutination tests; using as antigen both Weil and the Dutch East Indian strains of *L. icterohaemorrhagiae*, as well as *L. canicola*, as advocated by Professor Schüffner and his colleagues in Amsterdam, where sera from the first cases of the series were tested. The source of infection in the present outbreak is of considerable importance. The patients themselves were mainly employed in handling white fish, either as filleters and cleaners or as general distributors of raw material in rat-infested premises, the floors of which become covered with slime and offal. After depilation of the abdominal hair and experimental immersion in

¹ 1934, xxvi, No. 10, pp. 1749-1767.

water collected from floor washings and tubs, three out of twelve guinea-pigs died with jaundice, and leptospirae were demonstrated. The skin of the hands was often traumatized doing this work, so all the conditions necessary for acquiring the disease exist in this trade. The other outbreak, an account of which is given by Dr. Drew at page 1142, affected mainly Italians employed as cane cutters in the Ingham district of Queensland. Jaundice first appeared in October, 1933, and by October, 1934, some thirty cases had been put on record. In August *L. icterohaemorrhagiae* was isolated from a human source, and, later, leptospirae were discovered in the urine of rats, which showed a high incidence of infection. The cane fields were heavily infested with these rodents, and apparently the moist conditions existing after rain exerted a benign influence on the life of the leptospira, for after a prolonged spell of dry weather fresh cases ceased. In grasping the cane preparatory to cutting, the hands often become injured, and it is suggested that leptospirae may thus gain access to the tissues.

The incidence of Weil's disease in coal miners, barge-men, sewer labourers, fish workers, and cane cutters clearly indicates the necessity for regarding it from the standpoint of an occupational disease, and when it is realized that less than half the cases infected with *L. icterohaemorrhagiae* actually develop jaundice its industrial significance becomes increasingly apparent.

A MARE'S NEST IN CANCER RESEARCH

Reference was recently made in these columns¹ to a test proposed by Aron² said to be diagnostic of cancer. The repeated injection of an extract of the patient's urine into a rabbit was stated by this author to be followed by partial or complete disappearance of lipoids from the cortex of the adrenal; this reaction was obtained almost constantly in cases of malignant disease and never in a numerous variety of control cases. From the fact that the serum of a treated animal or of the patient himself conferred resistance to the action of the urinary extract on the adrenal Aron concluded that the active substance in the urine was a specific antigen (a departure from his original hypothesis, which only presupposed the excretion of abnormal metabolic products), and even went so far as to suggest that the antibody whose existence he claimed to have demonstrated might be used therapeutically. These extensive and dangerous assumptions were criticized in the *Journal*, and it was suggested that the nature and mechanism of the adrenal change upon which this hypothesis was built required further investigation. Under the formidable names of Roussy, Oberling, and Guérin³ a paper has now appeared which flatly denies that the test itself has any diagnostic significance. The lipid content of the adrenal as demonstrated by Aron's method is very variable in the normal rabbit, even within the age limits specified by Aron, and in both normal and test animals the conclusions of two different

observers from sections of the adrenal frequently differed. In sixty tests with human urine negative results were frequently obtained in cases of malignant disease and positive with urine from normal subjects or sufferers from other diseases; the distribution of the results obviously bears no relation at all to the existence of malignancy. However the contradiction between Aron's and his critics' findings is to be explained, it is evident that the appearance of the rabbit's adrenal cortex is too variable to serve as a reliable index, and for the rest we may assume that it is too easy to see only what one wants to see. This incident will add to the feeling of suspicion which surrounds any new and empirical method, whether of diagnosis or of treatment, particularly in the cancer field. There are always multitudes of people who are only too eager to adopt any new method for the relief of cancer; this disease, perhaps more than others which have the reputation of being invariably fatal, produces in the patient and his relatives, and even sometimes in his medical attendant, a state which may be described as pathological credulity. Workers who value their reputation should be very sure of their ground before claiming any advance in this department of medicine which is capable of clinical application.

A PSYCHOTHERAPEUTIC FOLLOW-UP

A very interesting follow-up study from a psychological department is published in a recent issue of the *Journal of Mental Science*.¹ Mrs. D. H. Hardcastle, the social worker in the department of psychological medicine at Guy's Hospital, has investigated the condition of the first hundred patients seen at that department in 1931. Of these, sixty-seven were children and thirty-three were adults. There could be no selection of cases, since the clinic was part of a general hospital: all those sent had to be accepted for treatment. One of the first things noticed about the follow-up was that the visitor was afforded a warm welcome, except sometimes among the parents of mental defectives. The visitor inquired into the present condition of the symptoms for which the patient had sought help, into the general health, the social contacts, the sex life, the present occupation, attitude of family, and the patient's own interpretations of the treatment received. If there had been recovery the patient or the family was asked to what this recovery was attributed. The highest standard admitted is "much improved," as the word "cure" is considered too sweeping in an investigation of this kind. The other categories are: "improved," "unchanged," "worse," "in institutions," "not traced," "dead," and "referred but never attended." The first analysis shows that 39 per cent. of adults and 64 per cent. of children were found to be improved or much improved, while 34 per cent. of adults and 15 per cent. of children were unchanged. The greatest improvement was among those whose condition might be grouped as "affective changes," while there was no improvement in six classes as organic or mentally defective. There seems to be no relation between the number of visits to hospital and the degree of improvement, except in four cases, where intensive educational training was given by the psychologist. When the cases

¹ *British Medical Journal*, July 28th, 1934, p. 178.

² *Presse Méd.*, 1934, xli, 823.

³ *ibid.*, 1934, xli, 1641.

¹ July, 1934, lxxx, 526.

were grouped according to age the only striking result was the high percentage of improvement in the age group 9 to 11 (87 per cent.): the number of patients in this group was, however, very small. Success in treatment was found to be more probable with children of normal intelligence, and very unlikely when the intelligence quotient was 75 or less. The greatest number of much improved patients were found among those with scholastic difficulties (67 per cent.). There appears to be very little doubt that the work is well worth the expenditure of more time and money. As this study points out, the Guy's Hospital clinic arose out of a definite demand from the community, and is being increasingly used by many kinds of local agency as well as by other departments of the hospital.

THE PARATHYROID AND URINARY CALCULI

That the urine can in some cases hold in solution quantities of uric acid which exceed by far the amounts soluble in an equal volume of water is common knowledge, and if one considers its extraordinary solvent properties it becomes clear that it must contain some substance or substances which enable the ordinary laws of solution to be transgressed. To explain such anomalies of solution it has been necessary to suppose that the urine contains substances of the nature of colloids which prevent the precipitation of certain of the urinary constituents present in supersaturated concentrations. The action and precise significance of a "protective colloid" are well known to the physical chemist, though these are perhaps not so clearly appreciated by the clinician when discussing the possible role of such a colloid in the deposition of calculi in the various sites in which they are found. Of the two classes of colloids—emulsoids and suspensoids—the latter are much more readily precipitated by solutions of electrolytes than the former—that is, for the same concentration of colloid suspensoids are precipitated by very much more dilute solutions of electrolytes. If an emulsoid is added to a suspensoid solution it is readily shown that a much greater stability is conferred on the latter. This protective or stabilizing action was known to Faraday, who demonstrated it on colloidal gold preparations. It has an interest for the practitioner in that it explains the effect of a little egg-white in preventing a massive precipitation of casein from the milk taken by the infant. In the application of these facts to biological fluids it should be kept in mind that if a substance is to be "protected" it must be in the colloidal state. The maintenance of cholesterol or bilirubin in the gall-bladder bile in such concentrations as are normally found calls for some mechanism analogous to that of colloid protection, and it is generally considered that the formation of biliary calculi is in some way due to a diminution in quantity or potency of a hypothetical biliary protective colloid. In the case of the blood very much larger amounts of, say, uric acid or calcium phosphate can be taken up into suspension than can be accounted for by mere solubility, and this phenomenon is undoubtedly due to the presence of the protective colloids, serum albumin and globulin (emulsoids). The substances thus protected or stabilized are, it must be clearly understood, kept in colloidal suspension. Now in the case of the urine the more or less generally accepted filtration-reabsorption theory

offers a picture of the transformation of a non-protein glomerular filtrate of enormous volume into the relatively minute fraction of excreted urine. When filtered across the glomerular capsule the volume of fluid is easily adequate to keep all the constituents in ordinary solution, but this no longer obtains after concentration has taken place, so that it is presumably at this stage that the addition of the protective colloid occurs. Further, it must be at this stage that the state of simple solution of certain constituents changes to that of colloidal. As to the nature of the added substance and its source nothing is known. The possibility of some relation with vitamin A deficiency is suggested by the work of van Leersum, who found that diets deficient in this vitamin led to crystalline deposits in the urinary tract of laboratory animals, and the prevalence of stone in India and China may in part be explained by these findings. The importance of the parathyroids in the metabolism of calcium and phosphorus suggests the possibility of some endocrine factor in calculus formation. In a recent contribution F. H. Colby¹ reports that out of thirteen cases of removal of parathyroid tumours eight—that is, 61 per cent.—showed definite evidence of calcification in the urinary tract, six were cases of renal calculi, one of vesical calculus, and two of calcification of the renal parenchyma. Generalized osteitis fibrosa was not a marked feature in any of them, although some decalcification of bone was noted. In three of the cases the typical syndrome of renal calculus was easily recognized, but the true nature of the cases was established by the high serum calcium and low serum phosphorus (15.8 mg. Ca and 2.8 mg. P in one case). The identification of the parathyroid tumours and their surgical removal, together with appropriate treatment of the already formed calculi, prevented recurrence during a fairly long period of observation. It is, of course, difficult to be certain that recurrence will be permanently prevented, but there can be no doubt that the results are very suggestive. The authors are inclined to attribute the calculus formation to the increased calcium and diminished phosphorus excretion which accompany an active parathyroid tumour. However, parathyroid tumours cannot explain more than a small minority of cases of renal calculus, though it sets one wondering whether the majority of cases may not be associated with some functional hyperactivity of the parathyroid. Routine examination of serum calcium and phosphorus in a series of cases of renal and vesical calculi should be instructive.

NUTRITION AND THE PUBLIC HEALTH

The paper with this title by Dr. H. E. Magee and the subsequent discussion at the health congress of the Royal Sanitary Institute at Bristol in July, 1934, are now available in full,² and the main impression is a striking plea for a broader, physiological outlook by public health authorities. As Dr. Magee points out, bacteriology and pathology, which supplied the knowledge responsible for the most outstanding successes of public health work in the past, seemed at one time as if they would dominate and dictate the activities of the public health services. Now, especially as

¹ *Surg., Gynecol. and Obstet.*, August, 1934, p. 210.

² *Journ. Royal Sanitary Inst.*, 1934, lv.

regards nutrition, there is an urgent need for harnessing the results of physiology to public health activities. The newer knowledge of nutrition, especially concerned with the mineral elements and the vitamins, stops short at pointing out that both are essential for health. Field work by public health authorities on the minimum requirements of many of the inorganic elements and of the vitamins is regarded by Dr. Magee as of great importance. "It should be possible," he states, "by dietary and sociological studies, and by co-operation with practitioners, to obtain data which would give some information on the part played by nutrition in the aetiology of diseased conditions." Another important aspect was also touched upon concerning the well-recognized factors of ignorance and prejudice in preventing that improvement in the general state of nutrition of the people which all are agreed is desirable. Income, as several speakers urged, may well be the fundamental factor in proper nutrition, but education through the public health service could do much to interpret physiological facts into the language of everyday life.

PATENTED LENSES

Among the many admirable activities carried on by our brother society, the American Medical Association, there is one that has high value—the reports of the Committee on Standardization of Instruments and Drugs. We know the work of this committee mostly through its examination of drugs and the claim of their vendors. The committee has adopted an article by Dr. Alfred Cowan of Philadelphia on the claims made for "patented lenses."¹ There has been a recent outburst of startling claims made for what may be termed "wide-angle lenses"—that is, lenses which by their curvature give a uniform value in all their parts, notwithstanding the wide movements of the eyes behind them. The report states that those having any acquaintance with the literature of geometric optics know that practically nothing of what has been stated is new. Deeply curved or meniscus lenses were mentioned by Kepler as early as 1604 and recommended by Hertel in 1716. Toric lenses were ground by Anton Wagner in Philadelphia fifty years ago. Although the theory of wide-angle lenses has been familiar for a great many years, certain manufacturers imply in their advertisements that they have made a new discovery, and that they, and only they, have the ideal ophthalmic lenses—corrected to the very edge for both the error of marginal focal power and the astigmatism of oblique pencils, even in bifocals. No one knows better than they that these claims are without substance. What is most glaring is that while no two of the many patented forms are alike, each is claimed to be perfect. In point of fact, a lens of this kind is a compromise at best; any one is just about as good as another—and no more comfortable to the average wearer. Clinically it is known that chromatic aberration, distortion, and curvature, in ordinary ophthalmic lenses, are not noticeable enough to cause discomfort to the wearer. Reflections from the surfaces are sometimes annoying, but can usually be remedied by proper adjustment. The spherical aberration that must be corrected in a photographic lens in order to produce a clear image

to the edge of the plate does not apply to an ophthalmic lens. A clear image is distinctly seen only over an extremely small area at the fovea; and therefore it is here and nowhere else that a clear image must be formed; imaged, sharply or not, on any other part of the retina, objects appear blurred. For this narrow pencil of light, necessary to form the foveal image, only a small portion of the correcting lens is used at one time. Dr. Cowan's paper gives in detail the evidence for these conclusions, and it is clear that neither the extravagant claims made for the patented lenses nor their high prices are warranted.

NEXT YEAR'S BUDGET

In a recent speech the Chancellor of the Exchequer, Mr. Neville Chamberlain, is reported to have uttered a warning against too confident an expectation that there will be reductions of taxation next year. He pointed to new expenditures, and suggested that there would have to be "very large increases of revenue . . . before anything is left over for the relief of the taxpayer in the next Budget." A warning that new commitments of expenditure necessarily involve taxation is often salutary, and excessive optimism sometimes meets with painful disappointment. The Chancellor's admonitions can be fully justified on these grounds, but we hope they will not be justified by the event. Last year he was able to give up a substantial part of what the income tax would have yielded on the 1933-4 basis, and was faced with the choice of two alternatives, or the possibility of combining both. He could either reduce the standard rate of tax below the 5s. level, or increase the personal allowances to something like their former amounts. There was not enough margin to do both, and to divide the relief between the two would have been less spectacular than a reduction of 6d. in the standard rate, and therefore would have had less psychological effect. The result was that the standard rate was reduced and the personal allowances were not increased. We thought then, and still think, that the choice was the right one, but only on the assumption that there was a reasonable prospect of something being done in 1935 to relieve the smaller taxpayers of the burden placed on them when the old personal allowances were reduced. On the basis of a 4s. 6d. standard rate that reduction costs a married taxpayer anything up to £22 10s. in extra tax. That additional sum is the same whether his income is £500, £1,000, or £2,000, though it is an accepted principle of our income tax code that the smaller the income the greater the burden of any fixed payment. It may be too much to expect a complete return to the old scale of allowances next year, but a long step in that direction will certainly be due, if not overdue. The psychological factor has had its turn; next year it is the turn of the ordinary taxpayer, who is still bearing the burden of an addition which never applied to, or at least was not felt by, the large financial concerns and wealthy taxpayers.

Messages received from Colombo this week report a very widespread epidemic of malaria in Ceylon, which began in the North-Western Province at the beginning of October and is said to have already affected 500,000 people.

¹ *Journ. Amer. Med. Assoc.*, November 3rd, 1934, p. 1277.

TREATMENT IN GENERAL PRACTICE

This article is one of a series on the management of some of the major medical disorders met with in general practice

THE TREATMENT OF PNEUMONIA

BY

W. H. WYNN, M.D., M.Sc., F.R.C.P.

Pneumonia is an acute medical emergency, and the patient's fate is to a large extent decided during the first forty-eight hours; but too often a diagnosis is not made until consolidation is apparent, which may not be for two or three days. During the preconsolidation stage, when the circulation through the lung is not yet impeded and toxæmia is slight, much can be done to control the infection by the timely use of a vaccine or serum. We should think in terms of immunity: a patient recovers from pneumonia by producing sufficient immune bodies. It is not possible to pick out beforehand those who will succeed in this, and 20 to 30 per cent. fail entirely. By early specific treatment a reduction of the mortality to 5 per cent. is within the bounds of possibility.

General Measures

Poor patients in crowded homes with unskilled attendants should be removed to hospital as quickly as possible. The modern ambulance service is so efficient that this can be done with little disturbance. With patients treated at home, day and night nurses should be obtained and precise instructions written down.

From the first, absolute rest in bed must be strictly enjoined and the nurse's main duty is by thoroughness and skill to reduce the patient's exertions to a minimum and to create a calm atmosphere with an absence of fuss. The bed should be in the middle of the room and the windows widely open. Fresh air is a fine tonic, but must be used with common sense, and the patient should be guarded against icy draughts or glaring sunlight. One garment should be worn, opening down the middle to allow easy access for examination and nursing attentions. During the initial chilly stage abundant bedclothes and hot-water bottles are required, but thereafter one sheet and a blanket should be ample. Gamgee jackets are relics of the days when pneumonia was thought to be due to cold and therefore to be exorcised by heat. Sponging with lukewarm water should be done as a routine night and morning and when the temperature taken four-hourly exceeds 102.5° F.

At least four pints of water should be taken in some form during the twenty-four hours. Glucose is the most easily assimilated food, and of this half a pound should be dissolved in a quart of water flavoured with the juice of lemon or orange. It can be taken freely at any time, and many patients will consume up to one pound a day. Milk need not exceed one and a half pints taken in amounts of five ounces four-hourly, and two grains of sodium citrate should be added to each ounce. To two or three of the feeds coffee or tea can be added. If additional food is desired, it can be given as albumen water: the whites of two or three eggs in a pint of water with a little meat extract added to flavour. Meat extracts in any quantity are undesirable because of the small amount of nutritive material and the large quantity of

extractives. Water, plain or with added fruit juices, can be taken in small quantities *ad lib.*

The mouth should be wiped out after each feed with a rag moistened with a weak watery antiseptic, liq. sodii carbolatis diluted with twenty volumes of water or listerine diluted 1 in 3. Washes containing glycerin should not be employed. An occasional use of a nasal spray with liquid paraffin or chloretone inhalant is comforting. Aperients should be avoided; they increase the fluidity of the bowel contents and favour fermentation and tympanitic distension. If the patient when first seen has had no action during the previous twenty-four hours, a soap-and-water enema should be given. During the active stage no enema should be given unless there is distension or a feeling of fullness in the rectum. A simple dia-phoretic mixture should be taken every four hours:

R	Pot. cit.	gr. xx
	Liq. ammon. acetat.	5 ij
	Syrup. aurant.	5 j
	Aq.	ad 3 j

Specific Treatment

When the patient is seen within the first three days a vaccine or serum should be given. A vaccine has the great advantage that it can be carried in the bag and is immediately available. It must be an active one of known antigenic power, made as far as possible from young primary cultures. The one I use contains equal numbers of pneumococci, streptococci, and *B. influenzae* (P.S.I. vaccine). While it is desirable that it should consist of the various strains, it is more important that it should be made from virulent cultures. For an adult the dose is 200 millions of each organism—that is, 600 millions in all. Larger doses can be given at this stage, as the patient is not yet sensitized. Children should have proportionately smaller doses, but even at 12 months 20 millions of each organism should be given. The object is to stimulate the production of non-specific antibodies in adequate amount; the specific effect is not seen for some days. If the temperature does not fall after the first injection it can be repeated every twenty-four hours until three doses have been administered. When such doses are injected on the first day of the illness, in the majority of cases the temperature falls rapidly during the next twenty-four hours, with a corresponding improvement in the general condition. With each day's delay such rapid defervescence is less easily obtained. When cases are not treated until after the third day the circulation through the affected part is interrupted, and toxins are fixed in vital tissues; little can then be expected of specific treatment, whose aim is to prevent not cure toxic symptoms.

Serum Therapy

There are at present many difficulties in the way of a widespread use of serum in general practice. The employment of concentrated anti-pneumococcus serum has a similar effect to a vaccine when given early. It is effective against infections with Type I pneumococcus and to a less extent with Type II. These types cause two-thirds of lobar pneumonias, but in recent years typical lobar pneumonia has been less common than a

mixed infection bronchopneumonia; so that, roughly speaking, serum is available for only about one-third of all pneumonias. If it is to be used economically the type of infection must be determined. Typing is not easily carried out for patients treated at home, and even in well-equipped hospitals there may be a delay of twenty-four hours. Sputum for typing may be absent in the early stages. Serum must be injected intravenously, and repeated injections require considerable dexterity. The cost is considerable. It would seem wise, therefore, at present to restrict its employment in private practice for patients seen within the first three days who already have considerable toxæmia. To such cases 20,000 units (10 c.cm.) of polyvalent serum should be administered *at once*. The serum is warmed to blood heat and injected slowly through a fine needle into a vein at the elbow. Sputum should then be sent for typing, and if Type I or II is present 20,000 units of Type I or Type II serum respectively should be given every six hours up to a maximum, if necessary, of 120,000 units. Unpleasant symptoms such as rigors, anaphylactic shock, and respiratory distress may occur, but are usually relieved by the subcutaneous injection of 1 c.cm. of 1 in 1,000 adrenaline chloride solution. Serum should not be prescribed for allergic subjects or for elderly arteriosclerotics.

Symptomatic Treatment

For the relief of pleuritic pain a linseed poultice or cataplasma kaolini is generally used. It should be applied only when there is pain, and to the back or sides of the chest, not over the front. The weight of a poultice is not inconsiderable, and the exertion of raising it forty times a minute is not one a seriously ill patient should undertake. Of all methods of relieving pain the introduction of 300 or 400 c.cm. of oxygen between the layers of the pleura is the most certain, but it requires experience and the necessary apparatus. The patient not only has pain but mental anxiety and restlessness, and for these there should, in most cases, be no hesitation in giving an opiate. Ten grains of Dover's powder in one of the doses of the saline mixture will often suffice. Morphine sulphate 1/4 grain is more effective. In lobar pneumonia this dose can be repeated if necessary for three or four nights. Contraindications to its use are the presence of much bronchial secretion—as in many cases of influenzal bronchopneumonia—cyanosis, and a tendency to meteorism.

With sleeplessness without pain it is usually waste of time to give ordinary hypnotics such as medinal or dial. The following is more useful:

R.	Pot. brom.	gr. xxx
	Chloral.	gr. xv
	Syrup. aurant.	ʒ ss
	Aq.	ad ʒ j

Or paraldehyde in doses of 1 or 2 drachms by mouth, for example:

R.	Paraldehydi	ʒ ij
	Ext. glycyrrhiz. liq.	ʒ ij
	Syrup.	ʒ j
	Aq.	ad ʒ ij

The unpleasant taste can be avoided if 3 drachms are given per rectum in four ounces of starch emulsion. With active delirium morphine in repeated doses may be needed, and in the most severe cases hyoscine hydrobromide 1/100 grain in addition. This latter drug has a bad reputation, but my own experience of it has been fortunate. Paraldehyde in doses up to half an ounce may succeed when morphine has failed or is contra-indicated. Expectorants are not required in lobar

pneumonia, but in influenzal bronchopneumonia, when sputum is abundant and the tubes blocked, ammonium carbonate should be given in doses of 5 grains four-hourly, increasing if necessary to 10 grains hourly for a few doses. The requisite dose should be dissolved in two drachms of water and given in a cupful of milk to avoid nausea.

Treatment of Circulatory Failure

Circulatory failure in pneumonia is compounded of direct toxic action upon the myocardium, vasomotor failure from action upon the centre, and dilatation of capillaries. Though much can be done by early specific treatment, absolute rest, fresh air, and glucose to prevent failure, our resources are slender when it occurs. The best way of helping the heart is to feed it, and the best foods are glucose and oxygen. At the slightest sign of cyanosis oxygen should be administered continuously. It is futile to give it for so many minutes in each hour, or when the nurse thinks fit. Apart from the oxygen tent the only method of value is intranasal. A No. 10 catheter is passed through the nose until the tip touches the pharyngeal wall, when it is withdrawn slightly. If a calibrated reducing valve is on the cylinder two litres a minute should be delivered. Otherwise the oxygen should be passed through water in a Woulfe's bottle at a rate just so fast that the bubbles cannot be counted. Adrenaline is of great value. It augments and accelerates the heart's contraction, constricts blood vessels, and raises blood pressure. It is the only drug which acts upon the poisoned heart. Five to ten minims of adrenaline chloride solution (1 in 1,000) should be injected subcutaneously every four hours, increasing to two-hourly if necessary. Pilitrin stimulates and contracts the capillaries and small arterioles. It is of value in peripheral failure in doses of 1/2 to 1 c.cm. six-hourly.

Digitalis and its allies should not be prescribed, neither early with the idea of preventing heart failure nor when failure has occurred. It adds another poison to the heart, does not slow the febrile pulse, and has no action upon the peripheral failure. Carefully controlled statistics relating to hundreds of cases showed an increased mortality of 7.7 per cent. in the digitalis-treated cases. Even in cases with auricular fibrillation digitalis gave a higher mortality. Alcohol may be of service in the early stage as a sedative and to help sleep in an anxious patient, but its routine use as so much brandy or whisky every four hours or so is strongly to be deprecated. After absorption it has no direct action upon the heart, but it will cause a dilatation of the blood vessels of the skin, and therefore a smaller amount of blood will flow through the internal organs. The skin in pneumonia is already hot and flushed, and there is no obvious indication for more flushing or restriction of the internal blood supply. Alcohol is not a cardiac tonic or a stimulant, but a depressant, and if called by its right name it would not so often be employed. With alcoholic patients it is customary to give it, but I have not found an increased delirium by withholding it in such cases. Statistics reveal an increased mortality with its use. Camphor, coramine, cardiazol, and similar substances injected hypodermically act as irritants, reflexly stimulating the medullary centre. They have no direct action on the heart, and are of no great value in serious heart failure.

It must be recognized that the present high mortality from pneumonia will be reduced not by treating poisoned organs incapable of response but by early diagnosis and prompt measures to prevent intoxication. Expectant treatment in the early stages too often means harmful drugging in the later.

PHARMACOLOGY AND NERVE ENDINGS

FIRST DIXON MEMORIAL LECTURE
BY SIR HENRY DALE

The first lecture in therapeutics and pharmacology in memory of Professor Walter Ernest Dixon of Cambridge was delivered by Sir HENRY DALE, F.R.S., in the Barnes Hall of the Royal Society of Medicine on December 11th. The chair was taken by Professor J. H. BURN, president of the Section of Therapeutics and Pharmacology, and the proceedings were opened by Dr. ROBERT HUTCHISON, President of the Society, who expressed the pleasure with which the Society had accepted from the organizing committee the trusteeship of the sum collected to endow the lecture. Professor Dixon was highly esteemed in that Society, and they felt that his splendid scientific work deserved commemoration.

Sir WILLIAM WILLCOX, chairman of the organizing committee, said that Professor Dixon, who passed away on August 16th, 1931, was one of the most distinguished pharmacologists of the day. In addition to his great scientific qualities, he was extraordinarily human. The speaker had heard Cambridge undergraduates declare that they would rather go to a lecture by Dixon than to a musical comedy, but the lectures imparted scientific material of the highest kind. Dixon was altogether a most attractive personality, a true friend, loved and respected by all who knew him. After his death the examiners in pharmacology at Cambridge talked over the question of a memorial, and went to see Mrs. Dixon, who was in favour of the establishment of a memorial lecture. Eventually a fund was collected amounting to between £700 and £800, and this was handed over to the Royal Society of Medicine for the foundation of a biennial lecture on some subject in which Dixon had been interested. Therapeutics and pharmacology had been rather neglected from the point of view of lectureships, though Edinburgh had had the Cameron lectureship for some years. The subscribers to the fund included a large number of students. The Society of Apothecaries subscribed handsomely, as did the Pharmaceutical Society. The British Medical Association was not permitted under its constitution to make such donations, but it had perpetuated Dixon's memory in another way by the foundation of a scholarship. Sir William Willcox ended by introducing the first lecturer, Sir Henry Dale, whom he described as one of the greatest biochemists in this country.

THE SCIENTIFIC CAREER OF W. E. DIXON

Sir HENRY DALE began by suggesting that Dixon's memory could best be honoured by considering some new and progressive phase of activity in the field of research and teaching which received so strong an impulse from his life and work. It would be a poor tribute to the memory of any man of science merely to recall at intervals the state of knowledge during his lifetime, or even newly to assess the value of each part of the harvest of discovery which fell to his own reaping. Far better to study some new and interesting growth from the ground where he dropped the seed, or, it might have been, only prepared the soil for later sowing. But with the loss of their friend still fresh in the memory, they could not be content on this first occasion to pay only an impersonal tribute. He was still remembered among them as a vivid and inspiring personality, who, more than any other, was responsible for the awakening in England of interest in pharmacology as a progressive science. Dixon went to Cambridge in 1899, and he was still there, as reader in pharmacology, at the time of his death, thirty-two years later. Sir Henry Dale said that he himself just missed the direct contact with him there, for Dixon went to

Cambridge as he was about to leave, but from his immediate juniors he soon heard of the new life which had been breathed into pharmacology in the university, where the subject could now be studied, no longer in terms of traditional *materia medica* and empirical therapeutics, but as a living body of experimental science, closely linked with physiology.

The attraction which he had for young workers was a part of Dixon's charming and generous personality. His kindness and robust humour endeared him to students and colleagues alike. He had real gifts as a raconteur, and his simple and vivid presentation of scientific matter made him an effective popular lecturer, and gave authority to his opinions far beyond the circle of those having expert knowledge of the subject. The subjects on which he worked and wrote had a wide variety. He had an almost exuberant interest in any new line of knowledge touching on pharmacology, and a desire to share in its exploration, and his conception of the scope of pharmacology tended to expand well beyond the study of drugs and their action, and to include any procedure finding application in therapeutics.

The lecturer dwelt upon Dixon's work with Brodie on the physiology and pharmacology of the bronchioles, which seemed to have provided a starting-point for the development of one of his predominant pharmacological interests. It was this work, he thought, which first brought vividly to his notice the remarkable resemblance between the actions of certain alkaloids and those of the autonomic nerves. With Brodie he reached the conclusion that adrenaline acted on sympathetic nerve endings.

THE AUTONOMIC NERVOUS SYSTEM

The suggestion was first made by Elliott that autonomic nerves transmitted their effects by releasing at their endings specific substances which reproduced their action. This worker suggested that the resemblance between the effects of sympathetic nerves and those of adrenaline might mean that sympathetic impulses, on arriving at the nerve endings, released small quantities of adrenaline, or something like it, in immediate relation to the effector cells, which would then give the same responses as to-adrenaline artificially applied. Dixon saw that if this were a true conception an analogous mechanism would almost certainly be used by parasympathetic nerves, and he pictured the substance transmitting their effects as something like muscarine. Dr. Dale showed a slide of Dixon's, illustrating what the latter held to be experimental evidence of its release when the vagus nerve was stimulated. It was now known that the vagus transmitter was not muscarine, but an extremely unstable ester of choline, and free choline was probably the substance responsible for the effects which Dixon observed. Dixon appeared to have been discouraged by the scepticism with which his evidence was received, but there was no doubt that he had grasped a true conception, with characteristic conviction and enthusiasm, though the evidence which really established it came many years later, from a much simpler type of experiment.

It was at the annual meeting of the British Medical Association in Toronto in 1906 that Dixon made the first mention of his heart-vagus experiments, and at the same meeting Hunt and Taveau described the intense activity of acetylcholine. (Both papers appeared in the same issue of the *British Medical Journal*, 1906, ii, 1807 and 1788.) Nobody at the time suspected any thread of connexion between the observations presented in two entirely independent communications. Sir Henry Dale himself made a thorough investigation of the actions of acetylcholine in 1914, but another fifteen years had to pass before the substance was found occurring in an animal organ in such quantity as to enable its isolation and

chemical identification to be made. This was done by Dale and Dudley in 1929 (*Journ. of Physiol.*, lxviii, 97).

THE CHEMICAL TRANSMISSION OF NERVE IMPULSES

The lecturer next described the work of Otto Loewi, who established by a simple experiment the transmission of the effects of autonomic nerve impulses by the peripheral release of specific chemical stimulants, and said that it was now generally admitted that parasympathetic effects were so transmitted by release of acetylcholine and sympathetic effects by the release of a substance related to adrenaline. The detailed evidence for these two kinds of chemical transmission of autonomic effects had been frequently reviewed. More recent evidence indicated that a chemical mechanism of this kind also effected the transmission of nervous activity at the synapses in peripheral autonomic ganglia and at the motor nerve endings on voluntary muscle fibres.

Feeling the need of terms to describe nerve fibres, or their impulses, in terms of a chemical function, which could no longer be regarded as corresponding to their anatomical origin, he (Sir Henry Dale) had suggested the term "cholinergic" to describe those which transmitted their action by release of acetylcholine, and "adrenergic," those which employed a substance resembling adrenaline. He thought it no longer possible to doubt that the liberation of a small quantity of acetylcholine when a pre-ganglionic impulse arrived at a synapse played an essential part in the transmission of the excitation to the autonomic ganglion cell, and that the post-ganglionic impulse was essentially a separate physiological event. The pre-ganglionic fibres and their impulses might be classed as "cholinergic," though the process by which their effects were transmitted to the ganglion cells differed widely in detail from that by which post-ganglionic parasympathetic impulses used acetylcholine to produce their modifying actions on the spontaneous activities of plain muscle and gland cells.

Sir Henry Dale asked his audience to consider the bearing upon all this of data, long available, which displayed the functional similarities and differences between different fibres of the peripheral nervous system by the method of regeneration after artificial cross-suture of nerves. He referred in particular to a series of papers published by Langley and Anderson between 1897 and 1904. Their work could be summarized in the statement that any cholinergic fibre would functionally replace any other cholinergic fibre, and that any adrenergic fibre would replace any other adrenergic fibre, but that neither could assume the function of the other.

REVISION OF PHARMACOLOGICAL CONCEPTIONS

The general conception of the mode of transmission of the effects of nerve impulses which was even now taking shape would obviously entail some revision of pharmacological conceptions and terminology. It had no longer any scientific meaning to say that acetylcholine and adrenaline reproduced the effects of parasympathetic and true sympathetic nerves, because they acted on the respective types of nerve endings. It was truer to say that parasympathetic nerve impulses reproduced the peripheral effects of acetylcholine, because, when they arrived at the nerve endings, they liberated that substance in relation to the effector cells; and the same was true of sympathetic nerve impulses and adrenaline, with the still necessary reservation as to the chemical identity of the transmitter—namely, that it was still open to question whether it was adrenaline itself. In either case the action of the chemical substance must be on the effector cells and not on the nerve endings. When atropine or ergotamine produced its specific paralysis it did so by rendering the effector cell specifically insensitive to acetylcholine or to

adrenaline. Similar conceptions, *mutatis mutandis*, applied to the actions of acetylcholine on ganglion cells and striated muscle fibres, and to the annulment of those actions with blockage of the corresponding nervous excitations by nicotine and curare respectively. It was still necessary to account for the fact that when a substance like acetylcholine was artificially applied the effector cells responding to its action were predominantly those in relation to which it was normally liberated as the transmitter of nerve impulses. It was similarly difficult to trace more than a general chemical similarity between adrenaline and some of the substances which shared, in varying degrees, its selective action. He doubted whether the use of such terms as "myoneuronal junctions" or "receptive substances" to describe hypothetical components of the effector cells, to which their selective responses might be attributed, would serve any longer to clarify the issue.

PROBLEMS YET AWAITING SOLUTION

As to the manner in which the nerve impulse on reaching the nerve ending caused the chemical transmitter of its action to appear, the evidence was meagre as yet, and not wholly consistent. The latest results supported the view that the transmitter was not newly formed by synthesis as each impulse arrived, but held in some inactivating and protective complex from which the nerve impulse released it, and from which it was easily separated by ordinary methods of chemical extraction. In the one case yet investigated, by Engelhart (1931), this "depot" was dependent for its maintenance on the integrity of the nerve endings, and disappeared or became depleted when the nerve fibres degenerated. By the interpretations given to the earlier evidence this disappearance might be taken to mean that the "depot" belonged to the nerve ending; but it might merely mean that its maintenance was dependent on the arrival of nerve impulses at a normal rate, and that its depletion with nerve degeneration was comparable to an atrophy of disuse. On either conception it seemed possible to give a clearer interpretation to the actions of the only two specifically stimulant bases for which an action on nerve endings appeared to be really supported by evidence. One of these cases was that of eserine, in connexion with which Anderson, nearly thirty years ago, recorded certain experiments showing that the normally potent constrictor effect of eserine disappeared entirely with degeneration of the post-ganglionic fibres. To-day Sir Henry Dale thought that the effect of eserine might be more reasonably attributed to the accumulation of acetylcholine, the liberation of which, by the play of impulses in post-ganglionic fibres, was normally balanced by the destructive action of the cholinesterase, which eserine inhibited. The other case was that of tyramine, certain sympathomimetic actions of which had been found to disappear with nerve degeneration and under the action of cocaine. Tyramine might act by liberating the transmitter from the depot, cease to act when this was depleted, and act again when it was replenished; and the same might be true of ephedrine.

In conclusion, Sir Henry Dale said that no nearer approach had been made to the fundamental pharmacological problem why a particular type of chemical structure, or several unrelated types, should be associated with a specific action on particular types of reactive cell. The newer evidence merely exposed the nature of the problem and cleared the ground for eventual attack. He could picture the eager interest with which Dixon would have welcomed this clarification. As pharmacology approached one of its fundamental tasks it would sadly miss his fertility in ideas and the stimulus of his buoyant optimism.

VOTE OF THANKS

Professor J. H. BURN, in proposing a vote of thanks to Sir Henry Dale, expressed astonishment at the progress which had been made in this pharmacological field. Even within the last twelve or eighteen months a very big step forward had been taken in respect of the fundamental facts of pharmacology, and the whole terminology was being revised. Since the time of Langley and Anderson (the beginning of the century) there had been no such important development as that which began with Loewi's work in 1921, and which had made astonishing progress during the last year or two.

REGISTRATION OF OSTEOPATHS BILL

LORD MOYNIHAN'S SPEECH

In the House of Lords, on December 11th, Viscount Elibank moved the second reading of the Registration and Regulation of Osteopaths Bill. This motion was carried by 35 votes to 20, and the Bill was referred to a Select Committee, with full power to call witnesses. A report of the debate, from our Parliamentary Correspondent, appeared in the *Journal* of December 15th (p. 1132). We print below the full text of Lord Moynihan's speech in moving the rejection of the Bill.

REASONS FOR REJECTION

It is to me a matter of no little regret that I feel myself compelled to oppose a Bill introduced by my noble friend Lord Elibank. I do not forget that when, a shrinking and timorous novice, I had the audacity to introduce a Bill to your Lordships' House, the fact that the Bill passed its third reading was due in part to the invaluable help and wise counsel of the noble Lord in special Committee. But, if I may be permitted to say so, I fear that the noble Viscount has not fully perceived the implications, still less foreseen the irreparable calamity that would result if your Lordships gave your assent to this measure. My objections come from two quarters.

LEGAL ASPECTS

In the first place the Bill involves a negation of all the principles already embodied in the Medical Act of 1858. Before this Bill, if passed by Parliament, could become effective this Act would surely have to be repealed. This Bill would defeat the intention and effect of the Medical Acts, which through the *Medical Register* provide a clear line of discrimination between those who have, and those who have not, passed through the recognized medical curriculum. The relevant purpose of this Act is the protection of the public from the ignorant and dangerous attentions of those who have undergone no adequate training or any training in the sciences upon which medicine is based, who know little or nothing of the normal structure of the human body by dissection, of the morbid changes appearing in disease, of the proper or disordered functions of organs, or of that multitude of scientifically discovered and scientifically tested truths upon which the clinical work of physicians and surgeons is founded. The Medical Act of 1858 is primarily an Act for the safeguarding of the public; and this Bill seeks to set aside all the carefully constructed substantial defence which time, circumstance, and opportunity have so frequently shown to be necessary, and to substitute a very frail protection and simulacrum. If by some miracle of perversity the Legislature should accept such a Bill as this, the claim now put forward would assuredly not end with osteopaths. If one particular "theory" of medicine were granted recognition contrary to the Medical Act of 1858 (Sections 23 and 28) a precedent would be created for the official recognition of any other cults which cared to include a smattering of medical subjects in the curriculum. There is nothing in the Medical Act to prevent any man, qualified or unqualified, from practising osteopathy. Many of your Lordships are far more competent than I to express a considered opinion upon this first point I raise—namely, that acceptance

of this Bill would require that the Medical Act at present in force, by which, so far as legislation can secure it, the safety of the public is protected, should be repealed.

PROFESSIONAL ASPECTS

The second objection I venture to offer concerns not the legal, but the professional aspect of this Bill. Its acceptance would involve a denial of, and would hold up to obloquy, the whole scientific basis of medicine. If there is one country in the world which should regard itself as the custodian, protector, and guardian of scientific medicine, it is our own; for it was in this country that modern scientific medicine had birth, and it was in this country that the greatest discoveries, foundation stones, and landmarks in the history of medicine were made. The claim may justly be made that medicine is at once parent and nurse of all science. For the methods by which all science advances are those first introduced, or in their originals most successfully applied and established, by practitioners of medicine.

The inductive method of logic was created not by Aristotle, nor by Socrates, nor by any philosopher, but by Hippocrates, of whose ancient and serious diligence Bacon reminds us: the full value and right application and appreciation of the experimental method we owe to Galen. It is by these two methods, and by these alone, that all scientific advance takes place. After Galen the methods used by him and by Hippocrates were submerged in the reign of authority which lasted for over a thousand years, a dark, sterile period in which denial of the teaching of Hippocrates was not only disloyal, but heretical, and might, and not seldom did, cost a man his life, as unhappy Servetus, discoverer of the pulmonary circulation, learnt at the guilty hands of Calvin in 1553. The first gleam of light was seen in Italy, in Salerno, oldest of her universities, and so far as medicine was concerned in the wealthier University of Bologna and in Padua, famous for great teachers.

THE FOUNDATIONS OF SCIENTIFIC MEDICINE

It was the magic of Fabricius of Padua which attracted our own William Harvey to that university, where he undertook those researches which ended in his discovery of the circulation of the blood a little over three centuries ago. That discovery is the one indestructible foundation upon which all scientific medicine is based; and Harvey was empowered to make it by bringing together once again the Hippocratic and Galenic methods of inductive inquiry, comparison, generalization, and experimental proof. But until John Hunter, the patron saint of the Royal College of Surgeons of England, created with the help of Morgagni the science of pathological anatomy, little was known of those structural changes in organs which enabled men to correlate them with the symptoms of disease to which they give rise. The lot of the patient was, however, little improved, in surgical matters at least, until immortal Lister, a member of your Lordships' House, basing himself upon Pasteur (already medallist of our Royal Society) and his work on fermentation, attributed infection in wounds to the propagation of living organisms within the wound, and so made possible the immense, almost incredible, advances that have taken place not in surgery alone, but in medicine also, since the recognition of the part played in general disease by focal infection. It is chiefly upon the work of Harvey, Hunter, and Lister that the science and art of medicine have been founded: three great Englishmen. That is my reason for asserting that we in this country are in special degree the custodians of scientific medicine.

OSTEOPATHY A DENIAL OF SCIENTIFIC MEDICINE

Osteopathy has not only no connexion with the main stem of scientific medicine: it is a complete denial of the truth of scientific medicine. If there be any truth in the fanciful and fallacious basis of osteopathy, there is none in the true science of medicine. The two systems do not run side by side, they are not complementary or mutually supporting. They are in direct and hostile opposition. If one is true the other must be false. If osteopathy is true the foundations of scientific medicine are not well and truly laid; then scientific physiology created by Harvey, pathological anatomy as founded by John Hunter, our knowledge of its infection and its relation

to disease which we owe to Pasteur and Lister, are false—even contemptible. The osteopath walks by faith and not by sight. When he speaks of the "lesion" he means something that neither chemical examination, radiological examination, nor post-mortem examination reveals to those trained in the practice of these methods. In place of knowledge gained in all the world by biologists, physiologists, pathologists, and bacteriologists we are asked to accept a cult fabricated not after arduous research, but springing up spontaneously by a process of serendipity in the mind of a layman in America, where it grew apace, though denied and derided from the day of its birth to this very moment by all scientific opinion in that country.

I do not deny that the problem presented to-day may contain elements of obscurity. Some of your Lordships may have heard, or even in your own persons may have experienced, a sense of benefit from treatment at the hands of an osteopath. I do not deny that such things are possible, nor do I deny that medicine has been slow to incorporate in its methods the art of those outside the fold—even, indeed, at times of those within the fold. Medicine is always slow to accept new methods because a heavy responsibility rests upon it to ensure that, within the limits of contemporary human knowledge, only the best, well-tried, and well-proven methods shall find a place in its orthodox practice. But to-day it cannot be denied that orthopaedic surgery embraces all the sound methods hitherto employed empirically either by bonesetter, manipulative surgeon, osteopath, or other "natural" practitioner. This we owe to the genius of my late dear friend Robert Jones, the greatest orthopaedic surgeon the world has known. He was the nephew and pupil of H. O. Thomas, whose name is for ever associated with the Thomas splint, which gave such splendid service during the war. Thomas was himself the son of a bonesetter, with whom he was in partnership before the Medical Act of 1858 rendered this illegal. Thomas was indeed the descendant of generations of bonesetters who flourished in Wales and settled at last in Liverpool. All the quick-fingered skill of the bonesetter was brought into medicine by Robert Jones, and there, after trial and great improvement and more rational application, has at last found a place and haven; and robbed of those perils which to my knowledge made it (though at times apparently successful) not seldom a cause of death in the hands of the untrained and unscientific bonesetter.

MISCHIEVOUS FEATURES OF THE BILL

I do not now venture to waste your Lordships' time in detailed criticism of this Bill. If opportunity ever came I think I could make it clear to the point of conviction: that osteopathy receives no clear definition in this Bill (for to say that what an osteopath may practise connotes the meaning of osteopathy is meaningless, and has many undesirable and even dangerous repercussions); that the Bill grants to foreign osteopaths the right to practise in this country, though the standards of other countries are sometimes grotesque; that reciprocity with other countries would almost certainly be denied; that the suggested training in medical subjects is too short to give a competence at all comparable with that of the general medical practitioner to-day; that if in future there is to be a medical training it must be equal for all those who are to practise medicine; that a shorter training would surely attract an inferior type of practitioner; that the Bill would create two standards of entry into the profession of healing, debasing the standard at a time when the medical profession is taking thought to exalt it; that the right to sign death certificates or to perform operations should in the public interest on no account be granted to those who have not, after passing through the recognized medical curriculum, been licensed by the General Medical Council, whose authority is conferred through the Medical Acts by Parliament; that Clause 8 (1), if strictly interpreted, would prevent the ordinary practitioner of medicine from using his own methods, which are being annexed by the osteopath; and that this clause would confer upon osteopathy a monopoly now denied to medicine.

Finally, I may point out that if osteopaths at long last are realizing that a formal medical training is essential before they may successfully practise their art, there is nothing to prevent them from passing through the present medical curri-

culum, and supplementing it in any way considered proper. This is the method followed by ophthalmologists, laryngologists, those who practise in public health, and others within the fold of orthodox medicine.

CONCLUSION

I do not desire to deal in anything but the most cursory manner with details of this Bill. It is to its principles that I offer most serious and most confident objection. It embodies an endeavour to destroy the Hippocratic unity of medicine, to foist upon the public, unaware of the danger, a spurious science which sets aside all the accumulated wisdom and expert practice of centuries. It seeks legislative authority for a "theory" of medicine that has in no country proved its validity, and is the derision of all competent and experienced minds.

MATERNAL MORTALITY

DEPUTATION TO THE MINISTER

Sir Hilton Young, the Minister of Health, received a deputation on December 11th from the Maternal Mortality Committee. The deputation, which was introduced by Mrs. H. J. Tennant, was representative of a large number of women's organizations, and of all three political parties.

Mrs. Tennant said the deputation represented over 3,000,000 women, and was the outcome of a meeting on the question of maternal mortality held on November 6th. Its object was to urge a wider provision of first-rate medical and midwifery services and the fuller maintenance and development of the maternity and child welfare services. Mrs. Barton said that malnutrition, though not a primary cause of maternal mortality, was a contributory factor. She feared that the Exchequer's block-grant system was less effective in stimulating local authorities than the former percentage grants. Mrs. Anderson referred to the recent inquiry into the death of Mrs. Taylor in Manchester. She feared that the facts brought to light by this inquiry had shaken public confidence.

Lady Barrett dealt with the question of ante-natal care and the desirability of appointing at ante-natal centres doctors who were also practising midwifery. She made reference to the necessity of improving the training of doctors and midwives. Miss Gregory said that midwives should receive a two- or three-years' course in a first-class hospital; she emphasized the dangers of employing "handy" women. Lady Limerick welcomed the announcement by the Minister of the proposed inquiries in areas in which the maternal mortality rate was abnormally high, and called for the establishment by local authorities of more gynaecological clinics. Mrs. Alderton held that county councils should be the maternity and child welfare authorities for all areas except large urban areas. She referred to the difficulties of establishing a satisfactory service in remote rural areas. Lady Denman said that at the last Conference on Maternal Mortality there had been a marked change in the attitude of the delegates; there was evidence of growing impatience at the failure to reduce the maternal mortality rate.

THE MINISTER'S REPLY

The Minister said that the problem of maternal mortality was one giving him, as it had given his predecessors, grave concern. Despite the improvement in the general mortality rate, there had as yet been no improvement in the maternal mortality rate. He was grateful to the deputation for its co-operation, and he had listened with interest to the helpful speeches that had been made. The maternity and child welfare services of local authorities were being steadily developed. No financial check had been placed upon them, and they were not affected by the transfer from the percentage to the block-grant system. When the transfer was made an additional sum of £5,000,000 was provided by the Exchequer for the development of local authorities' services, and the maternity and child welfare service had been recognized as a first charge upon that sum.

Some of the speakers had suggested that malnutrition was a cause of the high maternal death rate. There was no evidence, however, to show that there was any close relation between malnutrition and a high maternal mortality. Of the

actual deaths examined at least one-half occurred among well-to-do people, and it was significant that the maternal death rate for 1933 in such a depressed area as Durham was no higher than the rate in the relatively prosperous county of Middlesex. Nevertheless, the conditions in the depressed areas were undoubtedly such as to give rise to anxiety, and the position was receiving the close attention of the administration. In particular local authorities had been urged to make, in appropriate cases, full use of their powers to supply milk and other foods to expectant and nursing mothers.

The Government was at present engaged in co-operation with the local authorities in a strenuous and continuous effort to improve the maternity and child welfare services throughout the country. Fresh impetus had been given in October last to the development of the maternity services by local authorities, and there would be no relaxation until the maternal mortality rate had been reduced. Particular attention was being directed to: (1) improving the ante-natal service; (2) ensuring that the services of a trained midwife were available for all confinements; (3) securing the provision of maternity beds for complicated cases and for patients with unsuitable home conditions, such beds to be associated, where practicable, with general hospitals, preferably in small units readily supervised, and for which prompt specialist services for serious cases could be made available; (4) providing facilities for the adequate isolation and separate nursing of cases of puerperal sepsis; and (5) obtaining the services of a consultant for doctors needing assistance in difficult or complicated cases. In addition to this general work special inquiries were about to be made in those areas in which the maternal mortality rate had been found to be abnormally high. Further action would be based on the result of these investigations. Careful consideration would be given to the useful and practical suggestions which had been made by the deputation.

THE MEDICO-LEGAL SOCIETY

ANNUAL DINNER

The annual dinner of the Medico-Legal Society at the Holborn Restaurant, London, on December 14th, with Sir BERNARD SPILSBURY presiding, was attended by two of H.M. judges, various other notable persons in the legal world, and the presidents of the principal medical bodies, including Dr. S. Watson Smith, President of the British Medical Association.

Mr. Justice HUMPHREYS, in proposing "Medicine and the Law," paid a noteworthy tribute to the general practitioner. His own most frequent contact with the medical profession, he said, was through the general practitioner, and "I take off my hat to him. When it comes to deciding between his evidence and that of a gentleman who may be quite eminent, but who has not seen the patient, knows nothing about the patient, is probably unacquainted with the treatment which has been administered to the patient, and tells the jury, or, less frequently, tells me that the man who has attended that patient, probably for years, is quite wrong, wrong in his diagnosis and wrong in his ideas, my inclination is to invite the jury to pay more attention to the evidence of the man who has seen and attended that particular person than to the theories of anybody else, however eminent. The general practitioner, the family doctor, is a man whom I have always regarded as immensely overworked and grossly underpaid. He is expected to—and, good fellow that he is, he does—respond to any call to get up in the night and go and see any old woman who has a stomach ache, even though he knows the patient and knows what he will find when he gets there. That is the general practitioner, and when he gives evidence I feel that he has quite sufficient knowledge of medicine and surgery to enable him to give the evidence the jury will understand and to have treated the patient in a way which gave the best possible opportunity of recovery. The man I like most among all the doctors is the general practitioner, and to him I think we owe as great a debt

as we do to the heads of the profession or to the research worker."

Lord HORDER, in responding to the toast, commented on the fact that while patients never seemed to doubt the competence and devotion of their medical advisers, the profession as a whole, or groups within it, did not occupy in public esteem anything corresponding to the esteem felt for the individual doctor. Perhaps it was so in all professions. Lord Horder went on to speak on the question of the osteopath. It was difficult for him to conceive how it was possible to erect a single therapeutic measure into a system of medicine, to eliminate the art of diagnosis, and the basis of all medicine, which was pathology, and proceed straight to treatment. He wondered what was going to happen to the British public if for diagnosis and the pathology which underlay diagnosis there was substituted one single method of treatment, however important, and if the man who had only this one method of treatment at his command was to be elevated to the position of a registered medical practitioner. Still, if the public wanted it, let it be "tried out." He did not think they, as doctors, should protest too much against this sort of thing. The more they protested the more would osteopaths consider themselves martyrs, and martyrdom was valuable propaganda. Lord Horder concluded with the remark that the time was ripe for an institute in which research and teaching in medicine and law, in so far as the two subjects interacted, could be undertaken. He hoped that the link between the two professions would shortly be rendered more effective in that respect.

Mr. Justice SWIFT, in proposing "The Medico-Legal Society," paid a tribute to Sir Bernard Spilsbury, whom he described as the ideal expert witness, a man of great knowledge, great industry, and great power of expression. "I have met in my time witnesses of all kinds and degrees, but in the class of honest expert witnesses Sir Bernard is a bright and scintillating star. No case of first-class importance has been completed without his assistance, and the public has the utmost confidence in his opinion." Mr. Justice Swift added that he had that day been speaking with Mr. Justice Avory about Sir Bernard, and his brother judge had remarked, "Some day—some day he may be found to be wrong."

Sir BERNARD SPILSBURY spoke of the loss which the society had sustained in the death of Lord Riddell, who became a member in 1922, vice-president in 1927, and president from 1930 to 1933. Lord Riddell was full of projects for making the society better known, and his contributions to the discussions were apt, witty, and informed with wide knowledge. The membership of the society now stood at about 330. All who did medico-legal work appreciated the difficulties which the present isolation imposed upon them. He welcomed the establishment by the Government of a police college, also the appointment of a specially trained medical man to carry out scientific investigation in such a college, and he hoped that there would presently appear an organization which would embrace workers in medical jurisprudence, giving them the opportunity of teaching and research.

Dr. ROBERT HUTCHISON, in replying for "The Guests," avowed his personal liking for lawyers and his early hankerings after a legal career. He recalled the remark of one indignant lady who had brought her son to him during the war, when he confessed his inability to discover any impediment to military service, "Call yourself a doctor! You look just like a lawyer." Looking at many genial faces in the present company, he felt that that must be a compliment.

The Mental After Care Association, which exists to help those who have suffered from mental trouble, earnestly appeals for funds. This year over 3,000 people have been helped, and the extension of the work to early care for incipient cases of mental disorder urgently requires financial support, the results of the work being most encouraging. Contributions should be sent to the secretary, Miss E. D. Vickers, Church House, Westminster, S.W.1.

Scotland

Edinburgh Chair of Clinical Medicine

The retirement of Professor Edwin Bramwell from the chair of clinical medicine in the University of Edinburgh has been announced. Professor Bramwell is the eldest son of the late Sir Byrom Bramwell, the distinguished neurologist, whose works on *Intracranial Tumours* and *Diseases of the Spinal Cord* contributed much to the elucidation of nervous phenomena at the end of last century. Professor Edwin Bramwell was born in 1873, and after an early education at Cheltenham studied medicine at Edinburgh University and graduated M.B., C.M. in 1896. In 1902 he was appointed assistant physician to Leith Hospital and in 1907 an assistant physician to the Royal Infirmary of Edinburgh. He joined the Royal Colleges of Physicians of Edinburgh and London as a Member in 1900, becoming a Fellow of the Edinburgh College in 1903, and of the London College in 1907. He took the M.D. of Edinburgh in 1919. He played a considerable part in the inauguration of the post-graduate courses in medicine which have been held at Edinburgh since 1906. In 1919 he was appointed lecturer on neurology in the University, and in 1922 he was made Moncrieff Arnott professor of clinical medicine. He delivered the Morison Lectures to the Royal College of Physicians of Edinburgh in 1917. His varied contributions to the literature of neurology include "Myasthenia Gravis" in the *Encyclopaedia Medica*, 1901, "Epilepsy" in the *Index of Treatment*, and "Spinal Tumours" in *Allbutt's System of Medicine*, second edition.

The chair of clinical medicine was instituted in 1913 out of the funds derived from a legacy bequeathed by James Moncrieff Arnott, a former graduate of the university. A scheme has been mooted for merging this chair with that of systematic medicine when opportunity offers. Dr. Edwin Matthew, who was due to retire from the post of physician to the Royal Infirmary at the age limit on December 12th, 1934, has meantime been continued in office in order to carry on the duties of the clinical medicine chair. Professor Matthew is a native of Aberdeen and graduated M.A. at that University in 1889. After a medical course at Edinburgh University he graduated M.B., C.M. with first-class honours in 1897, proceeding to the degree of M.D. and receiving a gold medal for his thesis in 1908. As a student he gained a Vans Dunlop and the Ettles scholarships. He joined the Royal College of Physicians of Edinburgh as a Member in 1902, and became a Fellow in 1906. For some twenty years he was assistant physician and physician at Leith Hospital, and for twenty-five years assistant physician and physician to the Royal Infirmary, Edinburgh. He has acted as examiner in medicine at the Universities of Aberdeen and St. Andrews, and since May, 1933, has been a member of the General Medical Council, representing the Royal College of Physicians of Edinburgh.

The winter graduation ceremony of Edinburgh University was held on December 14th, when Principal Sir Thomas Holland conferred the degree of Doctor of Medicine upon fourteen graduates and those of Bachelor of Medicine and Bachelor of Surgery upon twenty-nine graduands.

Maternal Mortality

Professor J. M. Munro Kerr, in addressing the annual meeting of the Scottish Branch of the Queen's Institute of District Nursing at Glasgow on December 14th, expressed the opinion that a greater measure of co-operation between the different agencies interested in the problem of maternal care was the best method for reducing the present figures

of maternal mortality. Lord Provost A. B. Swan, who presided at the meeting, spoke of the highly successful results in treatment which the Institute of District Nursing obtained. The general community should recognize that they owed much to this Institute for the improvement in the health conditions of the people. Lady Kay Muir, who submitted the report, said that since the Local Government (Scotland) Act, 1929, came into operation, there had been a tendency for some of the grants made by former parish councils in aid of nursing work to be reduced or stopped. It would be regrettable if this became general, and it was hoped that local authorities would recognize the value of the work of attending persons in receipt of public assistance. Professor Munro Kerr said that much could be accomplished to bring maternal mortality down to an irreducible minimum, and in this the Queen's Institute was setting a splendid example. Geographical and social conditions, as well as the character of the population, affected this minimum, but the chief factor was the type and organization of the maternity service in any locality. At the present time maternal mortality was much the same as it was fifty years ago, and it was a matter for question why this should be so when there were so many willing workers, and when the causes of mortality were now known. The chief reason was that agencies concerned with the maternal mortality were not fully co-ordinated. These agencies were the obstetric specialists, general practitioners, midwives, nurses, medical officers of health, health visitors, and various hospitals and ante-natal clinics. He would emphasize the necessity for greater co-operation with expectant mothers themselves, who should realize that they ought to place themselves under supervision early in pregnancy. He believed in the provision of municipal midwives in large cities, a scheme which had been tried out already in Bradford. In the rural and semi-rural areas the Queen's Institute might undertake the routine maternity services, and if the work of the institute were correlated with that of ante-natal clinics, doctors, and specialists, there would be some prospect of improvement. In the report of the institute the statement is made that out of 86,546 births registered in Scotland during 1933 Queen's nurses attended 14,211. In 2,197 of these the nurses attended as midwives, and in the remainder as maternity nurses. In the births attended generally in Scotland otherwise than by Queen's nurses the maternal death rate was 6.5 per 1,000 births, while in the cases that had been attended by Queen's nurses the death rate was 2.8 per 1,000 births. The total assets of the Scottish branch of the institute now amount to £126,598, an increase during the past year of £7,201. It was also reported that the Gardens Scheme in Scotland, inaugurated four years ago for raising funds for the institute, had for three years running realized over £5,000, and in the present year the figure was £800 higher than that of any previous year.

Edinburgh Public Medical Service

The Public Medical Service instituted in Edinburgh two months ago has met with a large measure of success. Over two-thirds of the doctors in general practice in the city have joined the service, and patients are enrolling at the rate of 500 per week. Warm support is also being received from chemists, employers of labour, prominent social organizations, and leaders of public opinion. The wives of insured persons, particularly, have been quick to realize that benefits similar to those of the National Health Insurance Scheme can be obtained by the payment of fourpence per week per member of the family, and are eager to enrol their children. Subscriptions are paid through collectors to a central office, but in all other

respects the patients deal directly with their own doctor. A similar public medical service was inaugurated in the county of Midlothian last year, and another is about to be established in Ayrshire.

Welfare of the Blind: Advisory Committee

The Department of Health for Scotland has appointed the Scottish Advisory Committee on the Welfare of the Blind for a further term of office. The committee is representative of local authorities in Scotland and of organizations and agencies for the blind, and includes a number of persons appointed directly by the department. The personnel is as follows: Mr. J. M. Rusk (chairman), Mr. Mackenzie S. Shaw (vice-chairman), Mr. C. H. W. G. Anderson, Mr. James Balfour, Mr. William Bell, Mr. William Edgar, Mr. W. R. Halliday, Mrs. A. A. Kennedy, Mr. James Leiper, Mr. C. G. Lothian, Dr. George Mackay, Mr. W. H. Blyth Martin, Lord Polwarth, Mr. Adair Robb, Mr. James Ross, and Mr. Bertram Talbot. Mr. Rusk becomes chairman in place of the late Sir William Reid, and Mr. Mackenzie Shaw assumes the office formerly held by the Rev. Dr. Thomas Burns, who is unable to accept reappointment on grounds of health.

Bangour Hospital Extension

An extension of the nurses' home at the Bangour Mental Hospital of the Edinburgh Corporation was inaugurated on December 3rd by Lady Thomson, wife of the Lord Provost of Edinburgh. The extension provides accommodation for sixty-four nurses, the home now housing the entire nursing staff of 139 members. It also includes a lecture room and rooms for practical work and for reading and writing. The extension has cost some £11,000. Lady Thomson said that a great change had come over the mental hospitals in this country during the last half-century, largely due to the increasing extent to which female nurses had been employed. With few exceptions, acute cases, male as well as female, were now under the care of female nurses, and the results had amply justified what was at first regarded as a very doubtful experiment. The influence of the trained mental nurse had done more than any other single measure to transform the mental hospital of to-day into a place of care and healing.

Ireland

Bicentenary of Mercer's Hospital, Dublin

At a meeting in connexion with the bicentenary of Mercer's Hospital the question of amalgamation of the hospital with Sir Patrick Dun's and the Royal City of Dublin Hospitals was discussed. Dr. R. J. Rowlette said it had been realized by the governors and medical staff alike that a small hospital of the size of Mercer's, containing 100 to 200 beds, was not the most suitable to give efficient results to-day. The era of the small hospital had passed, and to secure thoroughly efficient service hospitals of a larger unit must be considered. While economy was necessary, it was not an essential question. There was under discussion a scheme for the amalgamation of Mercer's, Sir Patrick Dun's, and the Royal City of Dublin Hospitals in such a way as to have a hospital unit of about 400 to 500 beds, instead of three units of 100 to 150 beds each. The project had received the warm support of the chairman of the Hospitals Commission, which advised the Minister for Local Government and Public Health as to the disposal of the funds accruing from the sweepstakes. He hoped that the details of the scheme would be such as to get the approval of the Commission, and that the Minister would consider the

scheme with the greatest sympathy when it came before him. Dr. T. P. Kirkpatrick read a paper on "The Foundation and Ancient History of the Hospital," in which he went back to the twelfth century, when there was a Chapel of St. Stephen on the site of Mercer's Hospital. They had now, he stated, nine great hospitals in Dublin, and three of these owed their foundation to women: Mary Mercer, Madame Steevens, and Mary Aikenhead. Sir John Lumsden, in an address on the recent history of the hospital, said that during the early part of the eighteenth century certain auxiliary or private medical schools existed in Dublin, the certificates of which were accepted by the licensing bodies—Kirby's (1832), the Carmichael School of Surgery (1835), and the Ledwich School (1836) in Peter Street, the property later being acquired by the Adelaide Hospital. The number of students attending at Mercer's during the 'seventies and 'eighties was considerable, as it was one of the chief teaching hospitals, and a large proportion of Ledwich School students came there. In those days Mercer's had some outstanding men on the staff: the Ledwichs, the great surgeon Butcher (of butcher-saw renown), Dr. Mason, Mr. Nixon, and Mr. Stamer O'Grady.

Poor Law Medical Officers' Salaries

The substance of a letter from Dr. T. F. Armstrong, honorary secretary to the County Wexford Poor Law Medical Officers' Society, to the County Wexford Health Board is as follows. At a special meeting of his society the establishment of a State medical service was unanimously recommended, as the Poor Law medical system, designed over eighty years ago, was not adapted to present needs. Meanwhile some amelioration of the conditions was necessary if a full satisfactory service was to be maintained for the purpose of affording medical relief on the extended scale. Applications for increases of salaries might with every justification be made, but the society, recognizing all interests, asked only for two concessions, which were admittedly most reasonable and moderate: (1) that all salaries should be placed on a scale with fair increments, the maximum being reached in not more than ten years; and (2) that a substantial contribution should be made towards travelling expenses which were incurred in performing official duties. The average dispensary medical officer's salary was subject to deductions of 50 per cent. and more for such expenses, and as they increased the real salary diminished until, during influenza epidemics, there was no real remuneration whatever. The dispensary medical officers requested: (1) that the present maximum of £300 be attained in ten years by annual increments of £10; and (2) that an allowance of £75 be granted as a contribution towards travelling expenses. The hospital medical officers applied for the following scales: county surgeon, £500, and annual increments of £30 to £800; county home medical officer, £200, increasing by £10 to £300; fever hospital medical officer, £200, increasing by £12 10s. to £300; district hospital medical officer, Gorey scale salary to remain as at present. The scale fixed by sealed order a few years ago proved most unsatisfactory in the following respects: (a) the scale was £50 lower than in the neighbouring counties; (b) the annual increments were only £5, although the Department of Local Government and Public Health had itself suggested £10 increments as being most suitable; (c) it was contrary to the usual practice of the Department to fix a scale which was lower than existing scales in the county—for example, in Gorey Union area the scale was £50 higher, and the maximum was reached in five years; and (d) the scale lowered the initial salaries in certain areas and removed the privileges conferred by transfer to these areas.

Diphtheria in Cork City

Dr. Saunders, medical officer of health, in a report on the health of Cork City in October, called attention to the continued and undue mortality from diphtheria. The fall in the fatality rate had not yet kept pace with the fall in incidence of this disease; the latter was now much less than it was four or five years ago, when immunization was begun. Two deaths occurred during the month, which brought the total for the present year up to fifteen, one more than the total for 1933. None of these deaths occurred among immunized children, yet many parents still persisted in refusing to have their children protected. While the number of cases was much fewer than it used to be, the type of the disease was more severe and the risk of death greater. If every child in the city under 10 were immunized, Dr. Saunders added, the disease would disappear completely.

County Medical Officers of Health in Leitrim and Longford

Dr. McCormack, medical inspector of the Department of Local Government and Public Health, recently attended Leitrim County Council to urge the appointment of a medical officer of health. The question had been postponed from time to time. A suggestion of the Department that Leitrim and Longford should appoint a joint medical officer of health did not find favour. The Council expressed the wish that the positions of tuberculosis medical officer and county medical officer of health should be amalgamated, and that Dr. Reynolds, tuberculosis medical officer, should be appointed to the joint position. Dr. McCormack said the resolution could not be considered, since the filling of the appointment would be for the Appointments Commission.

England and Wales

Society of Apothecaries

The ancient hall of the Society of Apothecaries of London was the scene on December 11th of the Yeomanry Dinner, when the Master, Sir George Buchanan, supported by the Senior and Junior Wardens, Sir William Willcox and Dr. J. S. Fairbairn, presided over a company of about one hundred. Among the guests were Sir E. Hilton Young, Minister of Health, Lieut.-General J. A. Hartigan, D.G. of the Army Medical Services, Lord Horder, President of the Medical Society of London, Dr. E. K. Le Fleming, Chairman of Council of the British Medical Association, the presidents of various kindred societies, and the deans of London medical schools. Sir William Willcox introduced Dr. W. Langdon Brown, Regius Professor of Physic at Cambridge University, to receive the honorary freedom of the Society, and made appropriate reference to his distinguished career in medicine. The freedom, with the scroll enclosed in a specially designed casket, was presented by the Master. Professor Langdon Brown expressed his thanks for the high honour conferred upon him, and his pleasure in being introduced by such an old friend as Sir William Willcox. He could not help feeling that the honour had come to him less on personal grounds than in recognition of the ancient office he was privileged to hold. Cambridge University and the Society of Apothecaries were both ancient foundations, but both had always shown a faculty of adapting themselves to the needs of the time. Sir Hilton Young, in proposing the health of the Society, said that it would be impossible for any occupant of his office to stand before the present company without bearing testimony to the distinguished

record of public service of the Master, Sir George Buchanan. The Society itself, after a long and comparatively obscure record as a City guild, had taken up a number of fresh activities in the public interest. It had shown a facility for rendering service where service was most needed. He referred in particular to its institution a few years ago of the diploma of Master of Midwifery, designed to assist public health authorities and others in the selection of practitioners who had made a special study of ante-natal care, obstetrics, and infant welfare. Another noteworthy achievement of recent date was the Society's register of biophysical assistants. Above all, he greeted the Society as one of those important bodies working effectively for the maintenance of the standards and traditions of the medical profession. The Master, in responding, said that the Society had two sides—that of a City guild and that of a medical corporation. As a guild it had done good service, but as a medical corporation its service to the community had been in some respects outstanding. It had initiated certain lines of action, and later had surrendered control when the work became too big for its compass. At one time there was no register of persons licensed to practise save one kept by the Society of Apothecaries. Mr. Arthur Greenwood, M.P., a former Minister of Health and an honorary freeman of the Society, proposed the health of the guests, and also acclaimed the Society as an ancient body able to adapt itself to new demands. Brief responses were made by General Hartigan and by Mr. W. Girling Ball, dean of the medical college, St. Bartholomew's Hospital.

Establishment of Nutrition Clinics for London School Children

The Education Committee of the London County Council on December 4th announced to the Council its proposals for the medical and dental treatment of school children for 1935-6. These arrangements are the first to be put forward by the Labour majority, and they include the provision of additional treatment centres, dental inspection, and nutriment for children under treatment, the establishment of nutrition clinics, and the introduction of new methods for the early treatment of ear, nose, and throat defects. It is proposed to establish five nutrition centres in London in the programme of educational developments for 1935-8. Cases will be referred to the centres by school doctors, teachers, and care committees, and each child will have a thorough medical examination to ascertain whether its physical condition may be ascribed to dietetic deficiency. If so, advice will be given to the parents, and, where possible, nutritives and tonics, such as cod-liver oil, malt, and iron, will be provided. Additional facilities are to be available in certain districts for the treatment of eye defects. Operations for the removal of enlarged tonsils or adenoids are decreasing in number, but there are a great many children with conditions of the nose and ears which, owing to lack of early care, often result in an operation becoming inevitable. One type of preventive treatment is known as diastolization, and can be undertaken by specially trained nurses under the supervision of an aurist. Arrangements are being made for fourteen such cases to be treated per week, or about 600 a year; each case will need about twelve treatments. Further provision for the care of minor ailments is to be made, together with facilities at the minor ailments centres for the administration of nutritives and tonics in special cases when ordered by the physicians. As for dental treatment, it is proposed to arrange for the extension of dental inspection and treatment facilities in order that all children in the schools shall be inspected by the dental surgeons once a year, and the consequential treatment

ENGLAND AND WALES

Dec. 22, 1934]

given at the centres. At present the general rule is for the dental surgeons to inspect all children, with the exception of entrants, children of ages 7 and 11 years, and leavers—that is, those age groups subjected to routine inspection by the school doctors. To enable all children to be inspected annually will necessitate a total of thirty-six additional inspection sessions and 105 additional treatment sessions a week. The extra cost when the full programme is established will amount to about £12,000 a year, but the development is to be gradual and spread over three years, the age groups 7 to 8 years being added to the dental inspections throughout London for the first year, 1935-6. Arrangements at three selected centres for orthodontic treatment, as an experiment for six months, have been approved; the scheme will be reviewed in March next, when it will be possible to consider its extension. Observation centres for the early discovery and treatment of children suffering from rheumatic defects have proved of considerable value, and additional provision is being made in five centres. Additional centres are also to be established for stammering children.

Vital Statistics for 1933

The principal features of Part I (Medical Tables) of the Registrar-General's statistical review for 1933, which is now on sale at H.M. Stationery Office, price 6s., are as follows: The number of births registered in the year was 580,413, giving a rate of 14.4 per 1,000 persons living. This rate is 0.9 below that for 1932, hitherto the lowest recorded, and constitutes a new low record. The death rate was 12.3 per 1,000 persons living, 0.3 above that for 1932 (the same as that for 1931) but 0.9 above that for 1930. The rate for 1930 was, however, the lowest ever recorded, this being attributed to the exceptionally mild weather in the first quarter of that year. The higher rate for 1933 is almost wholly occasioned by an excess in the first quarter of the year, the rates for other three quarters showing very little variation. Infant mortality was similarly affected, and the deaths of children under 1 year numbered 64 per 1,000 live births as against 65 in 1932, 66 in 1931, and 60 in 1930; 1930 is, however, the only year showing a lower infant mortality than 1933. The death rate from cancer was 1,526 per million persons living as against 1,510 in 1932. If, however, allowance is made for differences in the age constitution of the population the comparative mortality from cancer shows a slight decrease. Tuberculosis again furnished a new low record of 824 per million living. Puerperal sepsis caused the deaths of 1.75 women per 1,000 live and stillbirths, 0.2 more than the rate for 1932 but 0.09 less than 1930. "Other accidents of pregnancy and childbirth" showed a rate of 2.57 per 1,000 live and stillbirths, compared with 2.49 in 1932, 2.36 in 1931, and 2.38 in 1930. Road accidents due to mechanical vehicles were responsible for 5,934 deaths. The figures for the last five years were 5,193, 5,752, 6,342, 5,892, and 5,671 respectively.

Old Epsomians at Dinner

The fifty-seventh annual meeting and dinner of the Old Epsomian Club was held at the Hotel Great Central on December 13th, under the presidency of Mr. R. M. Handfield-Jones. Among the guests were Lord Leverhulme, the newly elected president of Epsom College, Sir John Broadbent, vice-chairman of the College council, the Rev. A. C. Powell, head master, Lord Horder, and Professor T. B. Johnston. The projection of a cinematograph film showing events at the College on Founder's Day formed an interesting interlude. In response to the toast of his health Mr. Handfield-Jones mentioned that in the year he left Epsom—1910—he attended his first Old Epsomian dinner, when there were forty present, and the

total club membership was 300; that evening there were 140 at the tables, and the membership had risen to 1,100. Epsom was flourishing exceedingly, thanks largely to Sir Raymond Crawford, its chairman of council, who had guided it through the years of reconstruction. But it was not going to rest on its laurels. On certain matters the friends of Epsom who had studied public school administration felt strongly. As soon as it was financially possible the College should be divorced from the benevolent side. Epsom was being hindered from taking its proper place in the scholastic world because of the millstone of benevolence around its neck. So long as there were 125 local secretaries up and down the country appealing for money it would never rid itself of that incubus. It must not be imagined for a moment that anyone was suggesting that the benevolence should cease, but only that it should be separated. The public school education of the young could not go hand in hand with a system of benevolence to the aged; such benevolence was already being carried to a large extent by invested funds, and it was important that it should be separated from the school. On an actuarial basis it would take between twelve and fifteen years to establish a fund which would carry all their foundationerships (the fifty-six scholars, sons of medical practitioners, who were boarded, educated, and clothed free of all cost), and when that became possible they had at disposal at Epsom everything a public school in England. It was purely a question of policy and the founding of a fund. The head master, in reply to the toast of "Floreat Epsomia," said that the wishes which Mr. Handfield-Jones had forcibly expressed would meet with great acclamation from all concerned for the record of the year in study and sports. Dr. A. B. Howitt, M.P., proposed the health of the guests, to which Lord Leverhulme responded. A response was also made by Professor T. B. Johnston, who said that Epsom had links with all the medical schools, and particularly with Guy's, thanks to Sir William Hale-White, the honorary treasurer at Epsom, and to the existence in the medical school of a society of Old Epsomians.

Reports of Societies

MENTAL HYGIENE: PREVENTIVE MEASURES IN CHILDHOOD

Dr. DAVID FORSYTH, the president, took the chair at a meeting of the Section of Psychiatry of the Royal Society of Medicine, held on December 11th, and Dr. SUSAN ISAACS opened a discussion on the above subject.

Dealing with the years from birth to 4 or 5, Dr. Isaacs laid stress on the necessity for preliminary study of the facts of genetic psychology, including the unconscious mental life. The advice given to mothers and nurses had, she said, too long consisted of a set of ready-made rules, chiefly emphasizing the value of training in regular habits. On the other hand, some recent American attempts to apply psycho-analytic knowledge to mental hygiene seemed to be based rather naively on the facts of infantile sexuality alone. The practical advice these offered was mostly directed to avoiding stimulation and reducing the amount of libidinal gratification which the child might get in suckling, or in being tended, or in direct expressions of affection. The advice was based on a Spartan ideal of the relation between mother and child, the aim of which was to avoid fixations. Fixations, however, were far more likely to be the outcome of anxiety resulting from the aggressive wishes connected with the particular libidinal nucleus. Each of the pregenital libidinal zones, particularly the biting phase of oral

sexuality and the successive phases of anal erotism, had characteristic aggressive wishes connected with it, involving specific modes of attack and defence and specific fantasies. The pressure of these primitive forms of desire and feeling in the child from birth onwards was enormous, and his chief task was not to acquire a series of habits, but to learn to control and express his instinctual cravings towards his parent. As a first defence against the primary anxiety of oral frustration and aggression during the first six months of life, the infant took into his psyche two distinct imagos of the mother: the good, which yielded the bliss of satisfaction in suckling and removed painful stimuli; and the bad, which was created out of the experiences of pain and frustration and the child's own aggression, did not differ in character from the primitive wish-self of the child, and was endowed with all his own sadism. This internalized "bad mother" gave rise to a vast anxiety. The child suffered fantastic terrors of being bitten, cut, wetted, or burned in talionic punishment for what he had wished to do to the mother. This anxiety led to an imperative need to project the sadistic super-ego on to an external parent. In his obstinacies and tantrums the child tested his fantasies of inner danger by real action against the external parents, so as to gain constant reassurance of their power to control him without hurting him, and of their love and willingness to protect him. In his pleasure-seeking habits, such as thumb-sucking or masturbation, the child sought proof of the goodness of those parts of his own body which had been associated with aggressive fantasies. In his learning, his manifest affections, and his growing skills he gradually built up a more stable belief in the good parents inside himself, and in his own power of creating and making good, and brought this belief closer to reality.

A REGIME OF REASSURANCE

The problem of early mental hygiene was therefore to help the child to find satisfactory ways out of the anxious emotional conflicts of the first three or four years. The most general aim should be to discover a technique for giving parents and nurses responsible knowledge without increasing their guilt and anxiety. They should have a positive understanding and a wide comparative knowledge of the various aspects of development, to give them a sense of security and a correct perspective in regard to their own children. A regular routine, together with reliable and consistent modes of handling the child, avoided undue frustration, and gave him a mild external control in a form which he could understand. A temperate and appropriate authority reassured him against the first primitive parent-self within his own mind. If, however, his elders merely gave him a doctrinaire freedom to do what he liked, they yielded him over to the severest of authorities—the primitive mother-imago made in the image of the primitive infant-self.

It was also necessary to recognize individual deviations, and the fact that children could never be made to fit an exact pattern. Moreover, one could not give a disturbed mother greater help than by assuring her that the majority of children manifested emotional difficulties in the early years, and that these as a rule passed away if the general conditions of the child's life were kept satisfactory by providing adequately for the skills, interests, and friendships normal to his age. A very important consideration was the wisdom of avoiding coincident stresses. If, for example, there was a death at the time a child was teething; if he was to have an operation just after he had been naughty; if the new baby arrived after he had been specially dirty or aggressive, his difficulties would be increased to the breaking-point. It was, for example, unhelpful to send a child without warning to a nursery school within three days of the birth of a new baby. Again, the weaning of a boy of 10 months had been started a fortnight before the family moved from one country to another, was continued over a week's journey and a sea voyage of some days, and completed within a fortnight of the arrival. The child had immediately developed a most violent anxiety and aggression, screaming for hours on end in the night. Weaning should never be allowed to coincide with any such other important

change of circumstances, and if such a coincidence was unavoidable a prophylactic analysis was highly desirable. Not only hysteria and obsession, but also psychosis and delinquency could be diagnosed in the child under 5 years, and early therapy had here to be recognized as an essential part of mental hygiene. The number of children who needed actual treatment by psycho-analysis was not small.

Dr. WILLIAM MOODIE spoke from experience at the London Child Guidance Clinic of over 2,300 cases during the last five years, amplified by the examination of about 2,000 more children committed to the Remand Home of the London County Council. The manifestations of mental breakdown had been very diverse. The child might have caused disturbance to the community by violence, habitual stealing, disobedience, temper, or bullying. He might have truanted from school or fallen into the hands of the police. The trouble might have been within himself; he might have been nervous, fearful, shy, sensitive, unable to hold his own with others, or abnormally imaginative; or he might have shown some special symptom such as nail-biting, thumb-sucking, food fads, or bed-wetting. Many of the children had been referred because of school failure in one of its many forms, such as lack of concentration, so-called "word-blindness," and inability to calculate or remember. The delinquents had all been sent to the Remand Home through the juvenile courts. Many had been committed for stealing, gang activities, house-breaking, or bag-snatching. A few had been there because they were beyond control, and some because they had been found "wandering without visible means of support and lodging in the open air." In the clinic group signs were frequently found which suggested the neuroses and psychoneuroses of adults. About 8 per cent. were mentally defective, and some children suggested early psychoses. Delinquents, on the other hand, did not give the same suggestion of neurosis, but seemed mostly to be ordinary children, somewhat dull in intelligence. (Perhaps this factor had accounted for their capture.) Whereas about 20 per cent. of the clinic children were referred on account of backwardness, about 40 per cent. more were sufficiently behind in their work to cause difficulty, but had not been recognized for lack of standardized education and intelligence tests. The term "backward" was used in relation to the child's individual capacity. Every delinquent and practically every child sent to the clinic was given tests of intelligence and also of education.

THE NEED FOR INTELLECTUAL TRAINING

Many children whose education was retarded were found to present mental signs and physical symptoms suggesting an anxiety state. On tracing the history, however, it often became clear that the trouble had begun in anxiety which the child had suffered in early life from mental and nervous tension due to dammed-up mental energy. Such a child eventually became anxious, and developed fears of animals, of the dark, or of ghosts. These were merely an exaggeration of normal and natural dreads, but were exaggerated because the affective side of his nervous system was hyperexcitable. The majority of such children also gave evidence of precocity of thought in many directions. To allow them to run wild was worse than useless. The educational situation should be adjusted as far as possible. Subjects such as handwork, biology, and games did not give the necessary outlet for intellectual energy. Only intellectual subjects would do this, and much of the instability found among school children arose from under-education. A vicious cycle began, and the child, besides becoming tense, became unable to compete. An ambitious and frustrated father might coach him and worry him at home. The home atmosphere became charged with failure, and the situation became progressively worse. The corner-stone of mental hygiene in children was early and efficient teaching in the fundamental subjects of reading, writing, and arithmetic. The remedy was more knowledge about the value of intelligence and educational tasks, and less dependence on opinion. There was a tendency to over-emphasize the importance of sex in early years. Interest in sex matters varied indirectly as the standard of educational attainment, and the child whose mind was

DEC. 22, 1934]

MENTAL HYGIENE IN CHILDHOOD

adequately employed and who was given reasonable security would give little trouble in that direction. Among the delinquent group backwardness in education was very noticeable. It was amply clear in many cases that the delinquency was a compensation for lack of success in school. In the prevention of delinquency education was also of paramount importance.

Another factor that loomed large behind many of the problems was lack of discipline—not of punishment or repression, merely of that teaching which gave the child average decent rules to tackle life merely led to insecurity and indecision. The child's relation to the adult was of the greatest importance. The adult should form the base from which the child could work; he should be ready to help when difficulties arose, and even to check him when he was running into danger. Some parents avoided their proper responsibilities under the pretence of modernity and psychological insight. The remedy was the spread of reasonable information about bringing up children. The third cause of breakdown was lack of affection and normal home surroundings. An undisturbed home life stood high in the list of preservatives of mental health. Other important factors were bad physical posture, under-nourishment, lack of sleep, and fatigue. If greater attention were given to these points the mental attitude of children would immeasurably improve.

Another great menace to the child was abstruse psychological theory in the mind of the parent. It was surely bad psychology to teach parents to inquire whether their children had death wishes for them, or were abnormally sadistic, or were showing a desire for self-punishment. Interpretations in terms of unconscious mechanism should never be given, for if, as was assumed, the disturbances were based on repressed forces, any interpretation of them could arouse only antagonism or rationalization. The most difficult parents were those who, being inherently unstable, had seized upon psychiatric heresies and had become "mental hygiene" conscious. Psychiatricists should try to express their ideas with plain language and had become "mental hygiene" conscious. Psychiatricists should try to express their ideas with plain language and had become "mental hygiene" conscious.

Dr. EMANUEL MILLER pointed out the danger of over-stressing bad physical health, which was often a result of psychic disturbance. It also was a common level due to underrate the breakdown on the conscious level due to conflict with parents and teachers over current problems. Many children were backward because of an underlying emotional embarrassment. Many cases of educational difficulty could be cured by changing the method of teaching, especially where the child gave figures a symbolic interpretation. Some children did not want to learn and some were afraid of learning, and the underlying cause must be sought. Deep therapy was, however, only necessary for cases of psychoneurosis and behaviour disorders uncomplicated by backwardness and specific educational maladaptation. Its information was too valuable to spurn, but it was difficult to apply in child guidance units. He advocated prophylactic psychotherapy for couples intending marriage. He saw a future for the therapeutic method which aimed at bringing the child back into its social group through collective play.

Miss MARY CHADWICK emphasized the great strain on an infant's mind of being born into an environment in which it was not wanted or which it might be saddled with the aggressive tendencies of parents or nurses. Dr. MILDRED CREAK pointed out the necessity for segregating children who suffered from specific reading difficulties and those suffering from general emotional inhibition, and those masquerade as either of the other two. Much which might be saved, she said, by giving these children early special treatment. Dr. MARGARET LOWENFELD pointed to the importance of suiting the apparatus of learning to the age of the child. She mentioned Dr. Charlotte Bühler's work, which had shown clearly that a child might be prevented from learning by lack of the proper scaffolding. Children would not learn unless they

had an emotional reason for doing so. It was useful to discover how a child looked at the idea that it should learn. Sometimes the provision of an emotional incentive cured the trouble. Dr. F. S. NOBLE said that much good could be done by helping parents suffering from anxiety or unconscious guilt in relation to a child's illness, especially when this had no convenient label.

Dr. LETITIA FAIRFIELD pointed to the disastrous physical and material defects of rigid habit-training, and to the child's need for the stimuli of petting and playing in order to carry out the ordinary processes of life and to gain experience to build up its mental content. Some maternity and child welfare clinics had much to learn in this direction. The educational problem might be more important in the home than in the school. A child's earliest associations with print might be the *News of the World*, which it was slapped for touching, and its earliest contact with figures was only too often the family budget, which in poor homes was nearly always a source of sorrow and anxiety.

THE THYROTOXIC HEART

At the meeting of the Medical Society of London, held at 11, Chandos Street, W., on December 10th, with Lord HORDER in the chair, a discussion took place on the thyrotoxic heart.

Dr. B. T. PARSONS-SMITH defined the term as signifying the association of thyroid toxæmia with cardiac affections. A concise pathology of thyrotoxicosis had not yet been visualized; it was therefore not surprising that the clinical manifestations of the disease were by no means uniform. For many years it had been recognized that the symptomatology might be chiefly or entirely circulatory in character, with little or no obvious evidence of thyroid enlargement. Among fifty consecutive cases he had surveyed palpitation and breathlessness were outstanding symptoms, and cardiac pain was relatively rare. The frequency of the heart-beat. Breathlessness and frequent palpitation represented overaction, both in force and degree of exercise-tolerance impairment were frequent accompaniments of the thyrotoxic heart. When cardiac pain occurred its intensity varied from a mild feeling of weight or ache to the full anginal syndrome. Varying degrees of discomfort and cardiac pain were noted in 8 per cent. of the fifty cases, and one patient was subject to attacks of typical angina. The objective signs of thyrotoxicosis were characteristic. The apex impulse was usually diffuse, extending over two or three spaces. It was more often than not palpable as a distinct shock, and murmurs, usually systolic, might be audible. In a small proportion of cases a presystolic lengthening of the first sound might not be differentiated from the somewhat similar phenomena in mitral stenosis. The systolic blood pressure was usually raised, the diastolic remaining either normal or subnormal. Signs of cardiac failure were likely to arise sooner or later, thereby complicating the general progress of the disease. As to treatment Dr. Parsons-Smith said that the modern tendency was definitely to emphasize the value of operative interference. But, although the limited scope of medical treatment in operation toxic states was recognized, it should be given a trial in the majority of cases, if only as a preliminary to operation at a later date. A prolonged period of rest, quiet, and relaxation would always form the basis of such treatment, and in the milder types might suffice to control the condition, assuming that the general nutrition could be maintained. A further consideration of toxic foci, which might be responsible for cardiac dysfunction. Among drugs he mentioned potassium iodide, bromides, opiates, and other simple sedatives, iron and arsenic if anaemia was an obvious feature, and insulin to counteract persistent hyperglycaemia, also digitalis and mercurial diuretics. These principles of medical treatment were employed in twenty-one of the fifty cases he had mentioned, with the result that there was permanent cure in four, definite improve-

ment, though still obvious signs of thyrotoxicosis, in ten, and no appreciable change in seven. It was fortunate that an alternative method—surgery—was available, in view of the limited prospects of achieving efficient cure in the average case by purely medical methods. Thyroidectomy, not long since an extremely risky proceeding, was now moderately safe in the hands of a well-practised and expert surgeon. Of the twenty-nine cases submitted to operation, and excluding two patients who could not be traced, there was complete recovery in thirteen, partial relief from symptoms in nine, and no appreciable relief in five.

Lord HORDER noted that Dr. Parsons-Smith's list of drugs did not include belladonna, which had the sanction of no less a clinician than Trousseau a hundred years ago. As a general physician Dr. Parsons-Smith's general conclusions appealed to him. On reviewing his own practice, he was quite sure that he had come to invite the co-operation of his surgical colleagues in more cases and at an earlier stage than formerly. It was a very pathetic experience to discover, after months rather than weeks of a prolonged and tedious medical programme, that ground had been lost and structural damage done, involving greater risks in the future handling of the case than if an earlier decision had been made to embark upon thyroidectomy. All the same, this form of therapeutics, like many others, was a matter of evolution, and it was still a sound thing to treat these patients on a medical programme as a preliminary to surgical treatment if and when that was decided. One of the most extraordinary experiences in clinical medicine was to see a patient with Graves's disease, in dramatic ill-health, with the whole syndrome very strikingly manifested, so ill that surgical treatment was not recommended, and then, years afterwards, on meeting the patient, to find so little residue, sometimes no residue at all. One wondered what were the factors which determined that evolution of intense illness, especially when, later in life, there was no apparent relapse, in spite of septic conditions and physical, or perhaps psychological, strain. The cases that did not completely recover underwent exacerbations and relapses, but once the cure was effected, even without thyroid extirpation, they did not seem to get into the same condition again.

Sir THOMAS DUNHILL said that it was a pleasure to see the two sides of the profession co-operating in this field. Little by little they had each learned how much better was co-operation than rivalry. Of the pathogenesis of this condition there was still much to learn, and because of that the treatment of individuals could never be classified in round numbers. One never knew what was behind the scenes. He had felt that this disease should remain in great part in the hands of the physician, and that the physician and the patient together would realize when something more had to be done. He had, however, felt rather differently lately, when operating on patients in whom auricular fibrillation had been established and irremediable damage already done. Nowadays one had rather to fight to prevent operations for which the cases were not suitable, whereas originally the difficulty was to persuade to operation the people likely to benefit. Generally his feeling was that in middle age, when the heart had lost its earlier reserves, the individual was more likely to fall a victim to a form of intoxication which, though mild, continued for a long time.

Sir WILLIAM WILCOX said that the important thing about cases of hyperthyroidism was that they varied so much, and no set rules could be laid down. In these cases of thyrotoxicosis any added infection, just as in diabetes, exaggerated the symptoms and was more likely to bring about a fatal condition. The pathogenesis was complicated, and brought in psychological and hereditary aspects. In thyrotoxic cases some of the barbituric acid drugs had a very enhancing effect. Drugs such as nambutal were contraindicated. Dr. EVAN BEDFORD said it was generally recognized that the degree of damage to the heart did not run parallel to the severity of the toxicosis as judged by the basal metabolic rate and the nervous symptoms. He did not believe that thyrotoxicosis by itself would injure the healthy and youthful heart to the extent of causing either auricular fibrillation or enlargement. He had analysed

fifty consecutive cases of damaged hearts with thyrotoxicosis on which his surgical colleagues had operated, and in only about ten was there any other heart lesion, although admittedly the patients were of such an age that the coronary arteries were likely to be normal. He had seen a number of patients who in years gone by had been cured by medical measures and had presented themselves at the appropriate age with auricular fibrillation, without the least idea that it was associated in any way with their former condition. If the two conditions—thyrotoxicosis and a damaged heart—were present the cases could not be restored to normal by removal of the thyroid. Mr. L. E. C. NORBURY put in a plea for primary ligation of the vessels in severe cases where a thyroidectomy appeared too formidable. Dr. LEVY SIMPSON mentioned that some French physicians had been working on an anti-thyrotropic hormone. The results, although producing some benefit, were by no means conclusive. Mr. HOPE CARLTON questioned the distinction between primary and secondary toxic goitre.

Dr. PARSONS-SMITH, in reply, said that he had been rather disappointed in belladonna. As for auricular fibrillation, this might be only a disturbance of function, a temporary event in toxic conditions, not necessarily indicating structural heart disease.

HODGKIN'S DISEASE WITH ERYTHEMA NODOSUM

At a meeting of the Devon and Exeter Medico-Chirurgical Society, held on November 29th, with the president, Mr. R. WAYLAND SMITH, in the chair, Dr. C. J. FULLER showed and read notes on a case of Hodgkin's disease with associated erythema nodosum.

Dr. Fuller said that the case was that of a man aged 44. There had been evidence of glandular enlargement in the neck and axilla for the past ten months, and night sweats had been an accompaniment. Some twelve months before—that is, prior to the definite establishment of Hodgkin's disease—there had been an attack of erythema nodosum. Five weeks later erythema was noted on the back of the legs coincidently with a phlyctenular ulcer on the right eye. A month or so subsequently erythema multiforme had appeared on the back of the neck and on both forearms.

When seen at the meeting the man had enlarged glands on both sides of the neck and in the left axilla: the spleen could be palpated some two fingerbreadths below the costal margin. A portion of gland removed and sectioned had placed the diagnosis beyond dispute. Dr. Fuller said that the chief interest lay in the skin manifestations, and the reflections so called to the mind on the aetiology of erythema nodosum. Recent investigations had proved that a large number of cases of erythema nodosum were associated with tuberculosis, a few with streptococcal infections, and a very few with Hodgkin's disease. The question of treatment by deep irradiation was under consideration.

Dr. R. G. MICHELMORE, who had had the man under observation and treatment before admission to hospital, stated that prior to the appearance of the erythema nodosum he had complained of rheumatism in the knee. He quoted the work of Dr. Colles, published in December of 1933, on the aetiology of erythema nodosum, where figures gave 70 per cent. of cases with a tuberculous history, 20 per cent. related to streptococcal infection, and 10 per cent. with an indefinite origin. In Scandinavia association with tuberculosis had obtained special prominence, and it seemed now that erythema nodosum would no longer merit consideration as a definite entity. Dr. W. A. ROBB, who had sectioned the gland, reported that microscopically the findings were in support of Hodgkin's disease, and that the occurrence of erythema nodosum along with tuberculosis and lymphadenoma was pathologically acceptable. The presence of a phlyctenular ulcer tended to strengthen the relationship. Dr. C. WROTH said that the reaction to x-ray therapy was almost diagnostic in lymphadenoma. The general bath x-irradiation often proved more effective than local application, but in any case the success obtained would spell tem-

porary benefit only, the glands becoming resistant after several years' treatment, with resultant gradual retrogression in the symptoms.

Mr. A. L. CANDLER read notes on a case of non-malignant stricture of the hepatic flexure occurring in a boy, aged 6 years, who was admitted to hospital on August 16th, 1934, with extreme abdominal distension unassociated with definite pain or with vomiting. A history obtained seemed to make the symptoms of one month's duration only. At operation a hard stricture was found at the hepatic flexure, together with extreme dilatation of the proximal gut. The appendix was eight inches in length and distended to a diameter of one inch, thus affording a hope for means of relief of distension by appendicostomy. The latter was opened next day and a large tube passed into the caecum, but unfortunately the bowel remained paralysed up to the boy's death some five days subsequently. Mr. Candler added that the condition necessitating operation was not unlike that found in hypertrophic stenosis of the stomach. Dr. W. A. ROBB said that the section showed a predominance of muscular tissue with a considerable amount of fibrous tissue, and that there was no suggestion of malignancy. There were certain areas in the alimentary canal in which such spasms were likely to occur, and among these the hepatic flexure was included.

CORRESPONDENCE

London University and its Medical Schools

SIR.—The letter of Sir Ernest Graham-Little in your issue of November 24th raises a question which has caused no little anxiety among those who are connected with the University of London and its medical schools, and we are indebted to him for having put forward a concrete proposal designed to solve the problem of ensuring that those who go through the course of training and examination at the University should obtain a university degree. I think Sir Ernest conveys a rather more serious impression of the position than is actually the case, though this is bad enough. The figures at my disposal suggest that some 60 per cent. of those who pass the Second Examination eventually obtain the degree.

I am not sure, however, that the remedy he suggests really solves the problem, in spite of the support so ably given to it, on sentimental grounds, by Professor Greenwood. It is quite true that students coming to London from Oxford and Cambridge have a B.A. degree, but in no university in the British Isles, so far as I know, is a degree given merely on the strength of passing the Second Examination for a medical degree. At Oxford and Cambridge the degree is given after an examination in science (or arts), usually three years after passing the First Examination and one year after passing the Second Examination for medical degrees. A similar provision already exists in London; for any student may, after passing the Second M.B. Examination, remain for another year in the anatomy or physiology departments and obtain a B.Sc. degree. Similar provision is made in most other English universities.

Sir Ernest admits that some adjustment would be necessary to give the degree he proposes a standing comparable with the other degrees of the University, but this would surely increase the difficulty and prolong the time taken for the student to obtain the M.B., B.S. degree, which is really his chief aim. There would also be a distinct element of danger in giving a degree of Bachelor of Medical Sciences to a student at that stage of his career, for the studies of human anatomy and physiology, though preliminary to the study of medicine, are not essentially medical in themselves. It is not inconceivable that the public might consider a person possessing such a degree as having a medical qualification, although he may never

have done any clinical medicine. Further, we can well imagine that the public seeing B.M.S., M.R.C.S., etc., on a doctor's plate might easily be led to believe that the former letters meant Bachelor of Medicine and Surgery, when they may really mean "failed M.B."

No, Sir, what our medical students want is the M.B., B.S. Lond., and it is up to us to see that all reasonably intelligent students who have passed their Second M.B. get it. They want to be saved the duplication of Final Examinations, and also the duplication of examination fees. There appear to me to be two ways in which this is possible: one is by combining in some way with the other licensing bodies in London, and the other is by making the Final M.B., B.S. Examination sufficiently reasonable for the average student to take in his stride. Of the two, I think the former has certain advantages, and I believe it is perfectly practicable, given good will on all sides.

This is not the time or place to discuss this matter in further detail, but I feel convinced that some scheme must be evolved before long to bring about the result we all desire.—I am, etc.,

London, W.1, Dec. 10th.

A. M. H. GRAY.

Curarine in Tetanus

SIR.—May I solicit the collaboration of your readers in a field of research? Our investigation of certain plant ingredients of curare has enabled my chemical collaborator, Dr. Harold King of the National Institute of Medical Research, to supply me with curarine in pure form. This is the alkaloid responsible for the classical action of curare in paralysing muscular activity.

During the past eighteen months the action of curarine on animals and on man has been under full investigation. There is one condition—that of severe tetanus poisoning—in which not only may curarine be an effective weapon therapeutically, but in which the drug may have to be given in large dosage. During the past year Dr. Leslie Cole of Cambridge has recorded his impression that crude curare, given in small doses, may assist cases of tetanus.¹ The advent of curarine has increased the possibility of large, accurate, and safe dosage in severe cases of the disease. But if large doses are to be given a means of artificial respiration must be available in the event of serious weakening of the respiratory muscles. In a case in Oxford which I saw and treated last April (by courtesy of Dr. Mallam) I put the patient into a Drinker respirator. I think that the efficient and portable Bragg-Paul respirator would be the present choice.

From time to time cases of tetanus, with symptoms arising within three or four days of infection, are such that a fatal prognosis can be made with little hope of error. I think curarine combined with artificial respiration may possibly save life in some of these cases. If any of your readers can assist me to see and treat such a patient I shall be most grateful. I can reach cases within 100 miles of London or Oxford within a few hours of word being received at either of the following addresses: University Department of Pharmacology, South Parks Road, Oxford (tel. 3562); Dreadnought Hospital, London, S.E.10 (tel. Greenwich 1881). I shall have with me all the apparatus necessary for treatment, which can be undertaken in either a hospital or a private house.

It should be emphasized that this treatment is still at an experimental stage. Supplies of curarine are limited, the drug requires very cautious handling, and large dosage is only safe in experienced hands and only justified in severe cases.—I am, etc.,

Oxford, Dec. 15th.

RANYARD WEST.

Dangers of the Glass Catheter

SIR.—The following recent experience prompts me to bawail the continued existence of the glass catheter.

On December 1st a district nurse was catheterizing a woman of 46 who had had the misfortune to suffer a transection of the spinal cord twelve years before, and had since suffered from retention of urine which required instrumental relief. On this day, as the glass catheter was being withdrawn, it snapped, and a large portion was left in the bladder. The patient was admitted as an emergency to the surgical unit. Even with wide dilatation of the urethra and the use of the cystoscope it was impossible to withdraw the glass fragment through the urethra, and suprapubic cystostomy was carried out to accomplish this.

We are all acquainted with the dangers of the Higginson syringe and its hard nozzle for enemata, and in the majority of hospitals its use is rightly forbidden: should not the glass catheter be rigorously excluded also? A rubber catheter suffices in most cases; instances of special difficulty are surely dealt with more safely by a gum elastic or silver catheter than by the glass weapon. Can we not persuade all to abandon it?—I am, etc.,

A. L. D'ABREU,

Cardiff, Dec. 7th.

School of Medicine.

Physical Efficiency after Operations for Hernia

SIR.—In an article on the above subject published in your issue of November 17th I drew attention to the high incidence of recurrence in those policemen upon whom a double operation had been carried out at one sitting. Evidence in proof of this being a common experience was given by quotations from several large series of figures. My attention has been drawn to an omission in relation to this subject in the article in question, which in effect amounts to a misstatement. On page 898, in the first column, line 38, occurs the sentence: "In the forty-seven cases of recurrence bilateral hernia had been present and was operated on at one sitting." This reads as though all the recurrences had been observed in men in whom a double hernia had been operated on at one sitting. This is not the case. In the group of 206 policemen examined fifteen had had a double operation at one sitting, and a recurrence was noted as appearing later in eight of these. I should be glad if you would publish this correction. I do not think that the increased tendency to recurrence which has been proved after the double operation in one sitting is common knowledge. The cause of the tendency does not appear to be quite clear, but there is no doubt of its existence if any credit is to be given to statistical evidence.—I am, etc.,

London, W 1, Dec. 12th.

C. MAX PAGE.

Corpus Luteum Extract and Uterine Contraction

SIR.—A recent communication by Dr. Chassar Moir, read before the Edinburgh Obstetrical Society and reported in the *Edinburgh Medical Journal* (August, 1934), impels me to raise, through your columns, a pertinent point which ought not to go unmentioned—especially as it bears upon an apparent discrepancy between his clear-cut results and the equally clear-cut results of Professor Knaus of Graz, whose work is now widely accepted the world over. Moreover, Dr. Moir's results challenge experimental data of Dr. Willard Allen and myself, obtained under controlled experimental conditions in the unanaes-

thetized rabbit, in which we showed that potent extracts of corpora lutea exert a powerful *inhibiting* influence upon uterine contractions (*Amer. Journ. Physiol.*, 1932, cii, 39). Recent unpublished data show that crystalline progesterin is endowed with this property, 0.2 mg. being sufficient to inhibit maximal oestrin-induced contractions in five hours.

It is surprising, therefore, to learn that Dr. Moir finds evidence of spontaneous uterine contractions during the latter part of the menstrual cycle, concurrent with the existence of a corpus luteum. In the light of controlled experimental data, this circumstance should, I feel, induce one to look for other than hormonal factors as a cause of the discrepancy, and I submit, on the basis of Schultze's findings (*Zentralbl. f. Gynäk.*, 1931, xlii, 3042), that the results of this investigator as well as of Moir are explicable on the basis of purely local intrauterine factors. Schultze found that in the early interval the uterus is so irritable that it does not retain well the lipiodol which is placed in the uterine cavity, but passes it up the tubes. Later, after the mid-interval, the uterus is so sluggish that it becomes well distended with the oil. The *necessary physiological consequence* of this is that if contractions occur spontaneously, or if they be induced by sudden distension (mechanical, Schultze) or chemical (Moir) means, the length of the muscle fibres of the uterus is so increased and the intrinsic irritability of the tissue so altered that relatively feeble contractions give a net recorded effect of considerable magnitude. From this point of view the conditions in the latter phase of the cycle are not dissimilar from what one finds in the expulsive capability of a compensated heart. I have recently witnessed an example of this. After injection into a rabbit of 0.6 mg. of crystalline progesterin, which dosage in more than a dozen other rabbits effected *inhibition of motility* within two hours, the rhythmic contractions nevertheless continued with increased force and a progressive loss of tone, so that after four hours the contractions exceeded the *pre-injection motility* by more than 200 per cent.! At the end of this time, when the experiment was terminated, it was found that the balloon had become weakened on one side, giving rise to an aneurysm. As a result its capacity was increased at least fivefold. It is evident, therefore, that the hormonal influence of the progesterin was completely overridden by alterations in the *physical relationship* of the uterus to the recording system.

It seems possible, then, that a relatively high degree of tone in the early interval should minimize the possibility of intrauterine distension, and so reduce appreciably the contractions recorded at this time. This is what Dr. Chassar Moir has found. On purely physiological grounds the converse may be said to hold true while there is low tone associated with the corpus luteum, as Schultze reports.

In conclusion, I should like to refer to Dr. Pompen's excellent work (Amsterdam, Thesis, 1933), in which he shows that the action of oestrin on uterine muscle is to *co-ordinate* the otherwise uncoordinated contractions over the whole surface of the uterus. The result of this action is to induce rhythmic contractions, as I had found previously (*Amer. Journ. Physiol.*, 1931, xcvi, 706). It would appear then that the effect of progesterin is not to render the uterus *quiescent*, as I had suggested, but rather to render *uncoordinated* the rhythmic character of oestrin-sustained contractions of the uterine fistula in unanaesthetized rabbits.—I am, etc.,

SAMUEL R. M. REYNOLDS, A.M., Ph.D.,
Assistant Professor of Physiology, Llag
Island College of Medicine.

Brocklyn, Nov. 22nd.

Radiography and Pelvimetry

SIR,—I am delighted to read in your report (*Journal*, December 1st, p. 1009) of the Sections of Epidemiology and of Obstetrics of the Royal Society of Medicine that it falls to the lot of a general practitioner, Dr. T. J. Hollins, to call attention to the importance of radiographic methods in the accurate determination of the internal measurements of the pelvis. He held that "x rays should be used in all cases of primiparae, and in those cases of multiparae in which there had been trouble in a previous confinement." This exactly expresses my views, which I have held for a number of years now. In a paper I gave before the Section of Radiology at the Centenary Meeting of the British Medical Association, held in London in July, 1932, my opening paragraph was: "Every woman should have her pelvic measurements, accurately determined by radiography, engraved on the inside of her wedding-ring."

As pointed out by Dr. P. Hogan in the *Journal* of December 8th (p. 1076), "It is the minor grades of contracted pelvis which constitute the bugbear." Now it is just in these cases that radiography is so valuable, as the various diameters can be determined to a sixteenth of an inch if a proper technique, and a focus-film distance of at least four and a half feet, are used. Anyone interested can find the method I employ described in my paper published in the *British Journal of Radiology* of September, 1931. In this paper I also stated that

"It is universally recognized that accurate pelvimetry is of the utmost importance in obstetrics, and as the minor degrees of contraction are the more difficult to gauge by the ordinary clinical methods, the radiographic method should come into more general use, especially as it causes no discomfort to the patient. I believe that if radiographic pelvimetry were universally employed, maternal mortality, and even more so maternal morbidity, might be considerably reduced. In a national maternity service the cost would not be very great, as it is only necessary for it to be done once in a woman's lifetime."

In Leeds there are about 2,000 primiparae a year, and I consider that the total cost would not exceed one pound per head. I have been in communication with the Ministry of Health and the local medical officer of health concerning this matter, but up to the present no move has been made. I think it is a matter that might well be tried out in one large town for two years, and the effect be watched on the maternal death rate.—I am, etc.,

Leeds, Dec. 10th.

LEO A. ROWDEN.

Should Pelvimetry be Abolished?

SIR,—Mr. Aleck Bourne's letter on this subject raises issues of deep interest to all engaged in maternity work, and in it he asks his readers four questions. The first two are answered very perfectly and very adequately in Professor DeLee's *Principles and Practice of Obstetrics*, which reached its fourth edition ten years ago and may by now be regarded as common knowledge.

It is only with the third and fourth questions that I am concerned, and they may conveniently be taken together. Does the size and (although he does not say so, presumably it is to be included) the shape of the pelvis have much influence on the labour, and what is its importance? This, I admit, begs the question of what a normal labour is, and while no one has yet been able to define this, the gynaecological wards of the hospitals testify to what it is not. I think it will be agreed that a normal labour ought not to leave a woman on the waiting lists of a gynaecological department. In the year 1930 16 per cent. of the admissions to the Chelsea Hospital for Women were the immediate results of childbirth.

Mr. Bourne argues that "Holland and others" have shown that the vast majority of inductions of premature

labour (for contracted pelvis) are unnecessary. I make no comment on Mr. Holland's views and work, but has Mr. Bourne, I wonder, momentarily forgotten that the "and others" regard a prophylactic version in a breech case as also unnecessary, albeit a foetal mortality of 20 per cent. or more may be attendant upon it? Admittedly this necessitates some definition of what is to be regarded as "necessary." Naturally one is loath to refer to one's own work, and mention is made of it only because I do perform a good many inductions of premature labour for disproportion. As adviser, for the last eight years, to the Ilford borough I have been responsible for (in round figures) 500 deliveries a year in its maternity home, and in the last ten years the maternal mortality rate has been 0.74 per 1,000 live births (approximately one-sixth of the figure for the country as a whole). I admit that 4,000 births (in round figures) is a very small number, but I think it is enough to decide whether the methods employed are sound and safe or the reverse. I personally regard the introduction of a bougie three weeks in advance of term and the subsequent spontaneous delivery as preferable to a difficult forceps delivery at the end of many hours of labour, accompanied by a tearing of all the vaginal tissues off the ischial spines, a perineotomy perhaps as the alternative to a considerable perineal laceration, damage to the pelvic fascias and the resulting prolapse, and a foetus with intracranial haemorrhage or cerebral oedema.

In every walk of life the prudent leave a reasonable margin of safety, and it is here, I think, that Mr. Bourne answers his own questions (3 and 4). The estimate of disproportion is not, in the present state of knowledge, an exact science (even with the aid of radiology), and a reasonable working margin of safety must be allowed. Mr. Bourne is a most prudent mariner, and he would not put to sea without a spare sail in his sail locker, nor a few spare rations in the galley, nor would he regard them as unnecessary if at the end of a cruise they had not been used. I refuse to believe that he would conduct cases of labour (in which the risks are far greater) without using all the aids that civilization has to offer—including the pelvimeter—coupled with a little margin of reserve to compensate for deflection, uterine inertia, or a failure of moulding to occur. In conclusion, I submit that except in the more extreme degrees, it can never be established that an induction was unnecessary, nor the use of an instrument—even in its reversed position (when it is a little more accurate than a knuckle).—I am, etc.,

London, W.1, Dec. 12th.

EVERARD WILLIAMS.

SIR,—I am glad to see that so well known an expert in obstetric matters as Mr. Aleck Bourne has exposed the fallacy of pelvimetric measurements. As medical officer of a small ante-natal centre I have to perform these as a routine, but for some years have placed no reliance on them, for the simple reason that in numbers of cases with small measurements there has not been the slightest difficulty in labour, even with primiparae, whereas many with quite normal measurements have been found to have diminished internal conjugates or other signs of contraction. The only reliable tests I find to be the Munro Kerr method and the diminished internal (true) conjugate, as estimated with the left hand inserted into the vagina. Since this naturally involves an internal manipulation, I confine it to primiparae and those multiparae with a history of difficult labour. Obviously it is absurd to measure a woman who has already borne an 8 lb. child without difficulty for bony contraction of the pelvis.—I am, etc.,

Ryde, Isle of Wight, Dec. 15th.

L. FIRMAN-EDWARDS.

Ante-natal Care and Maternal Mortality

SIR,—May I suggest that the fault in the lack of results from our increased services, both private and public, may lie at the door of the patients themselves? I heartily agree with Dr. G. S. Swan (December 8th, p. 1074) in his outline of the ante-natal care and subsequent treatment necessary in every case; but does he find that all patients willingly submit to it? For the poorer classes he and others will agree that the clinic, followed by the midwife—plus the general practitioner (if necessary) and the hospital in special cases—must take the place of private consultations and attention, because the busy general practitioner cannot be expected to give a very great deal of time and work when no adequate payment can possibly be made. There is, then, a proved necessity for exceptional attention, whether given privately or free.

Now in either group (and I work in both) my personal experience is that it is very difficult to give really efficient ante-natal care except in a minority of cases. I find that the majority of women have not yet been educated to the importance of this branch of preventive medicine. We get a minority of sensible helpful mothers who submit to a proper course of care, and we get those who have had a fright in a previous pregnancy or in that of a relative, and those who develop some pathological condition which drives them to us; but the majority are not helpful. Continually I ask mothers of new babies why they did not come to the ante-natal clinic, and they say, "I felt all right," or "I didn't like to come." Of course, my experience may be unique; but if it is not then I must conclude that we have failed to reach the public.

Not only is there lack of co-operation by the women themselves, but there is lack of co-operation between the general practitioners and the medical officers of the clinics (here I refer to the poorer classes). If there existed a sympathetic understanding among the existing services much more might be achieved.

I would suggest, with regard to the education of the masses, that the powers that be might set afoot an advertising campaign in which our best brains and most persuasive tongues might be used to educate the mothers of Britain at meetings for mothers, and instil into them the importance of ante-natal care from the earliest possible moment, and plead for their co-operation with the medical profession in its fight against the maternal mortality rate. Much education might be done (and is done where there are facilities) among the poorer sections of the community in mothercraft classes held in connexion with child welfare centres; but I do not propose to go into specified methods of training the maternal mind, but only to suggest the need of it.—I am, etc.,

Monk-eaton, Northumberland, JANE H. THOMPSON, M.B.
Dec. 10th

Mortality from Haematemesis in Peptic Ulcer

SIR,—We much appreciate Dr. Bulmer's letter (*Journal*, November 17th, 1934, p. 920) criticizing our paper on the prognosis of haematemesis (*Journal*, November 10th, p. 858), and apologize for omitting his figures.

We agree that it would have been an advantage if the cases had been considered aetiological, but in approaching our investigation from a purely clinical aspect we decided that it was impossible, in the vast majority of cases, to state definitely the cause of haematemesis on admission, and that therefore the majority of cases were treated symptomatically. We have endeavoured to bring our figures into line with Dr. Bulmer's, and have divided our fatal cases into aetiological groups according to post-

mortem findings. It will be seen that the majority of cases in both groups are peptic ulcers, and assuming that non-fatal cases have a similar aetiological incidence, our total mortality is not seriously influenced by cases other than peptic ulcers. Our investigation was undertaken because of the unsatisfactory state of the treatment of haematemesis. There is no general agreement on the method of treatment or on the total mortality.

Considering our "moderate" group of 230 cases, the total mortality was 6.3 per cent., which appears satisfactory, but in the "severe" group of 153 cases the total mortality is 45.1 per cent. We have analysed our fatal cases of haematemesis due to peptic ulcer, have studied the post-mortem appearance of the ulcers, and have discovered that in approximately 70 to 80 per cent. of the cases a definite bleeding vessel was found. From the appearance of the vessels these cases could not be expected to respond to medical treatment. This raises an important issue. Is the method of treatment for haematemesis as now generally employed correct, and should not surgical or new medical methods be considered, especially in the "severe" group cases?

The results are summarized in the tables below.

SUMMARY OF FATAL CASES

Moderate

	Deaths			Necropsies Performed
	Total	Male	Female	
Acute ulcers	1	0	1	1
Chronic ulcers	11	10	1	11
Total ulcers	12	10	2	12

Dec. 22, 1934]

CORRESPONDENCE

A Mental Hospital Clinic

SIR.—In the matter of the milder neuroses no specialist can or should take the place of the family physician, whose good sense and scientific training should enable him to set at their proper value such subtleties as pseudo-psychology, psycho-analysis, dream symbolism, etc. The able physician understands his patient in relation to his environment as no one else can, and should take steps when he deems it necessary so that his patient may be afforded suitable rest, care, and further investigation, if desirable, away from possibly disturbing home influences. For my part I consider the principal function of a mental clinic to be the provision of a simple method whereby the practitioner is enabled to obtain another opinion as to the suitability of his patient for treatment away from home, and whereby associated with the independent practitioner; where also he can keep in touch with his patient if he so desires, and resume treatment on discharge with a full knowledge of his patient's progress and of such investigations of the case as were undertaken during the stay in hospital.

The word "authority" seems to act like a red rag to a bull in the minds of certain persons. It is surely time some protest was made. Rebellion is being fostered—rity, evolutionary order, and restraint is being fostered—and now because a doctor in the position of a medical superintendent is too accustomed to order and precision he is said to be unsuitable to have charge of a mental clinic. Surely the contrary is the fact. There is order in all natural processes. Mental activity, like every other activity, is a result of physical processes, and disease or disordered function is not possible without some underlying physical basis. Insufficient stress—practically none, in fact—is laid on the factor of variable metabolism, although it should be the first consideration. Stress and strain of varying kind and degree acting on varying metabolism is the *fons et origo* of mental disorder. Molecular processes subserving cellular metabolism—such as the balance of ions obtaining in different tissues, and even different portions of the same tissue; the conditions subserving diffusibility and the influence of hormones thereon; the factors governing oxidation and reduction, intra- and extra-cellular; chemical mediators; the physiology of the neurone; and the effect of toxins—are paid little or no attention to.

There are no two stones alike, there are no two faces alike; how much more are there no two metabolisms alike! And each epoch of development has varying physical influences. Persons with innately a given nervous metabolism are naturally affected by a given strain or stimulus in a more serious manner than are more stable individuals, and, dependent on degree of strain relative to abnormality of metabolism, the chances of ultimate recovery will necessarily vary. But it must be borne in mind that the lesion is primarily physical, and one which urgently calls for investigation, care, rest, and medicinal treatment directed towards elimination of irritants, a normal balance of ions, and restoration of disordered metabolism.

The more the true nature of the pathology of neuroses is masked by the cloudy verbiage of a pseudo-psychology and by energies directed into wrong channels, the less positive progress will be made in the direction of real ascertainment. It is quite impossible for a mental clinic to function satisfactorily if not in immediate touch with a mental hospital well equipped for full physical investigation, and with an efficient staff experienced in the many and varied forms of mental disorder.—I am, etc.,

B. H. SHAW,
Medical Superintendent, County Mental
Hospital, Stafford.

December 10th.

SIR.—The letter of "Medical Superintendent" in your issue of December 8th (p. 1078) no doubt invites a reply. The choice of words used in the annotation appearing in the *Journal* might, I think, have been a little happier: it is hardly correct to say that the visiting psychiatrist conducts the clinic.

The St. Albans Nerve Clinic consists at present of a diagnostic and sorting out-patient clinic at the general hospital, and of a treatment and investigating clinic at the mental hospital, where, in addition to the psychiatrist, a psychologist and a psychiatric social worker are available for their particular duties in the clinic work. The medical superintendent directs all these activities, and personally acts as diagnostic physician at the general hospital as a member of the honorary staff. The visiting psychiatrist undertakes the treatment of those cases which are selected, after a preliminary investigation of the case and after considering reports by the psychologist and psychiatric social worker at a conference at which they are present with the psychiatrist and the medical superintendent. Cases while under treatment may again become the subject of a conference, and will certainly become so before final disposal.

The visiting psychiatrist, it will be seen, is largely concerned with the psychotherapeutic treatment of the patient, but his activities cover more than this, so that it belittles the position to designate the practitioner as merely a psychotherapist. One of the reasons why a number of good men are lost to the service is, I believe, that there are no openings for them in it where they may confine themselves as specialists to the practice of their speciality, but as they become senior they are forced to accept administrative duties for which they may have little taste and for which they may be ill fitted. An appointment as a psychiatrist, not necessarily visiting but possibly whole-time, on some such lines as I have set out may well be a means of retaining the valuable services of such individuals and of enhancing the reputation of the service generally, so that it ill behoves anyone in the service to endeavour in any way to make the position appear less attractive.

There can be little doubt that a medical superintendent cannot carry on unless he has adequate and reliable officers to undertake the purely lay administrative work, though he must devote time to keeping in touch with them, if he is taking part in the work of the clinic on the lines set out; has ward rounds twice weekly in the hospital (where recent admissions and recovering cases are seen in consultation with the medical officer in charge and the house-physicians); has to consider the psychological aspects of the psychiatric social worker's reports after home visits, etc.; has a certain number of patients' visitors to see; and has to undertake the statutory requirements of the Acts as regards statements after admission and re-certification of patients, all of which are essentially medical duties. Your correspondent has apparently overlooked the fact that "in-patients at Hill End attend this clinic."

Few psychologists will deny, I think, that a person undertaking psychotherapy as I understand it—that is, any form of analytic treatment and readjustment—though he might do so with success if responsible for maintaining the discipline of the institution in which is the patient (who so often, as is characteristic of neurotics and psychotics, is constantly out to find objections to the routine and secure special privileges), does so at a great disadvantage, and in some cases would find it impossible.—I am, etc.,

W. J. T. KIMBER, L.R.C.P., D.P.M.,
Medical Superintendent, Hill End
Hospital.

St Albans, Dec. 11th

Corporal Punishment

A Plea for the Exemption of Girls

SIR,—I would be grateful if you would publish the attached correspondence with a view to finding out what is the opinion of the profession on the question whether the caning of girls can be justified on medical grounds. —I am, etc.,

Wetherby, Yorks, Nov. 28th.

R. L. KITCHING.

SIR,

Inglewood, Wetherby, Yorkshire.
October 14th, 1934.

About nine months ago I submitted to the Board of Education some criticisms of Corporal Punishment Regulations which seemed to me to lead to the conclusion that the caning of girls in public elementary schools should be prohibited on medical grounds. The reply was to the effect that the general policy of the Board was to leave the question of corporal punishment to the discretion of the local education authorities, and that the Board "have no reason to apprehend any abuse of this discretion which could be remedied by regulation."

It seemed to me that the policy of the Board was unsound, for the reason that it left the medical question of the effect of caning on the health of the school girl for the decision of individual county medical officers. It seemed to me that, when a county council refers a question of this sort to the county M.O., it is not a personal opinion that is wanted. I submitted this point to the Ministry of Health, and suggested that what is wanted in such a case is the opinion of the appropriate department of the Ministry of Health; and I asked if I might have an opinion from the Ministry of Health on the risks of caning girls during the menstrual period. I was informed on behalf of the Minister of Health "that the matter is not one within his jurisdiction," and that my request should be addressed to your department. I beg to submit two points:

1. The Corporal Punishment Regulations make it clear that young children must not be caned, but there is nothing in the regulations to suggest that a girl may be too old to be caned. Surely, if it is necessary to make regulations to prevent men caning young children it is just as necessary to make a regulation to prevent the caning of those girls who have developed the physique of womanhood?

2. I submit that the paramount reason for prohibiting the caning of girls in any circumstances is that it is the only certain means by which caning during the menstrual period can be prevented. There are, I suggest, two objections to caning during menstruation that are indisputable: (i) It must happen that some of the girls who are caned are suffering severe menstrual pain at the time, so that the pain inflicted must be more severe than was intended, and therefore may be more severe than is safe. (ii) Some of the girls must be suffering menstrual nervous strain, and the added strain may be more than the girl can safely bear.

It is obvious that caning is a form of punishment which involves serious risks, but it may well be that in the case of boys the risks must be accepted. The point I would submit to the Medical Department is that the risks are so much greater in the case of girls that this method of punishment cannot be justified. I would be grateful if I might be informed of the opinion of your department on this point. If your department is not prepared to advise the total abolition of corporal punishment in the case of girls, would you consider the suggestion that caning should be authorized in their case only between the ages of 8 and 10? I would be glad to know whether your department would make this suggestion to the Board.

I have the honour to be, Sir,

Your obedient Servant,

R. L. KITCHING.

The Secretary, Medical Department,
Board of Education.

SIR,

Board of Education, Whitehall, S.W.1.
October 18th, 1934.

In reply to your letter of the 14th inst., I am directed to state that the Board are not satisfied that any alteration of policy with regard to corporal punishment is necessary. The Board's views in the matter are set out in the paragraph

on discipline contained in the *Handbook of Suggestions to Teachers* (paragraph 4, page 12). Copies of this publication may be purchased directly from H.M. Stationery Office, York Street, Manchester, or through any bookseller (price 2s. net).

I am, Sir, your obedient Servant,

D. DU B. DAVIDSON.

SIR,

November 3rd, 1934.

Please accept my thanks for your letter of October 18th. Corporal punishment is not mentioned in the paragraph to which you refer me, but it is stated that "some special arrangements for disciplinary purposes . . . are undoubtedly necessary in Mixed Schools . . . and in any large Mixed Schools the head teacher will do well to delegate a considerable measure of authority to one of the assistants of the other sex . . ."

I infer from this that it is the view of the Board that girls should not be caned by men. On the other hand the county councils, in their *Corporal Punishment Regulations*, give authority to head masters to cane girls. The suggestion I have made as a family doctor is that girls should not be caned at all by anyone.

I should not have presumed to make any suggestions to the Board of Education if I had not been convinced, first, that the family doctor has far better opportunities than anyone else for judging the effects of caning, and, secondly, that the suggestion I made would be supported by an overwhelming majority of family doctors, and probably of all doctors.

In view of the fact that the Board are not satisfied that any alteration of policy with regard to corporal punishment is necessary, I have no doubt that the right course for me is to raise the matter in one of the medical journals. I propose, therefore, if you have no objection, to send a copy of the letter I sent to the Medical Department, with your reply and this letter, to the *British Medical Journal*.

I have the honour to be, Sir,

Your obedient Servant,

R. L. KITCHING.

The Secretary, Board of
Education.

Board of Education, Whitehall, S.W.1.
November 27th, 1934.

SIR,

With reference to your letter of November 23rd, I am directed to state that the Board have no objection to your taking the action proposed in your letter of November 3rd.

I am, Sir, your obedient Servant,

D. DU B. DAVIDSON.

Cervical Erosion and Discharge

SIR,—The interesting letter of Dr. Agnes Savill in the *Journal* of December 8th (p. 1077) encourages me to add something in the nature of a warning to those interested and likely to practise the treatment of uterine sepsis by zinc or copper ionization.

My father, the late Dr. Samuel Sloan, author of *Electro-Therapy in Gynaecology*, who taught me and many others the technique of this treatment, emphasized two points: (1) the fact that the ions penetrate the mucous membrane, so that the treatment is specially useful in gonorrhoeal infections; (2) that when using a Sloan's copper electrode the current must be reversed at the end of the treatment for two or three minutes to loosen the electrode, which becomes adherent to the mucous membrane through coagulation of the albumin of the tissues. We experimented with newly killed beef and new-laid eggs, and the penetration of the CuCl_2 was very interesting to observe. With regard to (2), serious, dangerous bleeding may result if the current is not reversed for a sufficient time to loosen the electrode. I advise that the first treatment should consist of eight milliamperes for eight minutes. The current should be reversed for one or two minutes. The full dose

"Applied Human Biology"

experience also.

Ionization is contraindicated in tubal infections and in most cases of ovarian inflammation. Therefore the medical electrotherapist should work in co-operation with the surgical gynaecologist.—I am, etc.,

ELIZABETH SLOAN CHESSEY, M.D.

ELIZABETH SLOAN CHESSER, M.D.

The Duodenum and the Kirby Grip

SIR,—In connexion with the recent correspondence on the above subject, the two following cases may be of interest.

Case 1.—A girl, aged 2½, swallowed a Kirby grip two inches long. Examination showed it to be held up in the stomach for three weeks. At the first time, to the

who had had persistent pyrexia in the
 was found to be due to a Kirby grip in
 who introduced it she would not say. When removed
 found to be embedded in a calculus the size of an olive.

—I am, etc.,

LIONEL LANKESTER, M.B.

LIONEL LANKESTER, M.B.

Influenza and the War

otherwise in the past was a victim of influenza. I found a case that was a victim of influenza, but I doubt if it was due, and it appears to me that the statement is caused by the war is purely conjectural.

It is to be hoped that in the next epidemic (about 1948) we shall learn its relation to minor epidemics of "so-called" influenza, or whether there is a reservoir in other genera. Apropos of the latter possibility, in 1917 there was an epidemic among the horses and mules of the field ambulance in which I was serving similar to the virulent influenza in humans of the following year. An affected animal held its head in a dejected attitude and would not feed. There was a slight injection of the conjunctiva and a little mucus in the nostrils. The animal soon got down, never again rose voluntarily, and very soon could not be made to rise. Infected animals became dyspnoeic and died within one or two days. The veterinary surgeon would give no name to the disease. Post-mortem examination showed a slight bronchopneumonia along the anterior border of the lungs after natural death, but if shot before they started to "blow" the post-mortem findings were negative. Others, no doubt, had similar experience, and could probably tell of the extent to which this epidemic prevailed generally.—I am, etc.,

"INTERESTED."

DENCE.
 "Applied Human Biology"
 SIR,—I, too, consider the Norman Lockyer Lecture of
 Professor J. B. S. Haldane "provocative," but little
 more so than the last paragraph of your article about it
 (*Journal*, December 8th, p. 1054). To applaud his state-
 ment that, unless the present fertility rate greatly alters,
 the diminution of population will rapidly become cata-
 strophic is to flout those who contend that the diminution
 will bring a progressive increase of the average income,
 which will certainly raise the birth rate to a replacement
 level within a few decades (unless people have really lost
 the desire to have at least one child of each sex). To
 applaud his view as to the uselessness of sterilizing defec-
 tives is to flout the Brock Committee. To applaud his
 statement that there is no evidence that the children of
 the poorer classes are innately inferior to those of the
 richer classes is to flout the opinion often voiced, even in
 your own columns, that the higher birth rate in the
 poorest districts is dysgenic.—I am, etc.,

UNIVERSITY OF BRISTOL

The following candidate has been approved at the examination indicated:

FISKE, M.B., Ch.B.—*Part II:* R. A. Mathews (with second-class honours).

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council, held on December 14th, the following appointments were made: Mr. J. C. Anderson, F.R.C.S., Lecturer in Applied Anatomy and Demonstrator in Anatomy; Mr. A. W. Fawcett, F.R.C.S., Lecturer in Surgical Pathology; Dr. E. F. Skinner, F.R.C.P., Lecturer in Psychology in the Faculty of Medicine.

VICTORIA UNIVERSITY OF MANCHESTER

Mr. Philip Godlee has presented to Lister House (the University medical hostel) a silver flagon, formerly the property of the late Lord Lister. This flagon was given to Lord Lister by his colleagues on the occasion of his appointment as Regius Professor of Surgery at Glasgow in 1860.

UNIVERSITY OF EDINBURGH

A graduation ceremonial was held in the Upper Library Hall on December 14th, when the following degrees and diplomas were conferred:

M.D.—Captain K. V. R. Choudari, I.M.S. (*in absentia*), R. T. Cooke, J. L. Cowan, † J. S. Faulds, † J. R. Innes, R. Y. Keers, R. M. Macfarlane, † A. C. McMaster, † A. S. Paterson, † Susanne J. Patterson, H. B. Porteous, D. C. Sutton, B. N. V. Wase-Bailey, † B. Williams.

D.Sc. (*Faculty of Medicine*)—E. B. Hendry, Dorothea M. Mowat. M.B., Ch.B.—G. L. Birnie, J. H. Bowie, B. H. Charles, A. O. Coker, S. H. Gibbs, G. R. Gunn, W. S. Harvey, R. M. Hayes, K. I. W. Klenberg, G. C. E. Laing, T. Leontsinis, J. M. N. Lockie, H. H. Lockwood, I. Macpherson, H. R. Morris, G. B. Petrie, Johanna M. Peniar, R. E. Prichard, M. A. Rifat, L. V. Roberts, G. G. Robertson, Una R. Roy, H. L. R. Sargent, F. Schwartz, G. A. Scott, I. M. Scott, G. A. M. Smith, H. Watson, H. Kai-ge Wong.

DIPLOMA IN RADIOLOGY.—A. R. Cowan.

* Highly commended for thesis.

† Commended for thesis.

NATIONAL UNIVERSITY OF IRELAND

At a meeting of the Senate on December 6th, with the Chancellor, Mr. Eamon de Valera, in the chair, Dr. Denis J. Coffey was elected a Pro-Vice-Chancellor of the University for the period January 1st, 1935, to December 31st, 1936.

A report from the President of University College, Dublin, as representative of the University on the General Medical Council, was approved.

Professor Thomas Walsh was appointed representative of the University at the Royal Institute of Public Health Congress at Harrogate in June, 1935.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A Council meeting was held on December 13th, when the President, Sir Holburt Waring, was in the chair.

Mr. R. St. Leger Brackman was elected a member of the Court of Examiners in the vacancy caused by the retirement of Mr. Ernest W. Hey Groves.

Dr. A. J. E. Cave, Senior Demonstrator in Anatomy of University College, was appointed Assistant Conservator of the Museum.

The secretary reported that at the Primary Fellowship Examination, held in Melbourne recently, forty-five candidates were examined, of whom twenty-two were approved.

A Diploma of Membership was granted to Mr. Garthowen Williams.

Diplomas of Fellowship were granted to the following forty-three candidates:

A. D. W. Jones, G. E. G. Peirce, A. N. Jones, B. Chaudhuri, J. A. Pocock, J. C. Nicholson, R. H. Franklin, Muriel H. E. Long, J. S. Butcher, J. W. S. H. Lindahl, J. Scholten, P. C. Sanyal, A. J. B. Goldsmith, H. H. Langston, G. T. Du Toit, F. J. S. Gower, A. F. Goode, F. Radcliffe, S. C. Sugat, W. G. Gill, H. M. Williams, S. C. Misra, J. A. S. Marr, G. K. Mulki, G. Qvist, J. Hardman, S. Ramshaw, J. K. Elliott, A. W. Badenoch, J. J. Brownlee, W. H. Graham, W. R. Henderson, R. J. Katrak, Hilda M. Linford, W. S. McGrath, J. A. McLauchlan, G. H. Macnab, W. H. B. Magauran, J. A. Martinez, R. Nagendran, H. K. Pacey, E. A. Rowlands, H. I. Turnbull.

Licences in Dental Surgery were granted to forty-eight candidates.

Recognition of Hospitals

The Council agreed to recognize the following first list of hospitals with the posts specified for the six months' post of resident house-surgeon, or other responsible post in charge of general surgical patients in the wards of a general hospital required of candidates before admission to the Final Examination for the Fellowship:

Dreadnought Hospital, Greenwich, S.E.—(two house-surgeons); Hampstead General and North-West London Hospital—(two house-surgeons); Prince of Wales's Hospital, Tottenham, N.—(two senior house-surgeons); Royal Northern Hospital, Holloway, N.—(one resident medical officer and three house-surgeons); Royal United Hospital, Bath—(first and second house-surgeons); Blackburn and East Lancashire Royal Infirmary—(one resident surgical officer and two house-surgeons); Royal Victoria and West Hants Hospital, Bournemouth—(three house-surgeons); Royal Devon and Exeter Hospital—(two house-surgeons); Gloucestershire Royal Infirmary and Eye Institution—(one resident surgical officer and two house-surgeons); Huddersfield Royal Infirmary—(one resident surgical officer and three house-surgeons); Hull Royal Infirmary (one resident surgical officer and three house-surgeons); Leicester Royal Infirmary—(four house-surgeons); Norfolk and Norwich Hospital—(three house-surgeons); Nottingham General Hospital—(four house-surgeons); South Devon and East Cornwall Hospital, Plymouth—(one resident surgical officer and two house-surgeons); Royal Portsmouth Hospital—(one resident surgical officer and two house-surgeons); Bolton Royal Infirmary—(one resident surgical officer and one assistant resident surgical officer); Preston and County of Lancaster Queen Victoria Royal Infirmary—(three house-surgeons); Royal Berkshire Hospital, Reading—(two house-surgeons); Salford Royal Hospital—(one resident surgical officer and three house-surgeons); Worcester Royal Infirmary—(two house-surgeons).

Primary F.R.C.S. Examination in India

The first Primary Fellowship examination to be held in India will take place in Madras on Thursday, December 27th. About eighty candidates have entered their names. The examiners appointed by the College are Professor William Wright of the London Hospital Medical School (anatomy) and Professor John Mellanby of St. Thomas's Hospital Medical School (physiology). Mr. Horace H. Rew, the director of examinations of the College, is travelling with them to supervise the arrangements. The party, returning by air, should be back in England on January 14th, 1935.

The Services

DEATHS IN THE SERVICES

Surgeon Commander Stewart Russell Johnston, R.N., died in London on December 13th. He was educated at University College Hospital, and took the M.R.C.S., L.R.C.P. Lond. in 1916, joining the Navy immediately afterwards. He became surgeon lieutenant commander on October 24th, 1922, and surgeon commander on October 24th, 1928. He served during the war of 1914-18, and had gained the Sir Gilbert Blane medal.

Lieut.-Colonel Denham Francis Franklin, R.A.M.C. (ret.), died at Bournemouth on December 1st, aged 76. He was born on February 8th, 1858, and took the L.R.C.P. and S. at Edinburgh in 1879, also subsequently the F.R.C.S. Ed. in 1888, and the D.P.H. in the same year. Entering the Army as surgeon on July 21st, 1880, he became lieutenant-colonel after twenty years' service, and retired on April 12th, 1904. He served in the South African War in 1899-1900, and took part in operations in the Transvaal and Orange River Colonies, including the actions at Paardeberg, Poplar Grove, Pretoria, Johannesburg, and Rhenoster Kop, and received the Queen's medal with three clasps. He also rejoined on February 7th, 1915, for service in the war of 1914-18.

Obituary

ELEANOR DAVIES-COLLEY, M.D., F.R.C.S.

Senior Surgeon, South London Hospital for Women

We regret to announce the death, on December 10th at the age of 60 years, of Miss Eleanor Davies-Colley, who was the first medical woman to be admitted to the Fellowship of the Royal College of Surgeons of England.

The daughter of a distinguished Guy's Hospital surgeon, the late Mr. J. N. C. Davies-Colley, and sister of Mr. R. Davies-Colley, surgeon to Guy's, she received her medical education at the London School of Medicine for Women and at the Royal Free Hospital. Soon after qualification Miss Davies-Colley was appointed house-surgeon at the new Hospital for Women in Euston Road, and, subsequently, surgical registrar at the Royal Free Hospital. She graduated M.B., B.S. Lond. in 1907, proceeded

M.D. in 1910, and in the following year obtained the F.R.C.S. As senior surgeon to the South London Hospital for Women and senior obstetrician at the Elizabeth Garrett Anderson Hospital, Miss Davies-Colley was noted for her skillful and conscientious work.

Mrs. D. C. NASMYTH, M.D., writes from Boars Hill, Oxford:

In the passing of Eleanor Davies-Colley there has left us not only a brilliant surgeon but one of the finest characters I have ever known. No one could work with her or be her patient without the realization that here indeed was a real nobility of soul. I have known her in both capacities: was of her generation as a student at the Royal Free Hospital, had the honour to be her friend, and, later, her patient in two major operations. She was, as a student, a striking figure, tall and beautiful, but never exactly popular. Her ideals were too high and too uncompromising, her sincerity too stark, perhaps. An intolerance of anything but the best, whether in work or in character, a shy manner, do not make for popularity. There was no pose of superiority—in fact, under an immense reserve a great humility of mind. Her faults were but the defects of her qualities, and as a colleague and friend she ranked among the best. In both these capacities she lived and worked with Miss Chadburn, M.S., in Harley Street, and the loss to her is irreparable. She had private means. With a cultured appreciation of all forms of art and a great feeling for real beauty in her surroundings she might have led a very different life, but something drove her to renounce all this and to live a life of austerity and self-denial and continual hard work.

She started her medical career later than most students, having already spent some years in a cheap flat in East London studying the condition of the poor. As a student she seemed to have all the makings of a really fine physician, and so much personal nervousness and a certain delicacy of constitution that I doubted her success as a surgeon and did my best to persuade her to stick to medicine. But her heart was set on surgery, and she was right. She made a splendid surgeon, and the kindness and skill of her after-care made one feel that one was also in the hands of a great physician.

I do not write only of my own experience. Our paths diverged: hers to Harley Street, mine to G.P. work in

the provinces. But I have sent her many patients from all walks of life, and they all returned with the same feelings towards her. Her everlasting kindness to many humble patients, both in and out of hospital, will live in their hearts as a constant memorial. She was a great surgeon with all the sensitiveness, intuition, and sympathy of a good physician, and above all she was a great and honourable lady.

THEOBALD SMITH, M.D.

Director Emeritus, Department of Animal Pathology, Rockefeller Institute for Medical Research

The death of Dr. Theobald Smith in New York, at the age of 75 years, removes one of the great pioneers in veterinary and medical research of our time.

Born in Albany, N.Y., in 1859, he graduated at Cornell and the Albany Medical College (1883) and subsequently held the positions of director of the pathological laboratory of the Bureau of Animal Industry under the Department of Agriculture and professor of bacteriology in the Columbian University. It was during this fruitful period that, by a series of decisive experiments undertaken in collaboration with Kilborne (1893), he made the epoch-making discovery of the transmission of red water in cattle by ticks, and demonstrated the passage of infection through the ova of one generation of ticks to the next. This was the first occasion that a protozoal parasite of mammals was proved to be disseminated by the bite of a blood-sucking arthropod, and in point of time preceded Ross's better-known discovery of the transmission of bird malaria by the mosquito by five years. That this great event in the history of medicine attracted so little attention at the time must be ascribed to the fact that it concerned cattle rather than man. He also published important work on the aetiology of blackhead in turkeys, and as early as 1895 found that scurvy supervened if guinea-pigs were placed on a diet deficient in greenstuff: he was thus one of the first experimental workers in the field of deficiency diseases.

From 1895 to 1915 Dr. Theobald Smith was professor of comparative pathology at Harvard University, and during this second phase of his career made many original contributions to the subject of animal disease in relation to man. In 1898 he investigated the problem of differentiating the bovine and human types of *B. tuberculosis*, and in 1904, in a letter to Ehrlich, wrote the original description of classical anaphylactic shock in the guinea-pig—a syndrome still known as the "Theobald Smith phenomenon."

In 1907 he actively immunized guinea-pigs by the injection of a balanced mixture of diphtheria toxin and antitoxin, and two years later suggested that the method invited further tests as to its ultimate application to human beings, thus anticipating by several years the use of toxin-antitoxin mixtures later described by von Behring and Park.

From 1915 to 1929 Theobald Smith was occupied as director of the department of animal pathology of the Rockefeller Institute for Medical Research, and subsequently became director emeritus. His work in 1915 on milk as a vehicle responsible for the distribution of streptococcal sore throat attracted much attention, and in 1922 he made another discovery of basic significance by showing that natural maternal bacterial antibodies were excreted in the colostrum of the milk of cows, and that if the calves were deprived of this colostrum they invariably died of bacterial infection.

Dr. Theobald Smith was the recipient of honorary doctorates in many universities, and, among others, was an honorary member of the Danish Royal Academy and the Swedish Medical Society, and a foreign member of the French Academy of Sciences and the Royal Society

of London, which awarded him the Copley medal. Since 1907 he had been an honorary Fellow of the Royal Society of Tropical Medicine and Hygiene and was a recipient of the Manson medal in 1932. Other awards included the Mary Kingsley, Kober, Flattery, Trudeau, and Gerhard medals. Not the least satisfactory feature of the life of this brilliant and versatile experimentalist was the world-wide recognition of the value of his work during his later years.

ANDREW BAXTER, M.D., D.P.H.

We regret to announce the death on December 8th of Dr. Andrew Baxter of Alderley Edge, Cheshire. After studying medicine at the University of Aberdeen he graduated M.B., C.M. in 1892, and proceeded M.D. five years later. In 1909 he obtained the D.P.H. of Manchester University. During the war he served as Lieut.-Colonel R.A.M.C.(T.) commanding the 2/2 East Lancs Field Ambulance, and was twice mentioned in dispatches. Dr. Baxter had been a member of the British Medical Association for the past thirty-four years.

We are indebted to Mr. WARWICK DEEPING for the following appreciation:

My friendship with Andrew Baxter began during the war. When I joined him in the 2/2 East Lancs Field Ambulance I realized that I should be serving under a very great gentleman. The war may have destroyed many illusions, but it gave us other realities, and to me my friendship with Andrew Baxter was one of them. He was the most lovable man I have ever met. I never knew him do a mean thing. He was so essentially human and so wise that he could be magnanimous and generous even under the stress of danger and difficulty. He could laugh and he could be angry, but always there was a clean rightness in his anger. It was easy for me to understand how the man I knew in the war was in peace the beloved physician. He understood so much, had such kindness. And he loved his work. He was essentially a healer. In my very last letter to him I said that if one was sick he would be one of the few people who would be more than welcome at one's bedside. This is but a small personal tribute to a man who was universally loved, and who was, as another friend says, "One of the finest types of general practitioner it will ever be our lot to know."

S. B. FENN, L.R.C.P. AND S.ED.

The death of Dr. Samuel Backwell Fenn, at the age of 71, took place in a nursing home in Southport on December 1st. He was taken ill only a few days before at his house in Settle, Yorkshire, to which he retired a few years ago. Dr. Fenn took the L.R.C.P. and S.Ed. in 1885, and shortly after went to Madagascar, where he had charge of the large medical mission hospital under the Society of Friends, and made a valuable contribution to the work there in training Malagasy medical students. After seven years he resigned this work, owing to the ill-health of Mrs. Fenn, and settled in Southport, where he built up a large general practice during thirty-three years—a proof of his devotion to his patients, whose interests he assiduously studied. He was prominent in the work of the Order of St. John of Jerusalem, as a lecturer and in forming the first nursing division in Southport. He was an honorary life member of the association and an officer of the Order. During the war Dr. Fenn took an active part in the formation and conduct of Great Britain's largest voluntary hospital, which was under the auspices of St. John in Southport. He was medical officer to the Southport Hydropathic Hospital, a branch of work that keenly interested him. He was a past president of the Southport Medical Society and in 1921 was chairman of the local Division of the British Medical Association, of which he had been a member for forty-six years. Apart from

his profession, Dr. Fenn took an active share in religious and philanthropic work. He was a wide general reader, a Fellow of the Royal Geographical Society, and a very fluent speaker and lecturer in several languages. He is survived by a daughter and three sons.

Dr. W. W. SHRUBSHALL (Burgess Hill) writes: I have no doubt others will write of the late Dr. S. Backwell Fenn's professional life; may I crave a small space for appreciation of his character and friendship? Dating back to 1883, our acquaintance continued from Edinburgh student days to his death, and though he was in Madagascar and I in the Far East for several years correspondence kept us in touch, and return to England again brought us to closer friendship. Fenn did not "wear his heart on his sleeve," but week-ends spent together in the then charming village of Aberdour on the Forth, walking tours in the Highlands, mountain climbing in Switzerland, and the domestic life of his home, revealed in heart-to-heart talks a manly character of high ideals, deep religious convictions, and a warmth of heart constantly expressed in kindly action. His friendship was firm and to be relied on, and none who experienced it can but have the sense of a very heavy loss now that he has gone.

Dr. HARRY SPURRIER died at the age of 59 at Benenden on December 8th. Born in 1876, and educated at St. Thomas's Hospital, he held several posts there after qualifying—these included casualty officer, house-physician, and obstetric house-physician. On leaving the hospital Dr. Spurrier settled in Maidenhead, where he soon built for himself a large practice. At the beginning of the war he succumbed to tuberculosis, and had to leave Maidenhead to undergo a long course of treatment, which, though it checked the disease, never enabled him to regain his full strength, and consequently prevented him from returning to general practice. Since that time Spurrier devoted his life to the treatment of tuberculosis, and held the appointment of senior assistant medical officer of the Middleton-in-Wharfedale Sanatorium. He was also at one time assistant medical officer to the Brompton Sanatorium, Frimley, and surgeon to the King Edward VII Hospital, Windsor. For the last thirteen years he had been medical superintendent of the National Sanatorium, Benenden. In spite of ill-health, which during the last few years had become steadily more marked, Spurrier never spared himself, and devoted all his energies to sanatorium work. He created a friendly atmosphere among the patients and staff, and made his sanatorium popular. He was always able to inspire hope, even in the most serious cases.

Dr. HUGH KERR, medical superintendent of the Bucks County Mental Hospital, died in a London nursing home on November 17th, after an illness lasting several months. An Ayrshire man, Dr. Kerr was educated at Glasgow University, where he took his M.A. He proceeded to study medicine, and graduated M.B., C.M. (commended) in 1892. His first appointment was that of A.M.O. at Abergavenny Mental Hospital. He stayed there until 1896, when he obtained a similar post at the Bucks County Mental Hospital. Three years later he took the Glasgow M.D. In 1908 he succeeded the late Dr. Humphry as medical superintendent—the committee offering it to him—and this appointment he held until shortly before his death. Dr. Kerr did much for the welfare of the hospital and its patients. Possessed of a quiet manner, he got through a lot of work without ostentation. He took interest in, and did much for, the welfare of the local village of Stone. He was a genial man, much liked, and very popular with the patients and staff of the hospital. He contributed several publications of interest to the medical journals. Dr. Kerr was a keen and prominent Freemason.

CORRIGENDUM

In the heading and first paragraph of Dr. R. F. Meigs-head's obituary (*Journal*, December 15th, p. 1130) he was erroneously described as secretary to the London Missionary Society. He actually held the post of medical secretary to the Baptist Missionary Society.

DEC. 22, 1934]

MEDICAL NOTES IN PARLIAMENT

THE BRITISH
MEDICAL JOURNAL 1183

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

In the House of Lords on December 17th Viscount ELIBANK moved that the Select Committee to which the Registration and Regulation of Osteopaths Bill was committed should have leave to hear counsel for and against the Bill, and to examine witnesses on oath. He said the course he suggested would facilitate the proceedings of the Select Committee and be of advantage to it in reaching a proper solution of the question. The resolution was agreed to.

Sir Francis Fremantle and Dr. Salter are appointed to the Publications and Debates Committee of the House of Commons.

The Government hopes to circulate the Housing (Scotland) Bill during the Christmas recess.

The St. Bartholomew's Hospital Bill (Superannuation) Bill will originate in the House of Lords.

The Educational Endowments (Scotland) Bill has passed through Standing Committee and was reported to the House of Commons with amendments on December 13th.

Health Services in India since 1921 Reforms

In the House of Commons, on December 10th, Sir SAMUEL HOARE moved a resolution to the effect that the House accepted the recommendations of the Joint Committee on Indian Constitutional Reform as a basis for the revision of the Indian Constitution, and considered it expedient that a Bill should be introduced on the general lines of the report. During the debate Mr. RAIKES referred to the manner in which the 1919 reforms had worked in regard to the welfare of the masses—the peasantry of India—and how the transferred Departments had worked. The money spent on education, he said, had gone up continuously in the last fifteen years, not to provide better education for the peasants, but secondary schools, colleges, and universities, into which the peasants never had a chance to go. No doubt the observation was brought before the Joint Select Committee that education had deteriorated in the villages. Turning to the medical services, he said that in almost every district of India criticisms were met not only of the amount of money spent on outwork and archaic Indian systems of medicine by the gentlemen who had taken charge, but of the fact that grants were made to the hospitals and colleges to provide those outwork systems of medicine which were simply producing the things that would have died out if Indian politicians had not debilitated matters. The peasant had to pay for that. It was also generally admitted that political wire-pulling was not unknown in the medical services since transfer. He put it no higher than that.

When the debate was continued on December 11th the DUCHESS OF ARHOLL spoke of the deterioration in the work of the local authorities in India and its prejudice to the welfare of the masses. She said an ex-director of public health had stated in a recent review that many local authorities had brought to an end the extension of schemes of drainage and water supply which had been steadily increasing before the reforms of 1921. In many cases, he said, they had got into such financial difficulties that they had not even been able to maintain the services of the kind which had been provided before. Let the House imagine what danger that meant to public health in a country such as India, with all its many epidemic diseases. An inspector-general of civil hospitals told the Joint Committee of grave deterioration in the health services due not merely to the deficiencies of local authorities but to the administration of the Minister himself and his constant interference in medical appointments. Most unsuitable men had been appointed. A professor of physiology was appointed, the Joint Committee was told, who admitted to the principal of a medical college that he had never lectured, never demonstrated, and had done no physiology since his student days. An ex-inspector-general of hospitals spoke of the thousands of eyes that were blinded every year in India through operations for cataract performed by unqualified quacks, who were trained in institutes which were now

receiving grants from public funds owing to the political pressure put on Ministers by provincial councils, which they had not been able to withstand. When they learned of facts such as those, was it not inevitable that members should feel that the greatest caution was necessary in giving further powers?

Miss RATHBONE asked the Secretary of State for India what was the position of the Women's Medical Service in the new arrangements, and was it not time that this service should be given a more stable and recognized position, possibly by setting it up as a definite branch of the Indian Medical Service? Since the women's service was already subsidized by the Government the change would not necessarily cost more money.

The resolution approving the recommendations of the Joint Select Committee was carried by 410 to 127.

Safety in Mines

Replying to Mr. David Davies, on December 11th, Mr. E. BROWN said he could not make any statement at present regarding the introduction of amending legislation to increase the safety of mine workers. A few months ago new regulations were made to secure improved lighting. Proposed regulations for the provision of fire-damp detectors were about to be published.

On December 11th Mr. FINKER asked the Secretary for Mines the name of the colliery where the ascertained depth was 3,800 feet and the temperature 103° dry bulb and 80° wet bulb. Mr. BROWN replied that these particulars applied to one district in the Arley Seam at Parsonage Colliery, Lancashire.

Punishment by Flogging

On the motion for the adjournment of the House of Commons, on December 11th, Mr. BERNAYS raised the question of the advisability of an inquiry into the punishment of flogging, which arose out of the case of the Dartmoor convict, Collins. Collins was condemned to twelve strokes with the "cat" and three years' penal servitude for an act of violence while trying to escape from Dartmoor prison, and he committed suicide in gaol on November 29th. Mr. Bernays stated that in a letter Collins left in his cell he said that he was being slowly murdered, and every night he was lashed with the "cat." His head was awful with all the worry, and he thought it might go back on him at any minute. He had tried to hide what was really the matter with him from the doctor, and did not tell him all. Mr. Bernays added that he was sure the officials at Dartmoor were humane men, and that nothing they did caused this terrible suffering. He asked for an inquiry to discover whether flogging was really a deterrent, whether it was not too brutally administered, and whether, if it was really necessary in the last resort, its use ought not to be more seriously restricted than at present. He called attention to a letter written to the *Daily Telegraph* on December 7th by a medical officer in a convict prison.

Mr. ISAAC FOOR said the evidence showed that the officials of the prison did all in their power in this case, and there certainly was no criticism of the medical officer. Mr. O'CONNOR said it was easy to work up hysteria. When he himself read the letter from the prison doctor which Mr. Bernays had quoted he thought that the doctor was making an unfair reflection on the men who had to perform the duty of flogging. He was sure, however, that the people who performed those sentences were scrupulously impersonal. Sir JOHN GILMOUR pointed out that, on the one hand, this form of punishment was ordered by the court after very careful consideration, and on the other, it could only take place after an inquiry by magistrates on the spot in the prison. It was subsequently brought to the Home Secretary, and it was on every occasion most carefully and meticulously supervised by the medical officer. If there was any doubt in the mind of the medical officer, his view was paramount in the matter, and, even when the punishment was being carried out, if there was the slightest sign that would lead the medical officer to suppose any serious and permanent injury was likely to be inflicted on the individual, on his word that punishment ceased, and was not continued. It was carried out with the greatest care and circumspection, and he trusted that the House would not ask for an inquiry of this kind.

The discussion then ended.

Disinfectant Mistaken for Shark Oil

In reply to Mr. Paling on December 12th, Sir PHILIP CUNLIFFE-LISTER said he regretted the occurrence by which doses of what was thought to be shark oil, which had been used with success at hospitals in Tanganyika as a substitute for cod-liver oil, were issued on the instructions of the head mistress, herself a doctor, to the native pupils at Malangali girls' school, Tanganyika. It had now been established that the liquid used was not shark oil, but some form of disinfectant resembling it in appearance but containing arsenic, with the result that all who had taken doses, including the head mistress herself, became ill, and thirty-five of the girls died. It was not yet known how the mistake occurred. Orders were issued immediately to every Government station and to all hospitals, tribal dressing stations, dispensaries, and mission stations to the effect that the use of shark's oil must be discontinued at once until after the matter had been investigated. The question of further action must depend on the investigation.

Working Conditions of Seamen

In the House of Commons, on December 14th, Dr. BURGIN moved the second reading of the British Shipping (Assistance) Bill.

Dr. ADDISON moved its rejection in a reasoned amendment, which regretted that the Bill was not accompanied by measures to ensure good working conditions on board ship. He remarked that Dr. Burgin had said nothing about the accommodation of the seamen. In 1906 a special committee of the Port of London Sanitary Authority specified nine conditions which should apply to accommodation aboard ship. These related to living quarters, ventilation, accommodation for food, and so forth. The only suggestion fully carried out was the provision about the cubic space per man. Two others, relating to a separate room for messing and to crews being berthed aft, were included in the standard ship which Lord MacLay encouraged. The rest of the provisions had not been adopted. Defective accommodation affected the health of the crews. The statistics of mortality issued by the Board of Trade in 1932 showed that 3,166 seamen died in that year. Only 642 were occupied seamen. Of the rest, 625 died within twelve months of leaving the service, 295 within three months of retirement. They left to die. Out of 3,000, 611 died from tuberculosis and other respiratory diseases. Parliament when giving a subsidy of £10,000,000 for building more ships was entitled to secure that men were not subject to accommodation which gave such results.

Mr. RUNCIMAN, in reply, cited the same report of 1932 on mortality in the mercantile marine as saying that "apart from drowning and injury, service in the mercantile marine is no more inimical to life and health than are many occupations ashore frequently regarded as healthful. Dr. Addison said the statistics showed large numbers of men retired from the service to die. Mr. Runciman stated that the report already cited declared that each such case required to be decided on its merits. He himself was anxious that seamen should have good ships in which to work. Employment of foreign seamen was largely a matter of climate, and to substitute white labour for lascar labour would be an expenditure in human life and health.

The Bill was read a second time by 384 to 121.

Boarding-out of Mental Patients.—Sir HILTON YOUNG told Dr. O'Donovan, on December 5th, that the boarding-out of rate-aided mental patients was receiving the attention of the Board of Control, particularly in view of schemes which were being put into operation experimentally by certain local authorities. The practice in England could not be accurately compared with that in Scotland, where conditions and the statutory provisions differed.

Corporal Punishment.—Sir JOHN GILMOUR told Mr. Bernays, on December 6th, that the experience of the prison medical authorities afforded no ground for the suggestion that corporal punishment was liable to result in serious physical injury. A prisoner had seldom to be admitted to hospital at all after undergoing such punishment. He knew of only one recent case in which a prisoner's suicide was attributable to the prospect of corporal punishment. He could not regard this case as furnishing grounds for an inquiry into the question.

Small-pox Isolation in India.—Sir SAMUEL HOARE told Mr. Groves, on December 6th, that the treatment of small-pox cases in isolation hospitals in India was rare, and, so far as he knew, was nowhere compulsory. The number of small-pox patients so treated in British India during the years 1928 to 1932 was: 1928, 3,784; 1929, 1,542; 1930, 2,126; 1931, 1,350; 1932, 4,493.

Model Diets for School Children.—On December 10th Mr. SALT asked whether, to avoid malnutrition in children of school age, the Minister of Health would consider drawing up and publication of model diets, to serve as a guide to parents. Mr. SHAKESPEARE said the preparation of diet schedules was a matter in which account had to be taken of local food customs and other circumstances. It would be impracticable to produce any schedule of universal application. Most of the information required for the construction of suitable diets for any groups of persons would be found in the published reports on the "Criticism and Improvement of Diets" and on "Diets in Poor Law Children's Homes," by the Advisory Committee on Nutrition, appointed by the Minister of Health.

Methylated Spirit Drinking in Scotland.—On December 11th Miss HORSBROUGH asked which local authorities in Scotland had reiterated their appeals for further regulations to deal with the drinking of methylated spirits. Sir GODFREY COLLINS said that he had received a representation on the subject from a conference of the burghs of Aberdeen, Clydebank, Edinburgh, Falkirk, Glasgow, Greenock, Inverness, Paisley, Perth, and Stirling. He was willing to receive a deputation at an early date.

Stone-dust on Colliery Roads.—Mr. ERNEST BROWN, replying to Mr. Tinker on December 11th, said that the stone-dusting of colliery roadways had been enforced for nearly fourteen years. He had no evidence that the practice had been injurious to health. The suitability of the dusts used was constantly watched by H.M. inspectors of mines, and steps were taken to prevent the use of unsuitable materials. If Mr. Tinker would give him particulars of cases where harmful effects were alleged he would have them investigated.

Improved Conditions in Hopfields.—Mr. SHAKESPEARE, on December 11th, informed Mr. Todd that the conditions found by the medical officer of the Ministry of Health who visited Worcestershire and Herefordshire during the recent hop-picking season showed noticeable improvement compared with the conditions found on the last occasion on which the areas in question were visited. There were still matters which the Minister proposed to bring to the notice of the responsible local authorities.

Thefts from Doctors' Cars.—On December 12th Mr. THORNTON asked whether Sir John Gilmour was aware of the increase of thefts from unattended cars of doctors' bags containing drugs, and if he intended taking any action in the matter. Sir JOHN GILMOUR replied that there had been a few such thefts, but he had no grounds for thinking that they were other than ordinary cases of petty larceny. He did not think there was any action he could usefully take in the matter. The remedy was for medical practitioners and others who had drugs in their possession to take reasonable steps to avoid the risk of their being stolen. He hoped the publicity now given to the matter would lead to greater care being taken.

Public Health in Sunderland and Seaham.—Replying to Mr. Storey on December 13th, Sir HILTON YOUNG said the statements concerning public health in Sunderland and Seaham, contained in a letter signed by Dr. G. F. Walker of Sunderland, and which had appeared in the Press, required investigation. The President of the Board of Education and he had jointly instructed qualified officers of the Board of Education and Ministry of Health to visit this area for that purpose. He had also communicated with the local health authorities concerned, and with Dr. Walker, asking the latter to put all his information at the disposal of the officers.

Removal of Mother after Childbirth.—Sir HILTON YOUNG told Mr. Macmillan on December 13th that the commissioners inquiring into the death of Mrs. Molly Taylor of Manchester had suggested a minimum, not a standard, in stating that at least an hour should elapse before the transfer of a newly confined mother to an ambulance unless the doctor in charge decided otherwise. It was highly desirable that a longer period than one hour should elapse before the removal of a maternity patient after delivery.

Medical News

The Food Education Society has arranged a symposium on "Problems of School and University Diet" at University College, Gower Street, W.C., on Tuesday, January 1st, at 11 a.m., when the speakers will include Dr. G. E. Friend.

The British Red Cross Society will hold a course of seven lectures and demonstrations on tropical hygiene, on Mondays, Wednesdays, and Fridays, commencing on January 4th, at 9, Chesham Street, Belgrave Square, S.W.1, at 5.30 p.m. The course will cover such questions as food, clothing, and medical and sanitary precautions necessary for health in hot countries. The examination for the society's certificate in tropical hygiene will be held on January 21st. Fees for the course are 5s. for members of the Red Cross Society and 7s. 6d. for non-members.

The twenty-fifth annual exhibition of scientific instruments and apparatus arranged by the Physical Society will be held at the Imperial College of Science and Technology, South Kensington, on January 1st, 2nd, and 3rd, 1935.

The Colyer prize was founded in June, 1926, to commemorate the twenty-five years' service of Sir Frank Colyer as honorary curator of the Odontological Museum. The accumulated income of this fund may be used every third year for the purpose of awarding a prize for the best original work in dental science completed during the previous five years by a dental surgeon educated at any duly recognized dental school in Great Britain or Northern Ireland who has not been qualified to practise more than five years at the date of the award. Applications from candidates for the second award (to be made in July, 1935) should be submitted to the Royal Society of Medicine, 1, Wimpole Street, W.1, not later than March 31st, 1935, together with a general account of their researches, both completed and in progress. A document declaratory of the award will be presented with the prize. If no work of sufficient merit be submitted the prize will not be awarded.

The fifteenth medical salon for the exhibition of works of art by doctors, dentists, pharmacists, and veterinarians will be held at the Galerie des Beaux Arts, 140, Faubourg Saint-Honoré, Paris, from January 17th to February 3rd, 1935. A section of photographic art will be a new feature of the exhibition. Further information can be obtained from the organizing secretary, P. B. Malet, 46, Rue Lecourbe, Paris XV.

The 150th year of the Vienna General Hospitals will be celebrated next year. On May 18th the Chancellor will unveil a memorial to the first director of these institutions—Johann Peter Frank—and Professor Wagner-Jauregg will deliver the official address. From May 13th to 25th will be held a series of medical celebrations, festivities, and meetings of societies. In the mornings there will be the sessions of the fifty-fifth international post-graduate course of the Vienna Medical Faculty, and in the afternoons speeches will be given by the leading members of the profession in that city and elsewhere. In the afternoons also there will be visits to places of medical interest in the city and its environs. A medico-historical exhibition will be on view in the Natural History Museum, where there will be displayed illustrations of the growth in medical technique and the development of the great pharmaceutical industry, giving some conception of the range of the discoveries that have been made. The evenings will be given over to banquets, receptions, and performances in the State theatres. Detailed information can now be obtained free from the offices of the Vienna Medical Faculty, Alserstrasse 4, Vienna IX.

The tenth International Congress of the History of Medicine will be held at Madrid from September 23rd to 29th, 1935, under the presidency of Professor Gregor Marañón.

Laws relating to sterilization resembling in their essential points the German law on the prevention of morbid offspring have recently been passed in Norway and Sweden, and will come into force on January 1st, 1935.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Ailology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Post-Herpetic Pain

Dr. H. LEWIS-PHILIPPS (Whitland) writes: A male patient, 70 years old, had a very severe attack of shingles some five weeks ago. He developed a severe rash over the left chest, the left axilla, and over the upper and mid-thoracic region of the back. The rash has greatly improved, and all that now remains is a brownish staining of the skin. Pain is very severe, and comes on in spasms, lasting for a few minutes at a time. The following drugs have been tried: (1) an aspirin, phenacetin, and caffeine citrate mixture; (2) allonal; (3) phanodorm; (4) nepenthe and paraldehyde (at night for sleep); and (5) omnopon, grain 1/3 has had to be given once. Nepenthe seems to constipate him severely; paraldehyde suits him best, and he gets rest at night, but has to be given two drachm doses. He is a left-sided hemiplegic of some five years' standing, and some two years ago suffered from a fairly severe pyelitis, which has since cleared up. I should be grateful for any suggestions as to treatment and relief of the pain.

Aural Diphtheria

Dr. W. A. MAYNE (Taunton) writes: I was called to see a child because she had a cold. The nasal discharge being unilateral I took a swab. The mother had a slight sore throat, and so I took another swab. Both swabs were returned positive to diphtheria. I then found that another child had a long-standing discharge from one ear. I took a swab, and this, too, was returned positive to diphtheria. The father remains perfectly healthy. I have not before come across a case of aural diphtheria; and I wonder whether one should swab more frequently cases of aural discharge which do not clear up with ordinary treatment.

White and Brown Sugar

A CORRESPONDENT (London, S.W.) writes: Lest it should be thought that there is no satisfactory answer to the very pertinent questions about sugar asked by "A. F. S." in the *Journal* of November 17th (p. 928), may I be permitted to try my hand at a brief exposition of the situation? The substances intended for man's consumption—the proteins, carbohydrates, fats, vitamins, salts, and catalysts—are in Nature associated with each other and with other substances in such a way as to render them readily acceptable to the human economy. If, in his presumptuous ignorance, man tampers with these substances by cooking them, concentrating them, and refining them, he may retain the main proximate principle, but he deprives it of the associates which render it tolerable to the human digestive organs. If, for example, he concentrates a bison into a beaker he may get the major portion of the protein, but he will get very little else, save perchance a stomach-ache. That is an extreme case. That of sugar is almost as extreme, though not quite. Pure sugar ($C_6H_{12}O_{11}$) is a very irritating substance, as may be seen from the eczema which is so apt to trouble the hands and arms of grocers who handle it. In its natural state, as in the cane or in fruit, sugar is associated with various substances which dilute and mitigate

the irritant properties of the pure chemical. The reason why brown soft sugar is more digestible than the white is that the brown is much less refined than the white; the browner it is the cruder and the more digestible.

European Children in the Tropics

Dr. NICOL (Carshalton), in reply to Dr. James Gardner (*Journal*, December 1st, p. 1025), writes: Dutch women can stand the climate in Java no better than can English women. The first Dutch settlers married native women. Later settlers married, resulting in half- and quarter-casts. At present the "casts" approximating to European type are much sought after by thrifty Dutchmen as being wives who can stand the climate and produce children who can do the same. A Javanese half-cast woman of European type has a high opinion of herself, and rates herself equal to a white woman. This policy was encouraged by the Dutch Government, and is now reaping its own reward in the form of a mixed Dutch-Javanese population outnumbering the pure Dutch and only too anxious to govern itself. This problem is outside Dr. Gardner's inquiry, but I trust my explanation will be of help.

Dr. MAUD C. CAIRNEY writes from Bordighera: The Dutch women and children in Java and Sumatra struck me as looking healthier than their British neighbours in the Federated Malay States. They don't, however, stay in the coast towns all the year round, but go up for a change of climate to the excellent hill stations which are to be found at a height of 5,000 to 6,000 feet in both Java and Sumatra. In the F.M.S. the hill stations are lower and wetter, and the accommodation available cannot be compared with the efficiently run Dutch hotels. That difference alone has a lot to do with the maintenance or loss of health. Both in Java and Sumatra there are schools in these hill stations where children can be sent. The Dutch also live more comfortably than the British in Malaya when they are in the coast towns. Their houses are screened to keep out mosquitos, whereas in the F.M.S. screened houses are rare. They have a great variety of vegetables, grown on their hills, in Malaya it was impossible up to 1932, when I left, to get any variety in vegetables.

Solution of Bismuth Salts in Oil

"WANG" (London, S.E.20) writes: Bismuth sodium potassium tartrate is used for intramuscular injection in oil. The oil must be sterilized at 115° C. for a certain time. But how is this substance dissolved in the oil? It does not dissolve hot, cold, or ground in bit by bit. Is there any book which tells how it is dissolved? The injection is very painful when given in water.

LETTERS, NOTES, ETC.

Antitoxin for Puerperal Sepsis

Dr. HENRY J. THOMSON (physician-superintendent, County Maternity Hospital, Bellshill) writes: I have just observed that in Professor Munro Kerr's book, *Maternal Mortality and Morbidity*, 1933, the County Maternity Hospital, Bellshill, is referred to on page 226, stating that "masks and gloves as well as antitoxin are employed in Bellshill," and a footnote stating that an outbreak of sepsis occurred in this institution in 1932. These statements are not accurate, and may be misleading to those who desire to prove the usefulness of antitoxin. The first case of the epidemic occurred on November 4th, 1932, and the administration of antitoxin was suspended from September 7th of the same year. I shall be pleased if you will kindly allow space for this correction in your next issue.

The Microscope in Modern Life

The microscope slide has evidently not lost its fascination, even for a generation accustomed to spectacular displays in picture theatres. witness the queues of interested people who followed one another on a round of a hundred microscopes throughout last week at the Central Hall, Westminster. John Milton, in *Paradise Regained*, wrote of the fair children to be seen in the "acry microscope"—surely almost the first reference to the microscope in literature (1633)—and certainly in such an assemblage of instruments there were "fair children" in plenty, which it was hard to believe were only the spinneret or the spider or the plumed palpi of the gnat. The exhibition was designed to illustrate the value of the microscope in research and education, and its indispensable role in research and industry. The industrial applications are manifold, and the microscope plays an essential part in the production of most fair children, the testing of steels and the analysis of rocks. A section of the exhibition was given up to specimens of medical or bacteriological interest, such as

the small fibres of asbestos in the lung of a mine worker, a section of kidney showing anthrax infection, and so forth. The exhibition was arranged by Messrs. W. Watson and Sons, Ltd., assisted by the Quekett Microscopical Club—the largest amateur microscopical society in the world—the Photomicrographic Society, and Kodak Limited. For those interested in the microscope itself, apart from what it reveals, there were demonstrations of the methods of illumination and the manufacture of lenses.

Science and Religion

Dr. H. G. BAYNES (London, N.W.1) writes: The chorus of protest that has been aroused by Dr. David Forsyth's presidential address at the Psychiatric Section of the Royal Society of Medicine is not untimely. The psycho-analytical attack on religion can claim no kinship with the genuine spirit of scientific scepticism. It is a kind of fascism of the intellect that is shielded from its own doubts by a certain primitive naiveté. For primitive mentality is likewise peculiarly prone to assume that analogous things are, *ipso facto*, identical. The use of analogy in psychological investigation has exactly the same technical justification as the use of dye stains in histology. For, without the application of appropriate mythological stains and associative analogies, many of the products of unconscious mental activity would be indecipherable. But Freud himself, in company with most of his followers, has regularly taken the symptom or dream material thus treated as being, thereby, proved to be identical with the mythic analogue. Certain features of the parent-child constellation suggested the application of the famous Oedipus stain, while certain characters of religious feeling were obviously inspired by the archetype of the human family. In the former case the analogy of the infantile attitude to the parents with the antique mythic pattern is held to prove that every child is caught in the fatal pit of incest, while in the latter the continuity of the primal condition of infancy with the deepest sources of religious feeling is taken to prove that religious experience is nothing but reproduced infantile fantasy. A primitive, idiomatic mode of expression can never be understood by minds that mistake analogy for concrete fact. The complacency which accompanies this type of rationalization is particularly infuriating, because although the reasoning purports to be the modest voice of scientific agnosticism it is at bottom the expression of a primitive belief in the infallibility of the deductive scientific method as such. The Freudian method is certainly deductive, but are the deductions made in the spirit of science? The misuse of method is a matter of real scientific concern. It can be unwitting, like the case of the examination candidate who was perfectly certain that the tubercle bacillus was a red microbe because he had actually seen it under the microscope. The fallacy, then, does not lie in the use of the analogical method, but rather in a superstitious adherence to the deductive technique, as though the employment of a certain style of reasoning absolved one from all inquiry into the validity of one's premisses. This characteristic Freudian fallacy has done incalculable injury, even though medical psychology owes an immense debt to Freud for his invaluable clinical discoveries. Psychological research would undoubtedly gain a new and vigorous impetus in this country if a fully equipped scientific survey could be carried out with the aim of salvaging the valuable grains of fact from the welter of fallacious inference.

Ingrowing Toe-nail

A Correction

Dr. P. F. CHAPMAN (Taynuilt) writes: In my letter on the above subject in the *Journal* of December 8th (p. 1073), the words "treated by this method" in the last paragraph should be omitted. The method of treatment is not the cause of the suppuration, but is the quickest way of curing it.

Fourteen British teachers of cookery have written a booklet for the housewife called "Christmas Fare." Over fifty recipes are given, and the preparation of every dish is described in detail. Copies may be obtained gratis from almost every gas undertaking or direct from the British Commercial Gas Association, 28, Grosvenor Gardens, S.W.1.

Vacancies

Advertisements of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 33, 34, 35 and 38 of our advertisement columns and advertisements as to partnership, consultancy, and locumtenencies at pages 36 and 37.

A short summary of vacant posts noticed in the advertisement columns appears in the *Supplement* at page 101.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, DECEMBER 29th, 1934

OESTRUS-PRODUCING HORMONES*

BY

E. C. DODDS, M.D., D.Sc., F.R.C.P.

(From the Courtauld Institute of Biochemistry, Middlesex Hospital)

I propose in this introduction to give a general outline of our present knowledge concerning the oestrus-producing hormones, so that with this background it will be possible for subsequent speakers to develop their own particular views in the various fields in which they work. No detailed account can be given owing to the lack of time and space. Those who require fuller descriptions are advised to consult the general references given at the end of this communication.

It will be noted that the title is in the plural, and refers to the oestrus-producing hormones. Presumably we are required to consider all the naturally occurring oestrus-producing substances. It will not be out of place to refer to oestrus-producing substances from other sources, since the knowledge of these helps us to understand the chemical relations of the naturally occurring substances.

The phenomenon of oestrus has been described on so many occasions that I do not think it is necessary to consider it fully here. To summarize we may say that oestrus is the outward and physical sign of the sexual cycle of animals, passing as it does from a stage of quiescence or rest to conditions of intense activity, during which time the animal is capable of impregnation. The biological changes connected with oestrus differ very considerably in the different animals. For the purpose of studying the hormones responsible for these changes the rat and mouse have been found most convenient. It is possible to keep large numbers of these animals relatively cheaply, and, at the same time, the progress of the oestrous cycle may be judged very readily by a study of the vaginal smear. It is for this reason, and for this alone, that the rat and mouse have been used. In many ways it is perhaps a little unfortunate, since in the minds of many people—particularly clinicians—any talk of oestrus-producing hormones automatically calls up a picture of rats and mice. Again, it is perhaps unfortunate that we have come to think in terms of these small rodents when we consider the necessity of associating the corpus luteum hormone with the cycle. Removal of the ovaries causes cessation of the oestrous cycle, and consequently these castrated animals are suitable for a study of the chemistry and biological activities of oestrus-producing substances.

Nature of the Hormones

In the first place active material was prepared from ovaries by extraction with volatile solvents. Later the active material was demonstrated in the placenta, and this was used as a valuable source of the substance. By the application of the most refined chemical methods it

is possible to show that the material contains only carbon, hydrogen, and oxygen, but as to the group of bodies to which it belongs there was until recently no indication. The brilliant researches of Aschheim and Zondek revealed the presence of an oestrus-producing substance in the urine of pregnant women. Here the material was relatively uncontaminated, and it was possible for organic chemists to study the constitution of the compound with much greater certainty.

Again it will be quite impossible to summarize the various stages leading to the generally accepted constitution of to-day. In general terms it may be stated that we are fairly certain that the oestrus-producing hormones in the urine of pregnant women belong to the group of sterols, and have in common a partially hydrogenated phenanthrene ring. Their relationship is shown in the following diagram.

Ketohydroxy-oestrin. Trihydroxy-oestrin. Dihydro-oestrin.

The Chemistry of the Hormones

It can be seen that in the urine of pregnancy ketohydroxy-oestrin and trihydroxy-oestrin are found, the former being considerably more active than the latter. It has been shown that trihydroxy-oestrin can be converted into ketohydroxy-oestrin by vacuum distillation with potassium bisulphate. Further interesting chemical compounds may be obtained by hydrogenating ketohydroxy-oestrin. The first of these, obtained by Schwenk and Hildebrandt,¹ is dihydro-folliculin. This compound is many times more potent than ketohydroxy-oestrin. If it be further hydrogenated by continuing this treatment the compound takes on the properties of the male sex hormone and passes out of the range of our discussion.

Up to the present, therefore, we have three oestrus-producing hormones—namely, trihydroxy-, ketohydroxy-, and dihydro-oestrin, of which the latter is by far the most powerful. At the present time we have no knowledge of the type of oestrin which is present in either the circulating blood, the ovary, or the placenta. There are certain other oestrus-producing substances to be found in nature. Plants contain a compound capable of producing oestrus. This has been shown to have the same kind of structure as oestrin, and has been called tokokin.

* Read in opening a discussion in the Section of Pathology, Bacteriology, and Biochemistry at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

A very interesting observation was made by Aschheim and Hohlweg,² who showed that extracts of coal and mineral fuel oil were capable of producing oestrus. They attributed this interesting phenomenon to the tokokinin of buried prehistoric forests which had resisted the process of carbonization.

Attempts to synthesize ketohydroxy-oestrin have not as yet met with success, and the failure may be due to the extremely complicated nature of the processes involved. But certain interesting results have developed out of the applications of synthetic organic chemistry to the study of oestrus-producing compounds. We³ have been able to show that a series of compounds obtained in the organic chemistry laboratory are capable of producing all the known phenomena of oestrus. In the main these compounds can be divided into two classes, derivatives of phenanthrene and dibenzanthracene. As an example of the former 1-keto-1:2:3:4-tetrahydro-phenanthrene, and of the latter 9:10-dihydro-9:10-dialkyl-1:2:5:6-dibenzanthracene may be cited. It is very interesting to note that the order of activity varies with the alkyl group, the maximum being at the three carbon atom stage. When the dipropyl compound is made it is more active than trihydroxy-oestrin. It has also been shown that two of the carcinogenic hydrocarbons are oestrogenic,⁴ whilst vitamin D in very large doses is capable of producing oestrus. From these observations it can be seen that the naturally occurring oestrus-producing hormones are linked on the one hand with carcinogenic substances and on the other hand with the vitamins and certain plant sterols. It must be noted that these compounds which produce oestrus in the rodent will also produce various of the secondary sexual characteristics in larger animals.

The specificity of the oestrus-producing hormones is not restricted to any one group of animals. Thus, by injecting oestrin into cocks or capons, it is possible to produce an alteration in the plumage from the male to the female type. It is also interesting to note that a synthetic compound can also do this. [Professor Dodds then showed a slide demonstrating the effect of 1-keto-1:2:3:4-tetrahydro-phenanthrene on the plumage of the capon, in that, following injection, an immediate change took place from the male to the female type of feather.]

Kaufmann's Work on Human Subjects

A long and elaborate series of researches have shown that all female animals respond to injections of these oestrus-producing hormones, provided sufficient quantities are given. Dr. Parkes will, I hope, describe to us his experiments with the baboon, since this work indicates the importance of dosage. Dr. Parkes's experiments prove successfully that the response to oestrin varies with the body weight. In other words, the amount required to produce oestrus is in direct proportion to the body weight. This has also been shown by Schoeller.

From the baboon we pass to the most recent and interesting development of this work—namely, that of Kaufmann.¹ This worker has shown that, provided sufficient of the hormone be given together with the corpus luteum hormone, it is then possible to produce menstrual changes in the uterus even in ovariectomized women. These results have been checked very carefully by currtage and careful microscopical examination, ovariectomized women being, of course, the subjects of the investigation. Kaufmann has shown that if on the first day of the treatment 250,000 mouse units be given, and this be followed by similar doses on the fourth, eighth, eleventh, and fifteenth days, and that if on the nineteenth, twentieth, twenty-first, twenty-second, and twenty-third days seven rabbit units of the corpus luteum

be given, the full menstrual period will commence on the twenty-fifth day. The great point of Kaufmann's work is that it is always possible to induce menstruation by this method, and I think this is the first occasion that it has been possible to state definitely that this natural phenomenon can be produced at will in castrated women.

I myself have fully confirmed Kaufmann's work, and I believe that others who will speak after me will describe their own experiments, which are also of a confirmatory nature. It must be noted that these results can only be obtained in ovariectomized women when enormous doses are used. It would be very interesting to know whether it would always be necessary to use these doses even in castrated women, since experience with animals shows that once a series of regular cycles have been induced in castrated animals the amount required is nothing like so great as that necessary to initiate the first changes after castration. There can be no doubt that if the ovaries are present very much smaller quantities are required to produce these effects, and in some cases it has been possible to produce them without the use of corpus luteum hormone.

Kaufmann also brings out another interesting point, which makes plain the pathology of certain gynaecological conditions. In some cases he demonstrated with large doses, using over 5 million international units, spread over several weeks, the development of a pathological and clinical picture of cystic hyperplasia of the endometrium. As he points out, however, there is very little fear of developing this condition with the doses used in the treatment of ordinary conditions. These results have the utmost value, and for the first time they prove successfully that these hormones have a definite place in therapeutics.

Practical Applications

Having once established the fact that menstruation may be initiated at will, it is necessary to consider the practical applications of these new weapons. Judging from the fact that it is possible to produce menstruation in women long past the time of menopause, it would appear that the menses can be induced in persons suffering from both primary and secondary amenorrhoea. It has always been felt that some other hormone would be required for the treatment of primary amenorrhoea, but in view of Kaufmann's results this would not appear to be true, provided that sufficient oestrus-producing hormone and corpus luteum be administered.

In menopausal cases very good results have been reported with doses of 50,000 mouse units twice per week, with alleviation of the psychic symptoms. In a private communication to me recently Kaufmann has described very successful treatment of chronic conditions of inflammation of the vulva associated with the menopause and senility. It would appear that there is a very valuable field of application for the hormones in these conditions. Again, the use of the corpus luteum hormone has resulted in the controlling of certain types of menorrhagia, and also patients suffering from successive abortions have been successfully brought to term.

In conclusion, only the barest outline of the clinical possibilities of these substances has been given, but I hope that those who will follow me will give their own experiences. It is perhaps not going too far to say that the biochemist and biologist have placed an entirely new set of weapons in the hands of the practitioner and physician, and many gynaecological conditions which we have hitherto considered would only respond to surgical intervention will now be able to be treated with injections of the hormones.

THE PROBLEM OF THE SEPTIC HAND *

BY
R. KENNON, M.D., F.R.C.S.,

HONORARY SURGEON, LIVERPOOL ROYAL INFIRMARY

The problem of the septic hand is of interest to all. The public should be warned not to suck or squeeze minor injuries and to seek medical advice more frequently. Nurses should be forbidden to hand instruments, especially knives and needles, to the operator. The surgeon should always sew towards himself and pull out the thread horizontally, not vertically, if the hand and eye of the assistant are not to be endangered.

Most septic hands arise from puncture wounds. The thorn, needle, and safety-pin, however contaminated as they enter the tissues, are cleansed as they penetrate, by the glove in the case of the surgeon and American artisans who often work in gloves, and by the horny hand of toil; yet beneath the thickened epithelium over the heads of the metacarpal bones, known in the North of England as

FIG. 1.—The horizontal use of a razor blade to remove the epithelium in pricked fingers, thereby extracting thorns and relieving tension.

a "seg." infection may occur, which, if not relieved of tension, macerates and infects the underlying tissues, leading to palmar abscess. Realizing, therefore, that in the superficial layers of the epithelium the penetrating object has left most of its infecting organisms, it is our duty to remove with a razor blade the surface epithelium over the punctured area (Fig. 1), thereby relieving tension during the inflammatory reaction which must follow all trauma, whether infection is present or not. Through this weak spot serum will ooze, carrying to the surface products of the inflammation.

All pricked fingers should be kept dry, or dressed with spirit, and never until infection is established should they be subjected to fomentations, hot or cold. A splint should be applied to prevent the patient squeezing the wound and to ease the pain of muscle spasm.

* Read in the Section of Surgery at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

If the septic hand is to be prevented more consideration should be given to trivial conditions involving the fingers, especially the nails. The nail is often the source of mechanical irritation which is delaying recovery. Conservative treatment of the nail is essential; if it must be sacrificed then it should be dissected off, and not wrenched from its bed, but, wherever possible, it should be preserved to splint the nail bed and to keep for the soft regenerating nail an area of adequate width to avoid irregular nail formation. When the nail bed requires removal for recurring deformity of the nail the distal half of the phalanx should be excised to relieve tension on sutures. The crushed finger or subungual haematoma, if associated with fluid beneath the cuticle, should be drained by insertion of a sharp hook, tenotomy knife, or needle beneath the cuticle—the first step in the treatment of paronychia—to avoid maceration and diminish the tendency to infection.

The Congealed Hand or Finger

Imagine the healthy hand or finger plunged into boiling water; the result would be that all avascular structure would undergo aseptic necrosis, the palmar fascia, the dorsal expansion of the fingers, and the deep fascia on the back of the hand suffering most. In 1929, under the title of "Sore Fingers and Such Trivialities," I published in the *Lancet* an attack on this brutal method of treating injured tissues, and pointed out how it was possible to recognize the severity of previous hot-water treatment by the fact that the nail bed of other fingers, which must be simultaneously plunged into the bowl of hot water, became tender and even developed paronychia; also the annular nature of the swelling so characteristic of the carbolic finger and so different from the irregular edge of a spreading infection. The effect of treatment is dramatic, and many must have observed the immediate improvement that has followed the change to a dry dressing or cold compress: pain ceases and sleep follows. If the possibility of a congealed finger or hand is recognized and improvement has followed a change in the treatment, it becomes urgently necessary to get these fingers moving to prevent stiffness. With the institution of active movement there may be complete recovery; not infrequently, however, small areas of fascia contract, giving rise to a Dupuytren's contracture, or these areas soften, and at the end of two or three weeks liquefaction of the fascia occurs and abscesses form about the base and dorsum of the finger or below the styloid processes of the radius and ulna, sites which have been subjected to greatest pressure as the finger or hand was held in scalding water.

The Septic Hand

Boils usually form on the dorsal surface of the index and middle fingers at their base, and may involve the opposite hand about the same time, so that coap and the nailbrush become a factor in the causation. When boils are present the finger should be splinted and painted with iodine. If the follicle shows signs of sloughing, denude the area with a razor blade and apply a thick paste of glycerin and magnesium oxide or sulphate. This will save many fingers from an incision. If a localized cellulitis forms round the boil, then an incision stretched widely open by a pair of Spencer Wells or the crucial incision is necessary; but these should never be made under ethyl chloride, otherwise an extensive slough of the avascular fibrous tissue beneath will delay healing and render the graver forms of septic finger possible. Minor degrees of paronychia have already been considered. If pus develops at the base of the nail, the nail bed should be exposed by lateral incisions and the reflection of the tissues, dissecting off the nail and removing its proximal portion.

Streptococcal Fingers

The pulsating fingers of nurses, dressers, and doctors will always be our gravest problem. Within a few hours the site of infection is pink, slightly swollen, and throbbing, and from it red lines of lymphatic infection spread to the nearest gland. With an injury in the zone of the ulnar nerve distribution the epicondylar gland is enlarged. Infection from the thumb and outer two and a half fingers spreads to the axilla. If, when seen, these lines are broken, a good prognosis may be given. The case must be watched from two equally dangerous foci—the finger and the glands; and absolute rest must be given to both areas. Incisions at the site of the injury have been condemned, yet many patients owe their lives to them. I think a compromise is necessary, and that it can be found in the manoeuvre already described, in which the surface epithelium is removed and the area subsequently dressed with a hypertonic saline dressing or glycerin and magnesia, in order to establish a flow of serum from the wound into the dressing.

For lymphangitis heavy moist towelling, ichthyol ointment, or kaolin paste may be employed, because these are heavy enough to splint the tissues. Bier's treatment has its advocates, but it should only be applied on healthy tissues. On occasion it will be found that with a rigor on the third day after infection, the glands empty themselves into the general circulatory system with a variety of interesting sequelae—bacilluria, albuminuria, haematuria, erythema nodosum, synovitis, or septicaemia. Those who fear the effect of protein shock to the body developing a resistance against infection may withhold the administration of antistreptococcal serum, but it must be administered if toxæmia is intense or rigors have occurred.

Returning to the site of injury, in three or four days pus will have formed, and the case now falls into line with other less fulminating conditions of the fingers and hands. The glands, however, may persist. If they suppurate they should be opened. If they do not suppurate they may remain enlarged for many months, and care should be taken not to remove them under the mistaken diagnosis of tuberculosis. At least three months should elapse after infection before these glands are removed, otherwise local erysipelas, cellulitis, and septicaemia may develop. Many manual workers have bilateral axillary glands, which, without any recognizable injury or infection of the hand, may undergo spontaneous suppuration and involve the patient in a claim for compensation.

Suppuration of Finger or Hand

My interest in septic fingers was stimulated by the remarkable researches of A. B. Kanavel, whose book *Infections of the Hand* should be in the library of all medical practitioners. Most of us will have learned to classify whitlows as the subcuticular, the subcutaneous, the subtheal, and the subperiosteal. A subcuticular whitlow readily yields to treatment if the cuticle is sufficiently removed to prevent maceration. Yet it penetrates to deeper layers in the case of the "seg," and often leads to useless incisions on the back of the hand by those who do not realize the backward drainage of all lymphatics from the fingers and hand, so that, with pus in the palm, the greatest swelling is on the dorsum. The subcutaneous whitlow (or pulp infection) was at one time opened through the centre of the finger, resulting in a fibrous scar which subsequently interfered with delicacy of touch. Then it was attacked by means of the "cod-mouth" incision, which left the finger with a hideous deformity; this method cannot be too severely condemned. Now, I hope, it is only approached from the side. Frequently the operator is

puzzled to make the finger fit the incision, and often he must wish to follow in the line of infection; if such be imperative, again the horizontal line of attack with a lateral incision will help.

The Subtheal and Subperiosteal Whitlow

Difficulty appears to arise in the recognition of tendon sheath infection. We are told that movement of the finger

FIG. 2.—An illustration from Kanavel's book *Infections of the Hand*, showing points of termination or narrowing of tendon sheaths.

is painful and limited, and that on bending the finger backwards if pain is experienced the tendon sheath is involved. But I think careful study of these cases and of the diagrams of tendon sheaths, as revealed by the researches of Kanavel (Fig. 2), will show that where the tendon narrows or terminates, there, in the presence of infection, will be a maximal point of tenderness in the swollen finger or hand (Fig. 3). The tendon sheath must then be opened by a short central incision, if its contents are to be evacuated and the tendon saved. These are also the points at which, by ulceration, the dead tendon will separate as a slough. Full movement is possible with a dead tendon. It must be appreciated that tendons require ten to fourteen days to separate, and that any force used to pull away the tendon before it has completely separated can only spread the infection into the palm and give rise to palmar abscess.

If the infecting agent pierces the bone and still carries organisms with it osteomyelitis may be expected, but osteomyelitis is not present as often as is supposed, especially by those who persist in probing wounds in pulp infection. For bare bone is not dead bone, and we should be very chary of acting upon an x-ray report describ-

FIG. 3.—Maximum points of tenderness present in tendon sheath infections; of importance in early diagnosis and treatment. They are also the points at which a sloughing tendon separates.

ing decalcification of a terminal phalanx and half the adjacent bone. This decalcification will also be seen in the small bones of the hand in palmar infection; it is as natural as the disappearance of fat in all wounds—hence the depressed scar. It is the result of active hyperaemia. When this passes calcium will return to the bones. Amputations should not be performed for such decalcification.

With osteomyelitis of the terminal phalanx spontaneous fracture is common, and if appreciated may then perhaps be prevented by splinting the whole of the forearm. That a sequestrum occasionally forms is not unnatural; it will make its presence felt clinically by a copious discharge of pus, and radiologically it will be seen as a piece of bone still loaded with calcium. It is useless to squeeze the finger or probe it daily in order to obtain this sequestrum; at the end of three weeks it will be loose and may then be picked out.

Palmar Abscess

Palmar abscess may be prevented if the tendon sheaths are opened early, especially those of the thumb and little finger, which, when completely distended, give rise to points of maximal tenderness half an inch above the wrist. With regard to the little finger and common flexor sheath I should like to direct attention to the following words of Kanavel: "I wish to emphasize that it is upon the ulnar incision that I depend for drainage of the upper end of the bursa," and with him to advocate that this incision be made whenever the bursa has been under tension for forty-eight hours. The terms "radial" and "ulnar" bursa have been applied by this author to the tendon sheaths of the flexor longus pollicis, and the flexor minimi digiti and common flexor expansion respectively. If tension within these sheaths or bursae is great they will burst beneath the palmar fascia.

Kanavel's researches show how the palm may be divided into three spaces: (1) the thenar, stretching from the thumb to the third metacarpal bone; (2) the middle palmar space from the centre of this bone toward the fifth metacarpal bone; and (3) an unimportant hypothenar space in direct contact with the fifth metacarpal bone. From these spaces pus may track forward along lumbrical muscles to the base of the fingers and upwards under the annular ligament to accumulate in front of the pronator quadratus muscle, or, in the case of the thenar abscess, backwards between the adductor transversus and adductor obliquus to the back of the first interosseous space. His incisions should be followed, and his warning observed concerning the motor branch of the median nerve as it crosses the ridge on the trapezium.

Treatment of a Septic Hand

With a working knowledge of Kanavel's incisions the operator will proceed under a general anaesthetic and a tourniquet to establish adequate drainage of the finger or hand, using a breast knife to avoid carrying infection into deeper parts, as may happen with a pointed knife employed in the dissecting position. No drainage material should be used across the fingers; but for palmar and forearm abscesses it should be rubber dam or corrugated rubber, never gauze, which can only plug a wound and prevent the escape of pus.

The dressing immediately after operation and throughout the greater part of healing should be a moist one, and it is here that hot fomentations become the most important of all dressings—not that it is necessary to apply them at anything greater than body temperature. By its dead weight the moist dressing splints the tissues, moist gauze absorbs blood and serum more quickly than dry gauze, and it can be changed without damaging the tissues. All dressings should be moistened to remove them without haemorrhage, which reopens tissues to

further infection. A dressing may be kept moist by the further addition of saline, etc., every two hours during the day; this will disturb the parts less than the hourly or two-hourly fomentations of the past.

Oiled silk, etc., should be used to protect the surrounding clothes from being soaked, not to prevent evaporation from the dressing. It is sometimes used so closely to the wound that the pink dye of boric lint can be seen upon the skin. Such a dressing is physically wrong; if particles of dye are passing from the dressing into the wound, then poisons cannot leave the wound.

The idea that antiseptics can kill organisms in human tissue without destroying the tissues themselves dies hard; any antiseptic we may employ should be used to keep the dressings from becoming in themselves a hotbed of bacterial activity, as seen in a poultice.

The Stiff Finger

Every effort should be made to prevent any stiffness developing in the diseased or adjacent fingers; this can only be done by very careful timing of the removal of the splint and the institution of voluntary movement in the adjacent fingers. The sooner the swelling of the fingers is dispersed the better for the patient. In the beginning all fingers should be kept straight, but after three or four weeks, when it becomes obvious that stiffness is likely to follow, they should be allowed to become slightly flexed at all joints. It is difficult to apply extension to the diseased finger, but there is no reason why adjacent fingers threatened with stiffness should not be extended and their joint surfaces kept separate by means of a splint, taking its bearing from the front of the arm.

Imbert³ protests against the low assessment sometimes given for ankylosis at the metacarpo-phalangeal joint, the interphalangeal joints being free. For the right thumb he allows 15 per cent., and 10 per cent. for the left; 12 per cent. for the index finger, and 7 per cent. for the others, slightly less on the left hand. In spite of the grave possibility of a finger showing ankylosis or limited movement, I think it is our duty to allow three months to elapse after healing has been completed before urging an amputation. During this time a willing patient may have learned to adapt himself to his disability, so that he may be quite unwilling to face an amputation. A patient can play the piano with both interphalangeal joints ankylosed. During this three months recovery, often surprisingly good, will be helped by stretching and rocking the fingers several times a day after they have been vascularized by radiant heat or immersion in warm water, paraffin, etc., strict attention being paid to the acquired Dupuytren's contraction, due to shortening of the palmar fascia.

Amputations

Apart from suppurative arthritis or loss of the tendon, amputations should not take place at an early date. If the tendon is not loose at the time of operation it should not be cut short, since by its retraction it will infect the palm. It should be brought to the surface between the loose stitches necessary in such cases, and in a few days it will separate naturally. Three months after healing it will be possible to discuss with the patient how much of a finger it will be best to sacrifice for his particular type of work, pleasure, and social status. All amputations of the fingers should be as conservative as possible, and leave a patient with a scar free from pressure and neuromata.

Knowing how well patients in sheltered occupations can manage with considerable finger loss, as, for instance, after the roller or calender accidents in laundries, it is necessary to remind ourselves that the assessments are high, and reach for the loss of the terminal phalanx of the thumb 15 per cent. for the right hand, 10 per cent. for the left,

and about 5 per cent. for the other fingers. Amputations at the proximal interphalangeal joint are best performed by a steam hammer, for then the balance between the flexors and the extensors is maintained from the outset by these tissues being crushed into the bone. Surgically we do not obtain such good results, and a lagging finger stump, especially of the middle finger, is a serious disability demanding re-amputation.

In performing amputations at the proximal interphalangeal joint a towel clip should be forced through the

FIG. 4.—Use for a towel clip to prevent retraction of the flexor tendon during amputation of a finger at the interphalangeal joint.

flexor and extensor tendons down to the bone with the finger held in a position of rest—that is, 45 degrees flexed at the metacarpo-interphalangeal joint. This will prevent retraction of the flexor tendon during the amputation, and enable the operator to suture the tendons over the bone end in a correctly

balanced posture (Fig. 4). The advantage of a successful proximal interphalangeal amputation to the patient is great, for with the hand at rest he can successfully hide his deformity.

To the writers of textbooks, especially those dealing with practical surgery, I would appeal for more careful illustrations of finger amputations (Fig. 5). The incision should start at the metacarpo-phalangeal joint, which is half an inch above the web of the finger, and not, as so often illustrated, somewhere near the base of the metacarpal bone. It should be carried in the axis of the finger as far as the middle of the proximal phalanx; it may, with advantage, be placed nearer the mid-line of the hand in the case of the index or little fingers. From the middle of the phalanx the incision should pass horizontally round the finger almost at right angles to the vertical incision, and never so obliquely that it skirts the web, and would, in the case of the index finger, thus give rise to difficulty in covering

FIG. 5.—Incisions for amputation of a finger at the metacarpo-phalangeal joint, by the Racquet method.

the bone end, and, on occasion, to the serious mistake of removing the head of the first metacarpal bone, which ruins the grip.

Summary

The problem of the septic hand involves careful consideration of the mechanical, chemical, and thermal factors in treatment, which may delay healing of a non-infected wound. Adequate incisions under a tourniquet and general anaesthetic are necessary. Uninfected wounds should be splinted and kept dry; infected wounds require moist dressings. No drainage material should be used on the fingers. Stiffness may be minimized by careful judgement in each case of the time when movement or finger extension may be allowed. Amputations are necessary in only 2 per cent. of cases, and, wherever possible, should be designed to suit the work and social status of the patient.

My thanks are due to Mr. Douglas Kidd for the drawings he has made.

TROPICAL SPRUE AND ITS MODERN TREATMENT*

BY

N. HAMILTON FAIRLEY, M.D., D.Sc., F.R.C.P.

ASSISTANT PHYSICIAN AND DIRECTOR OF PATHOLOGY, HOSPITAL FOR TROPICAL DISEASES, LONDON

Tropical sprue in its typical form is characterized by apyrexial morning diarrhoea with pale, gaseous, bulky, fatty stools, sore tongue, buccal aphthae, intestinal flatulence, megalocytic anaemia, marked wasting, and profound asthenia associated with a low blood pressure. The abdomen is distended, and its thinned parietal wall but scantily covers the coils of gas-distended bowel beneath. Definite skin pigmentation, cramp, tetany, and oedema may be superadded. At times the stools do not conform to the classical type, in other cases intestinal symptoms, characterized by fatty diarrhoea and abnormal carbohydrate fermentation, may occur unaccompanied by anaemia, while occasionally—especially in relapses following respiratory infections—severe megalocytic anaemia may develop in the absence of intestinal features. I have never observed subacute combined degeneration in sprue, though neuritic manifestations are common enough.

The syndrome itself is explicable in terms of a dysfunction of the gastro-intestine, characterized by defective gastric secretion and malabsorption of fat, glucose, calcium—and probably the p.a. factor—in the small bowel. Three cases recently examined within one hour of death by Mackie and the writer failed, as in Thaysen's case (1931), to reveal specific atrophy or inflammatory lesions in the gastro-intestine, and we now regard the intestinal and visceral atrophy, the small heart with its characteristic brown atrophy, and the megaloblastic red marrow as secondary to a gastro-intestinal derangement, the essential cause of which is still under investigation. The absence of a demonstrable parasitic agent such as a virus, bacterium, or fungus, the apyrexial course of the illness, and the essentially non-inflammatory nature of the tissue changes are against an infective origin.

Aetiological Considerations

Sprue generally affects adult Europeans or those of mixed European stock after some years of residence in an endemic area: it may directly follow hill diarrhoea, as emphasized by Rogers (1921), and is not infrequently preceded by a history of dysentery or chronic malaria necessitating prolonged quinine administration. Except in Porto Rico native populations are rarely affected, while damp coastal climates favour its development. Peculiar features are its rarity in Africa and its occasional onset in tropical patients after many years' residence in Europe.

Various theories regarding its causation have been put forward. Ashford (1915) regarded it as a moniliasis of the digestive tract, and later considered the yeast infection to be engrafted on an unbalanced dietary. Elders (1919) regarded it as a primary deficiency disease due to lack of vitamin A and B and amino-acids. Scott (1923) postulated parathyroid deficiency as the aetiological factor. Strauss and Castle (1932) suggested that pernicious anaemia, sprue, tropical macrocytic anaemia, and coeliac disease were conditional deficiencies caused by a lack of a specific reaction between the extrinsic factor taken in the food and the intrinsic factor secreted by the gastric juice; they regarded vitamin B₁₂ as the source of extrinsic factor.

My own view is that sprue arises as a functional breakdown in the gastro-intestine, and that any factor or factors depressing its secretory or absorptive function will predispose. It is known, for example, that certain tropical infections such as malaria and dysentery may depress

* Read in the Section of Tropical Medicine at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

TROPICAL SPRUE

DEC. 29, 1934]

gastric secretion, while residence in a humid climate involves an increased distribution of blood to the skin at the expense of the splanchnic vessels—a state of affairs which, if unduly prolonged, appears likely to depress alimentary function. Again, a diet rich in fat and carbohydrate and poor in first-class protein, which is the main source of extrinsic factor, is the one known to precipitate relapses in sprue, and is probably the most potent single factor in the initiation of the disease in the first instance. From this viewpoint a careful analysis and comparison of the dietaries of Europeans resident in Africa and endemic areas of sprue in India respectively would prove of great interest.

Laboratory Findings

Laboratory investigations—especially those carried out at the Hospital for Tropical Diseases, London—have revealed a biochemical background to sprue which, though not invariably complete in every patient, is very characteristic of the severer cases, and often affords valuable information in recognizing atypical types. Thus well-established cases generally show an excess of adequately split fat, the total fat constituting 25 to 70 per cent. of the dried faeces, a glucose-tolerance curve with a delayed or low maximal rise rarely exceeding 40 mg. per 100 c.cm., a decreased serum calcium associated with a normal serum phosphorus, a blood cholesterol below 100 mg. per 100 c.cm., and a decreased or absent secretion of HCl as revealed by the fractional test meal curve. Acid secretion follows histamine injection in approximately 70 per cent. of sprue cases, a finding which helps to differentiate it from true Addisonian anaemia. The plasma bilirubin rarely exceeds two van den Bergh units, and not infrequently it is normal.

Following appropriate treatment, as outlined below, the percentage of faecal fat is markedly reduced in quantity, the blood calcium and cholesterol increase, the glucose-tolerance curve returns to normal, and the original curve of acid secretion becomes gradually re-established, though this may take many months or even years to accomplish. Haematological investigation generally reveals a megalocytic anaemia of moderate or severe degree, which in advanced cases may be indistinguishable from Addisonian anaemia; the Price-Jones curves in the two diseases are also similar.

Differential Diagnosis and General Treatment

Other megalocytic anaemias—especially those associated with Addisonian pernicious anaemia, gastro-jejunal fistula, intestinal ulceration with stricture, and tuberculous ulceration with fistulae—may lead to confusion, while diseases giving rise to fatty diarrhoea, such as idiopathic steatorrhoea, abdominal Hodgkin's disease, and tuberculous adenitis of the mesenteric glands with lymphatic obstruction and interstitial pancreatitis, may occasionally need differentiation. In the diagnosis of atypical cases of sprue clinical experience combined with a careful case history, physical examination, and detailed laboratory and x-ray investigation are essential.

The patient with sprue must be put to bed on an appropriate diet for a period of five to eight weeks, and must receive liver extract, per os, in adequate dosage if the anorectic requirements of the patient and permits alimentary rest, which is of fundamental importance in recovery.

Diarrhoea and Flatulence.—On admission the patient should be given oleum ricini (2 drachms). When the diarrhoea is severe, pulv. bataviae co. (1/2 to 1 drachm t.d.s.) is useful. Several different diets have been advocated empirically, including the fruit diet of van den Bergh, the milk diet of Manson, and the red meat diet of Canthel. On the basis of the biochemical findings Fairley (1930) successfully employed a series of five graded

high protein, low fat, and low carbohydrate diets, with an energy value varying from 700 to 3,000 calories, and possessing a protein : fat : carbohydrate ratio of 1.0 : 0.3 : 1.3 instead of the usual 1.0 : 1.0 : 4.0. The source of protein was lean red meat, and more recently a defatted high protein milk powder (sprulac) has been introduced by the writer (1932). As the intestinal features subside and the stools become more normal diets of increasing caloric value are gradually substituted, a convalescent high protein diet including fruit and vegetables being generally permitted about the fifth or seventh week.

Anaemia.—Bloomfield and Wyckoff (1927) noted great improvement in a case of sprue given the high liver diet of Minot and Murphy. Ashford (1928) and Fairley (1930) confirmed this result in a larger series of cases, employing liver extract (Lilly No. 343). Almost invariably the anaemia is megalocytic and often hyperchromic in type, and, provided the diarrhoea be controlled by suitable dietary as outlined above, the administration of commercial liver extract in adequate dosage is followed, as in pernicious anaemia, by a maximum reticulocytosis inversely proportional to the red cell count and by rapid blood regeneration. In a severe case I employ liver extract, per os, in a dosage equal to 1½ lb. whole liver for the first month and 1 lb. for the second month, or until such time as the blood has returned to normal. Thereafter a maintenance dose equal to 1/2 lb. whole liver daily may be employed for another month or two, but in the ordinary case a maintenance dose is not necessary over a longer period.

Results of Treatment

The haematological findings on admission and discharge in a recent series of thirty-three cases of sprue treated with high protein (meat), low fat, low carbohydrate diet and liver extract are included in Table I. The haematological findings in another series treated by liver extract, per os, and sprulac are included in Table II.

TABLE I.—Average Haematological Findings in Cases of Sprue Treated with Liver Extract and High Protein (Meat), Low Fat, Low Carbohydrate Diet.
(Average stay in hospital = 42.5 days)

Time of Observation	R.B.C.s. per c.mm.	Haemoglobin per cent.	Colour Index	Average Diameter of R.B.C.s (microns)
Admission ...	2,660,000	57	1.0	8.1
Discharge ...	4,520,000	77	0.85	7.8
Improvement ...	1,660,000	20	0.15	0.3

The total cases numbered thirty-three; the reticulocyte response was investigated in nineteen, the maximum figure averaging 17.1 per cent.

TABLE II.—Average Haematological Findings in Cases of Sprue Treated with Liver Extract and Sprulac
(Average stay in hospital = 43 days.)

Time of Observation	R.B.C.s. per c.mm.	Haemoglobin per cent.	Colour Index	Average Diameter of R.B.C.s (microns)
Admission ...	2,589,000	57.0	1.12	8.0
Discharge ...	4,321,000	76.5	0.83	7.7
Improvement ...	1,735,000	19.5	0.24	0.3

The total cases numbered ten.

It will be seen that the results obtained in these two series were very similar, and from both a clinical and a haematological viewpoint it appears immaterial whether meat or milk protein be utilized provided liver extract in adequate amount is administered.

One of the unexpected features of sprue is the satisfactory haematological response to the oral administration of

liver extract, and only rarely, in my experience, has it been necessary to resort to parenteral injections. Occasionally, however, intractable cases are encountered, and here absorption is either defective or a dosage of liver extract greatly in excess of the normal is required to initiate an effective marrow response. The chart of Case I illustrates this feature. The patient, a woman aged 60, had contracted sprue in Shillong in 1924, and had never satisfactorily responded to liver therapy per os. Extralin in full dosage was given for a fortnight without benefit. Following a series of intramuscular injections of campolon (6 c.cm.) there was a remarkably rapid blood regeneration, a reticulocytosis of 35 per cent. being noted on the seventh

1 drachm) may be given thrice daily after meals with benefit when acid secretion has been found defective. Blood transfusion should be employed only as an emergency measure to tide a 'gravely anaemic patient over the few days which liver extract takes to exert its action on the megaloblastic marrow. Marmite is only occasionally effective, and, in my experience, neither it nor ventriculin is as satisfactory as liver extract in sprue.

Provided the patient is on a diet low in fat the complication of tetany only calls for the administration of calcium lactate (40 grains) thrice daily; the hypocalcaemia rapidly decreases under this regime, and the blood calcium is restored to 9-10 mg.-per 100 c.cm. within three weeks.

Chronic sprue showing lack of blood regeneration with extralin per os and rapid haematological response with intramuscular injections of campolon.

day and an increase of 3,400,000 corpuscles occurring in twenty-four days. Complete recovery ensued. In my experience parenteral injections of liver extract in the ordinary dosage advocated have proved disappointing in sprue, and for this reason I always inject excessively large doses parenterally or administer, in addition, liver extract per os.

As blood regeneration proceeds the rate of red cell production generally exceeds the percentage increase of haemoglobin, so that by the time normal counts are reached the colour index approximates to 0.9. There is a simultaneous decrease in the average diameter of the corpuscles, anisocytosis gradually disappears, and the Price-Jones curve, which generally shows a well-defined displacement to the right and broadening of the base at first, returns to its normal position and symmetry. Sometimes a lag in the production of haemoglobin occurs, cells appear hypochromic, and the colour index approaches 0.7; in these circumstances iron in full dosage is indicated (ferri et ammon. cit. 30 grains t.d.s., p.c.). This is not often necessary, and, when it is, intercurrent disease or some complication such as intestinal ulceration should be suspected. Acid. hydrochlor. dil. (B.P.) (1/2 to

After-care

Once recovered, the sprue case should continue with a well-balanced diet, adequate in protein and vitamins, avoiding fat and carbohydrate excess, rich spiced foods, and condiments. Aperients should be taken with caution, and worry, chill, and respiratory infections avoided so far as possible. Though it is impossible to say definitely that a given case of sprue will never relapse, patients under 55 years of age may be permitted to return to the Tropics, provided there have been no alimentary symptoms and the blood picture has been normal for six months following cessation of treatment, and provided they are otherwise healthy.

A FATAL CASE OF SUBACUTE YELLOW ATROPHY OF THE LIVER AFTER CINCHOPHEN

BY

THOMAS N. FRASER, M.B., Ch.B.,
HOUSE-PHYSICIAN, VICTORIA INFIRMARY, GLASGOW

Cases of toxic cirrhosis with jaundice following the use of cinchophen (atophan), whether fatal or non-fatal, are very infrequently met with in this country or reported in our literature. Most of our knowledge on the subject is obtained from cases reported in the American clinics. The case to be recorded is of interest owing to the fact that toxic symptoms appeared after a dose of only 37½ grains had been taken during a period of five days.

Weir and Comfort¹ published an account of 117 cases of toxic cirrhosis due to cinchophen; nineteen of the cases were seen at the Mayo Clinic, and ninety-eight were collected from the literature on this subject: of the 117 sixty-one were fatal. According to Weir and Comfort the toxic symptoms arose after doses ranging from 54 grains in five weeks to 7,200 grains in four months; but they mentioned that fatal results have also occurred with relatively small doses.

Various explanations have been given as to the action of this drug, and as to why it has such profound toxic properties in some cases. Its use in rheumatic affections has been based on the property which it exerts as an eliminating agent of uric acid, and on this its efficiency principally depends. To the property which the liver has for the breaking up of such chemical agents may be attributed the toxic action of the drug. This view was propounded by Rake.² The chemical formula of cinchophen shows it to be a combination of benzene and pyridine, as follows:

Under liver influence the compound becomes broken up and the benzene ring element separated off. The benzene element is then considered to attach itself to or combine with the liver cells, in which destruction and atrophy is produced, with general toxic characters. Similar behaviour had been noted in connexion with cases of trinitrotoluol poisoning, which occurred during the war.

In cases of jaundice associated with a gastro-duodenal catarrh it has been put forward that certain toxic substances can give rise to a phlegmonous gastro-enteritis, and this condition is regarded as responsible for the obstructive or intense character of the jaundice. This view has been prominently held by Perman and Goehring³ in connexion with the two cases they have reported.

History of Case

The patient, a female aged 38, saw her doctor at the beginning of April, 1934, and complained of sore throat and acute pains in the joints. She was given aspirin and methyl salicylate applications on account of a previous rheumatic history. After a few days this treatment was changed, and sodium salicylate (15 grains) and sodium bicarbonate (20 grains) were administered four times a day. She made a fairly good recovery, the temperature settling and the pain disappearing from her joints, which, however, still remained stiff. She went back to work against her doctor's orders.

About three weeks later she again saw her doctor, who gave her twelve tablets of cinchophen (7½ grains each), with

instructions to take one nightly and to stop immediately if any gastric symptoms should appear. After five days she visited him again, when he noticed very faint jaundice. He stopped the cinchophen and prescribed *mistura alba*. Altogether she had taken only five tablets of the drug. The jaundice progressed slowly, but the patient continued at her work until May 25th, 1934—that is, twenty-five days after the onset of jaundice—when, owing to weakness, she had to take to bed. Four days later she became partially comatose, and was removed to hospital.

She was admitted on May 30th, and her condition then was as follows. She was deeply comatose and continually spitting, yawning, and rubbing her nose. The skin and eyes were intensely jaundiced, and she vomited several times. Some paresis of the right side of the face was present. Temperature was 99.2° F., and the pulse 104. The urine contained bile. The liver dullness did not appear to be altered. The following day she developed a cerebral cry, the right knee-jerk became very brisk, both plantar responses were extensor, and bilateral ankle-clonus was elicited. The temperature rapidly rose to 104.7° F., and the pulse and respirations to 144 and 40 respectively. The patient never regained consciousness, and died that evening.

Post-mortem Findings

Necropsy revealed the following points: lividity of the face and lips, a condition of intense generalized jaundice, and a number of petechial haemorrhages in the skin.

Some bile-stained fluid was present in the pericardial, pleural, and abdominal cavities. The heart was normal, but a number of small areas of extravasated blood were seen in the endocardium of the left ventricle at the septum. The lungs were congested and oedematous, and petechial haemorrhages were present on their surface, while the bronchi contained blood and bile-stained mucus. The stomach was normal. There was no evidence of gastritis. There were a few haemorrhages in the serous coat of the intestines, but no lesion of the mucosa.

The liver was reduced in size and weighed 36 oz. Although it felt somewhat soft and was finely nodular on surface, it appeared firm on section. It had a yellowish brown coloration, with areas of congestion, but the softened yellow areas of acute yellow atrophy were not a feature. The bile ducts on section were dilated. The gall-bladder was normal; no stones. The spleen was slightly enlarged, firm, and congested. The kidneys were bile-stained, and there was evidence of cloudy swelling; there were a few small haemorrhages in the pelves. The bladder was slightly distended, and there were several small haemorrhages on the mucosa and some degree of cystitis. The brain was congested and oedematous, and a few small haemorrhages were observed at the base and over the cerebellum.

Histology.—Sections of the liver revealed a generalized necrosis of liver cells with an increase of the fibrous tissue between areas of necrotic cells. In places the fibrosis was more apparent, and a large number of bile ducts were recognized. Small aggregations of round cells were noted in different parts of the section. The appearances were those of a case of subacute liver atrophy. There was a marked degree of cloudy swelling of the epithelium of the convoluted tubules of the kidneys: a similar condition, but of less degree, was observed in the straight tubules. The glomeruli were only slightly affected, and for the most part seemed normal. Congestion and minute extravasations of blood were also a feature. In the spleen there was some proliferation of the stroma cells and well-marked congestion. The heart muscle was unaffected.

Summary

1. This was a case of acute rheumatism which failed to respond properly to the usual remedies, and was then treated with cinchophen.
2. The total amount of cinchophen taken was only 37½ grains, at the rate of one tablet on five successive days.
3. The early appearance of jaundice—namely, five days after the beginning of treatment—is worthy of note.
4. The question of idiosyncrasy has been raised by some authorities (Rabinowitz,⁴ Weir and Comfort), and

probably had some connexion in this case on account of the small dose of the drug that was taken.

5. The pathological features are quite classical and are similar to those of other reported cases; they are of interest from the close resemblance to the condition met with in cases of trinitrotoluol poisoning.

6. The advisability of the abandonment, or at least better control, of the administration of cinchophen should be considered.

I should like to thank Dr. Buchanan for notes of the case prior to admission, Dr. Mackenzie for permission to record the case, and Dr. Anderson for notes on the post-mortem report and histological findings.

THE ADVANTAGES OF NITROUS OXIDE AND AIR ANALGESIA IN THE MIDWIFERY OF GENERAL AND HOSPITAL PRACTICE

BY

JOHN ELAM, M.R.C.S., L.R.C.P.

The value of nitrous oxide and oxygen anaesthesia and analgesia in maternity has been recognized for some years, and yet because of certain technical difficulties this relief could never become available for all women in their confinements. But by making use of air instead of oxygen Dr. Minnitt of Liverpool has devised an apparatus which appears to fulfil all the necessary requirements.

The apparatus is an adaptation of a McKesson oxygen therapy apparatus.¹ Gas flows from the cylinder through a reducing valve into a bag contained in a metal drum. The flow of gas is controlled by an automatic valve so that it stops when the patient ceases to inhale.

A mixture of approximately 35 per cent. nitrous oxide in air is delivered to the patient. The method of administration is simply to turn on the gas, give the face-piece to the patient, and tell her to breathe in and out when a pain comes on, ceasing to make use of the apparatus when the pain goes away.

The Minnitt gas and air apparatus has been in use at the Wellhouse Hospital, Barnet, for the past eleven months, where I have been privileged to observe its use, and from personal observation of some 250 cases, both in this hospital and in private maternity work, I feel convinced that we have now come to the time when there can be no reasonable objection to all women enjoying the relief which gas and air can give.

Any method which is to be of general value for relieving the pain of maternity must fulfil certain requirements. These may be briefly enumerated as follows: (1) There must be satisfactory relief to the patient. (2) The normal process of labour must not be interfered with. (3) There must be no danger to mother or child. (4) The technique of administration must be one that can be used by midwives and nurses without constant medical supervision, and must be one which will assist the nurses in their work. (5) The apparatus must be readily portable, and not too expensive either to buy or to use. Let us now consider these requirements, and see how far they are fulfilled.

Relief from Pain in Normal Labour

The first 200 patients to receive gas and air at the Wellhouse Hospital were asked to give their own opinion of the method. Eighty-eight stated that they felt no pain whatsoever, 106 that they found great relief, and six that they found some relief. The almost complete silence that reigned in the ward while patients were having gas and air in the second stage of labour was most noticeable. This in itself was an eloquent testimony to the value of this form of analgesia.

In both hospital and private cases there was no evidence that labour was in any way prolonged. Patients being relieved of all, or much, of their pain were enabled to make great use of their voluntary muscles, thus helping delivery. Instead of an excited hysterical woman we found that we had a patient silent and contented, doing her utmost to assist. In 250 cases, some 60 per cent. of which were first confinements, there were nineteen forceps deliveries.

Safety of Mother and Child

Scientific work at Liverpool has shown that there is no danger to mother or child by the use of gas and air.^{2,3} Electrocardiograms for series of patients showed that they did not appear to be influenced to any significant extent as a result of their experiences. The alteration in the mother's pulse and the foetal heart rates estimated at approximately equal intervals during analgesia were within normal limits.

A biochemical study was made of the blood taken from a maternal vein and the umbilical cord in a number of patients immediately after delivery with and without analgesia, and conclusions were drawn that although the administration of gas and air reduced the oxygen content of the mother's blood that of the umbilical cord did not show any marked alteration. Clinically it was observed at the Wellhouse Hospital that with all five air ports of the machine open it was not possible to obtain full surgical anaesthesia in a normal healthy woman. Further, when the patient was breathing regularly in and out cyanosis did not occur, but when she held her breath and pushed down in the second stage of labour cyanosis did occur in a few cases, although this was not of a dangerous degree.

In the first 200 cases at this hospital there were four stillbirths; these were in no way due to the administration of the gas and air.

Is the Method a Help to the Nurse or Midwife?

We now come to a most important consideration, and one which, in my opinion, makes the gas and air technique of Dr. Minnitt superior to any other method.

At the Wellhouse Hospital for the first fifty cases a medical officer was present during the entire time gas and air was being administered. Gradually, however, as time went on and greater confidence was felt in the safety of the method the nurses took more charge, until it became evident that they were perfectly capable of managing a case on their own responsibility. The nursing staff now administers the gas and air to the patients after receiving instruction in its use, so that there is no need for the medical man or woman to be constantly present at the bedside of the patient.

According to the present rules of the Central Midwives Board there must be medical supervision when a nurse or midwife administers any form of anaesthesia or analgesia, but with gas and air the supervision can be very much reduced, thus assisting greatly in the administrative problems of a medical superintendent of a municipal hospital. Without this assistance it would be impossible for the general use of analgesia in labour in these hospitals.

DEC. 29, 1934]

NITROUS OXIDE AND AIR ANALGESIA IN MIDWIFERY

The immense benefit of being able to leave the administration of the gas and air to a nurse is even more noticeable in general practice.

At the Wellhouse Hospital the sisters and nurses are enthusiastic supporters of the use of gas and air, since they find it helps them in their work and makes the patients more easy to manage. The superintending sister-midwife of Wellhouse Hospital states:

"(1) Unlike my experience with other anaesthetics gas and air rather tends to increase the contractions. (2) Even after long labours, there is no evidence of any harm to the child. (3) The patients are enthusiastic. (4) The patient is happier, less excitable, and more controllable. (5) I would prefer my patients to have gas and air in future. They can manage it quite well themselves after a little help and advice."

Expense

The cost of the complete machine fitted into a convenient carrying case is at present 17 guineas, but there does not appear to be any reason why this cost should not be very much reduced should the demand justify the manufacture of the apparatus on a large scale. It is readily portable, and the consumption of gas is about forty gallons an hour, intermittent flow. The actual cost in hospital practice has worked out at about 2s. per case. In private practice the cost is a little higher.

Comparison with Gas and Oxygen

Lastly it would be well to consider how gas and air compares with gas and oxygen for everyday midwifery.

1. The gas and oxygen apparatus at present on the market is rather expensive, and because one must carry oxygen cylinders as well as gas cylinders it is heavier to carry.

2. To administer gas and oxygen in maternity work with satisfactory results does require considerable experience and skill in anaesthetic technique. For the use of gas and air very little skill is required. The method is self-administrative: the patient is given the face-piece and simply told to breathe in and out when a pain comes on. The only requirements are a well-fitting face-piece and a patient who will co-operate.

3. With gas and air this vomiting frequently occurs; with gas and oxygen vomiting is but rarely seen. Patients can, and do, take fluids freely during their confinements.

4. Excitement and cyanosis of the mother can readily occur when gas and oxygen is used, but these troubles are not found to any marked degree with gas and air. The absence of excitement is indeed an important and pronounced feature.

5. With gas and oxygen we can certainly guarantee absolute relief from pain in 100 per cent. of cases, but to do this we must again have a really expert anaesthetist. Our experience is that with gas and air we get 44 per cent. of patients who, without any premedication, have no pain whatsoever; 53 per cent. experience great relief; and 3 per cent. some relief. With premedication a much higher percentage of patients have no pain, and no expert anaesthetist is required.

The nursing staff at the Wellhouse Hospital has assisted us to its utmost to make the investigation a success, and the patients themselves have co-operated. Our sincere thanks are due to Mr. Rutherford, chairman of the Hertfordshire Public Assistance Committee, and to Lord Knutsford, a member of the Hertfordshire County Council, for their unflinching assistance and support.

THE BRITISH MEDICAL JOURNAL 1197

THE POST-OPERATIVE MANAGEMENT OF ACUTE EMPYEMA THORACIS*

BY

GEORGE A. MASON, M.B., B.S. DUNELM,
F.R.C.S.

HUNTERIAN PROFESSOR AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND; THORACIC SURGEON TO THE NORTHUMBERLAND COUNTY COUNCIL; SENIOR SURGICAL REGISTRAR, ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE

Acute empyema thoracis is a common disease, for which operations are frequently performed, yet the importance of careful post-operative care does not appear to be generally appreciated. Operation usually consists of some form of drainage, either open or closed. Blockage of, or ulceration around, the tube often necessitates the conversion of a closed drainage into an open one. The tube is less likely to become obstructed if all visible masses of lymph have been removed through a relatively wide thoracotomy incision when establishing drainage, provided that the condition of the patient permits. It is not intended to embark upon a discussion of the relative values of these operations—each having its own uses—but it is obvious that while open operation would be disastrous in certain cases, it is quite possible that some of the bad results attributed to this method may be partly due to faulty after-treatment.

General Treatment

The patient should be placed in the sitting position as soon as possible after returning to bed from the theatre. These cases are best nursed in the open air. Opiates may be given, if needed, during the early post-operative period to facilitate sleeping and to relieve pain. Fluids should be imbibed freely until the temperature has fallen to normal. Appetite returns as toxæmia diminishes, and full diet is permitted as soon as desired. Purgatives are administered as required. Massage should be given to the arms and legs to improve the general muscle tone, and the patient should be encouraged to move about the bed as much as possible. If the haemoglobin index is low, iron is beneficial. If the general condition has sufficiently improved, and the temperature has been normal for a fortnight, improvement is often accelerated by allowing the patient to get up.

Care of the Wound

Where a "closed" or, as I prefer to call it, a "siphon" system of drainage is used, the wound may be smeared with bipp and covered with a layer of sterilized dry dressing arranged round the tube fastened by adhesive strapping or elastoplast. Usually such a wound need not be disturbed for several days, the sutures being removed about the eighth or tenth day. The tube should be long enough to enable the patient to move about the bed without pulling it off or upsetting the bottle. Redundant coils of tubing are undesirable: lying on the floor, they are apt to become occupied with stagnant discharge.

It is advisable to have the drainage tube connected to a glass tube passing through the cork to the bottom of a bottle containing coloured antiseptic fluid (flavine), rather than to allow the rubber tube itself to be freely beneath the surface of the fluid. In the latter case the tube is only too often found gaily suspended above the level of the liquid. The attendants should, of course, be warned that the tube must be first clamped before it is

*Read in the Section of Surgery at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

disconnected from the bottle for any purpose. Movement of the coloured fluid up and down in the glass tube in the bottle is evidence that the siphon system is working satisfactorily. In unfavourable cases, infection of the wound or blockage of the tube may make continuance of the siphonage undesirable or impossible in such circumstances, and later, in the more favourable cases, where only a small residual cavity remains, the tube should be withdrawn and a shorter clean one inserted—that is, the system of drainage should be changed to the ordinary "open" method.

Where "open" drainage is employed, frequent anti-septic dressings are required, one of the most satisfactory being gauze wrung out in corrosive sublimate (1 in 1,000), unless the discharge is fetid or the wound foul, when eusol should be used. Dressings should be changed as soon as there is any evidence that they are saturated with discharge, or at least once a day. Tubes should be changed at least every second or third day, or more frequently if blockage occurs. To secure and facilitate this, it is my custom to suture a safety-pin, attached to the tube, by its two ends to the edges of the wound. After opening the pin, the dirty tube can be easily detached, removed, and replaced by a new one.

In foul infections, gross thickening of the pleura, or loculation, it is advisable to irrigate the cavity with eusol. The eusol should be warmed by the addition of a little hot water, actually at the bedside, so that it does not disintegrate before entering the chest. A convenient way of avoiding excessive intrapleural pressure during irrigation is to keep two tubes, of different sizes, in the wound, connecting the smaller by means of a catheter to a funnel; fluid can thus escape both around the tubes and along the larger one. Syringing should be avoided.

Persistence or recurrence of temperature after drainage, in the absence of other explanations, is another indication for irrigation, and under these circumstances warm flavine (1 in 1,000) is useful and safe. Rather too much has been made of the supposed dangers of irrigation. If the simple precautions already mentioned of warming the fluid and avoiding undue increase of pressure are adopted, reflex collapse and air embolism are unlikely to occur. There has been cerebral abscess in only two of my cases, and in neither had irrigation been employed. The presence of a bronchial fistula, unless minute, is a definite contraindication to irrigation.

Re-expansion of Lung

The degree of lung collapse found after evacuation of an empyema varies, complete collapse being associated with the large diffuse type, and partial collapse with small and more localized collections. In the latter case, collapse is limited by adhesions between the parietes and the lung at the periphery of the cavity.

Natural obliteration of pleural cavities by re-expansion of the lung follows the establishment of adequate drainage if the general health improves and infection subsides. Raising the intrabronchial pressure causes the lung to expand. As it expands it comes into contact with, and becomes adherent to, the chest wall. Further expansion facilitates the formation of more adhesions around the periphery of the cavity, and so the expanding lung steadily creeps outwards. To assist these processes, within a day or two of the operation, unless the general condition is too poor, the patient is instructed to blow fluid from one Woulfe's bottle to another. Small bottles of about a pint capacity are used; later a larger size may be substituted. Five minutes' blowing during each waking hour is not too exhausting, and suffices. Children prefer to blow up balloons. If the services of a masseuse are available, carefully graduated breathing exercises undoubtedly hasten

re-expansion, and minimize the risk of flattening deformity of the thorax and scoliosis. The "pull" of the sub-atmospheric intrapleural pressure present where siphon drainage is employed is an additional help to re-expansion. Continuous suction by a water vacuum pump is used in some clinics for the same purpose, but of this I have no personal experience.

Drainage is sometimes abandoned when the discharge is no longer profuse, or is thin, or if the temperature has been normal for a number of days, irrespective of whether there is any evidence of complete re-expansion of the lung or not. This rule-of-thumb method leaves too much to chance; it may succeed—probably in the majority of instances it does—but where it is adopted a number of patients are certain to develop a chronic empyema sinus. Drainage must be maintained until the lung has expanded to the parietes and completely obliterated the empyema cavity. If the parietal wound is permitted to close earlier, a residual cavity is left in which pus is almost certain to accumulate; this gives rise to toxæmia, evidenced by wasting, muddy anaemia, sweating, pyrexia, loss of appetite, and ultimately lardaceous disease. There is no constant rate of re-expansion of the lung; that is why there can be no constant interval after which it is safe to abandon drainage. It is sometimes stated that prolonged retention of a drainage tube gives rise to a chronic empyema. A chronic empyema due to this is speedily and simply avoided by removal of the tube, but if it is due to premature stoppage of drainage it is often only cured, if at all, by serious operative procedures.

Breath sounds and vocal fremitus in the vicinity of the wound show that the lung is in contact there with the chest wall. An x-ray picture is the best way of showing the degree of lung expansion that has occurred. If there is a cavity between the lateral chest wall and the lung it will be clearly shown in the film; if, however, the cavity is behind or in front of the lung its extent can be more accurately demonstrated by inserting a length of fine rubber tubing through the wound, the coils of tubing being easily seen through the lung substance. Lipiodol may be used for the same purpose. There need be no hesitation in retaining the tube for prolonged periods; apart from slight discomfort it need be the cause of little disability, and patients can even follow their employment while waiting for obliteration of their cavities. Actually at present a patient of mine, with a tube in a thoracic cavity, is working in a coal mine, and has even played in a game of football!

In a few cases expansion of the lung may come to a standstill before the cavity is completely obliterated. The lung may remain completely collapsed in very rare cases. If drainage is adequate and there is no foreign body in the cavity, failure to re-expand is probably due to thickening of the pleura. Occasionally a bronchial fistula may be the cause, but in my experience, unless the fistula is large, it usually has little, if any, adverse effect on expansion. Repeated irrigations with Dakin's solution or eusol apparently dissolve the layers of fibrin—pleural rind—which, thickening the visceral pleura, imprison the lung. Failure of this chemical decortication necessitates either the surgical removal of this rind or an extensive thoracoplasty.

Operations for acute empyemata, being simple and easy to perform, are often done by relatively inexperienced surgeons in small hospitals or even in the patient's own home. Similarly, in the larger hospitals their performance is often left to the residents. If the principle is recognized of maintaining drainage until the cavity is obliterated by expansion of the lung, no matter how slow the process is, the incidence of chronic empyema will be much less.

CLINICAL MEMORANDA

Clinical Memoranda

A COLLODION-GAUZE SPLINT

Of any two effective treatments for a given condition the simpler and easier will yield consistently better results. This may be because the easier treatment does less damage to important tissues, and/or causes less shock, or because the surgeon, having to devote less thought to the simpler *modus operandi*, can pay more attention to the effect of his manipulations and to the position of parts, splints, bandages, etc. Simple and easy methods also relieve him of much mental and physical fatigue—of importance when there is a long "list" to be got through or many patients to be seen.

Particularly when carrying out orthopaedic treatment does one notice these facts, and it is for this reason that I describe the following simple yet little-known form of treatment. The method is not original. I do not claim this. But I ask the reader to note that the materials are always at hand, of slight cost, and very easy to use. Nearly four years' experience has convinced me, and others to whom they have been demonstrated, of the effectiveness of the splints.

FOR FRACTURED PHALANGES

Whether of hand or foot, the commonest of these fractures have no displacement of the fragments. The only necessary treatment is to immobilize the fracture for the requisite period of time in the correct position. Finger splints can be applied in the correct position, though far too often the anterior concavity of the phalanges and the necessity for slight flexion of the joints is forgotten. Sometimes the splint was correctly applied, but so inefficiently that within a few days it has slipped down the finger, or around to the side, or has even come right off. Owing to their shape it is notoriously difficult to splint the toes effectively. Fortunately, strapping is usually all that is required, but even this has a marked tendency to slip off, being softened and rendered slippery by heat and perspiration. At best one finds on its removal that the skin is sodden and may be abraded.

A simple solution of these difficulties is to use a splint made on the phalanx from collodion and ribbon gauze. Using the convenient width of one inch, from three to six layers of the gauze are wrapped evenly and firmly round the phalanx, interlaying them with a liberal amount of collodion flexible, much in the manner that the old Unna's paste bandages were applied. Cuts and abrasions are painted with liquor iodidi mitis. They require nothing else. While the "splint" is drying any desired position is obtained by digital pressure.

ACCIDENTAL CUTS OF FINGER

Any treatment almost will do for these. But a deep cut heals better if splinted so that the skin edges do not move on each other. Collodion and ribbon gauze provides this so effectively that sutures may be omitted. There is a further advantage, which is that it is waterproof and undamaged by cold water. The patient is able to wash his hands easily and frequently without assistance and without danger to the wound. And the bulk is so small that the hand is hardly crippled, while if applied to a foot a shoe can easily be worn. Surgeons in particular will appreciate the advantage of being able to do most, if not all, of their work during the period of healing. From personal experience I can say that after a deep cut I was able to carry out all the manipulations and apply all the plasters I wanted, and that on the nineteenth day the wound stood up to the trauma of ten minutes' "scrub up" prior to operating.

STIFF FINGERS

When these require traction on the tennis racket principle of Baldwin (modifications Sinclair, Bohler), or for difficult fractures of the phalanges where extension is required, it has been usual to insert a small pin or needle through the pulp of the finger to ensure that the tapes did not slip. Using collodion and ribbon gauze, even when applied only to the terminal phalanx, one obtains a very effective adherence, so that there is no need to perform an "operation" requiring asepsis and its attendant complexities. It is advisable to allow several hours to elapse before actual traction is applied, or else the tapes slip out.

Everyone knows that ordinary wounds are frequently dressed by this method, and many know that it is a useful form of splintage on the face in facial paresis. One hopes that the general practitioner will find the second of the above suggestions useful, and that surgeons will not have cause to regret using all three.

Late Orthopaedic Registrar, Royal
Infirmary, Liverpool.

A CASE OF BOTULISM: RECOVERY

In the *Journal* of November 26th, 1932, two cases of botulism were published, one of which was under my care. I have recently treated a man with similar, but milder, symptoms. The case is recorded below.

H. P., aged 60, a strong, healthy man with very temperate habits, went beagling on October 16th, 1934, which was a very cold day. I mention this as when I saw him on October 18th I thought a chill might have caused the sickness and diarrhoea. On October 17th he ate some jugged hare at supper. Next morning, about 10 o'clock, he began to vomit, and during the day his bowels acted three or four times. I saw him in bed at 6 p.m., on account of frequent vomiting. His pulse and temperature were normal. On October 19th he had double vision, dryness of mouth, and great dizziness and weakness. He could not stand. There was no headache. The systolic blood pressure was 125, and the diastolic 65. The symptoms suggested botulism, and on inquiry suspicion fell on the jugged hare. The hare was bought on October 11th, and the next day was skinned and cooked. On the 14th it was jugged with the lid on, boiled, and left until the 17th, when it was reheated and eaten by three persons, including my patient, who had the largest helping. No one else suffered any discomfort.

On October 21st the patient's bowels acted with aperients after three days' constipation. The bladder was sluggish in action and the urine deficient in quantity. There was no albuminuria, but there was still dislike of light and vision was improving, but there was still double vision. The pupils were contracted and did not react to light. The knee-jerks were active. On October 25th the diplopia had gone. On October 27th the throat and tongue were normal, the pupils sluggish, and the appetite improving. He was still very giddy.

On October 30th he could walk a few yards with difficulty, and was still giddy. After this he made continuous progress, and on November 19th went to Bournemouth. The treatment was complete rest for a fortnight, strychnine, and mild stimulants. On October 31st I sent a specimen of his blood to the Ministry of Health, where Dr. Scott tested it with eight strains of *Salmonella*, with a negative result.

Dr. W. A. Lethem, medical officer to the Ministry of Health, has taken great interest in the case, and suggests, if it is a case of botulism, its mildness may be due to the cause being *B. botulinus*, Type B, which is found in English soil. He suggested publication of the case, in order that attention be drawn to the possibility of similar mild cases occurring and passing unrecognized.

W. GURROD NASH, F.R.C.S.

Bedford.

Reviews

A PAEDIATRIC BAEDEKER

With a charming adaptation of the title-page of Izaak Walton's classic Dr. W. C. DAVISON begins his unique new book, *The Compleat Pediatrician*,¹ in a way that might be calculated to disarm criticism. The subtitle, "Practical, Diagnostic, Therapeutic, and Preventive Pediatrics," strikes an ambitious note, while a preface and introduction explain the purpose and mode of using this book. It is essentially a record of practical facts, arranged and tabulated in seven main chapters. The basis of the book consists of the following arguments: there are 307 distinct diseases or conditions in paediatrics, of which 158 are common and 149 rare, separated into ten groups; there are seventy-nine most important symptoms and signs with 214 variations; there are thirty-seven preventable diseases (causing 56 per cent. of deaths in childhood) and sixty-three (causing 21 per cent. of deaths) which should respond to adequate therapy; in the remainder the patients usually recover, or succumb regardless of therapy. The result of systematizing these facts is not unlike a telephone directory or a Baedeker's guide, especially as paragraph numbers rather than page numbers are used to facilitate reference, and certain diseases are marked with asterisks, etc., to designate those which are "very common," "common," "rare," and "very rare." Therapeutic procedures (including dietetic measures) are dealt with in much the same way, and there is a chapter on laboratory methods. Three appendices contain details of history-taking, physical examination, and, lastly, the contents of a "paediatrician's bag."

The amount of work which Dr. Davison has put into this production can only command admiration and respect, and it is impossible to judge of its value by existing standards. The information tested by random sampling appears to be sound (allowing for differences in American practice, such as that which makes malaria a common cause of unexplained fever); and once the principles are grasped it forms an amazing work of reference. As a guide to the difficulties of paediatric practice Dr. Davison's book can be made to serve a useful purpose.

SCIENCE AND PRACTICE OF SURGERY

In the case of ROMANIS and MITCHNER'S *Science and Practice of Surgery*² edition follows edition as regularly and almost as rapidly as one year follows another. To attain the seniority of a fifth edition in 1934, when the first only appeared in 1927, must assuredly indicate the high-water mark of popularity for a large book of this kind. It must be so well known now to students and practitioners that no useful purpose would be served by more than a brief notice of the principal changes incorporated in the latest edition. The paragraphs on the treatment of peritonitis, fractures, burns, and varicose veins have been rewritten. Mr. C. L. Gimblett has rewritten the chapter on diseases of the eye, and added an article on retinoscopy and the prescription of glasses. Mr. F. A. Neilson has revised the chapter on diseases of the ear, nose, and throat; and Dr. A. F. Potter has re-

edited that on anaesthetics. Throughout both volumes all descriptions of operations and operative procedures have been put into small type; this has been done to save space and also to keep the technical details separate from the general clinical and pathological text. By this means, although additional subject-matter has been included, the total extent of the two volumes has been reduced by about twelve pages. We have no doubt that this edition will prove every bit as acceptable as the previous ones have been, and that before very long urgent calls for another will be heard.

PSYCHO-ANALYSIS

*Outline of Clinical Psychoanalysis*³ is a translation from the German of a monograph by Dr. OTTO FENICHEL, who has been for some time editor of the *Internationale Zeitschrift für Psychoanalyse*, the official journal of the psycho-analytic movement. It is the aim of the author to provide in his book a systematized presentation of clinical data which psycho-analysis has collected in the course of forty years. In successive chapters the psychopathology of the hysterics, the compulsion neuroses, the sexual perversions, the neuroses related to perversions, the schizophrenias, the manic-depressive group, and the character disorders is discussed from the standpoint of psycho-analytic theory. In addition, both the possibilities and the limitations of psychotherapy in the various morbid reaction types are fully set forth. As might be expected, a knowledge of the mechanisms of mental disease does not necessarily enable the psychotherapist to bring about a healthy state of mind. Dr. Fenichel finds especially that manic-depressions, schizophrenic states, and character disorders are particularly resistant to psycho-analytical treatment. It is his view that the biogenetic psychoses require modification of the psycho-analytical technique, and that these cases are most suitably dealt with in mental hospitals. This book would seem to be the most comprehensive monograph on clinical psychiatry that has hitherto been written from the standpoint of psycho-analytical theory and practice. It will be read with advantage by those who are engaged in the study of the obscure problems of mental disease.

In a book entitled *Facts and Theories of Psychoanalysis*⁴ Dr. IVES HENDRICK aims to give, as completely as brevity allows, an epitome of psycho-analysis, a survey of the whole science as it is understood by the specialist practising it to-day. The book is oriented especially by the desire to make a clear distinction between the facts which are observed by all who practise psycho-analysis, and the theories. The subject-matter is divided into four parts, dealing respectively with the facts, theories, therapy, and the present status of psycho-analysis. A useful table is included which shows the results of psycho-analytical treatment at the Berlin Psycho-analytic Clinic. This table is an abbreviation of the reports compiled by Dr. Otto Fenichel. The author rightly observes that a logic-tight demonstration of the therapeutic results of analysis is utterly impossible, and he points out that even in medical therapies the smaller number of variables and the questionable reliability of some data present an onerous and often impossible task to the scientific statistician. As might be anticipated, the favourable results of treatment of the psychoses are almost negligible. In respect of the manic-depressive group it would seem that only those cases which are preceded by definite psychological trauma are

REVIEWS

likely to be helped by psycho-analysis, and those in which the biochemical constitution of the individual is the dominant causal factor psycho-analysis is of no therapeutic value.

DISEASES OF THE HEART

The method usually adopted in textbooks is the classification of diseases and the description of each one in terms of aetiology, pathology, symptomatology, and so forth. In his small manual on *Diseases of the Heart* Dr. WILLIAM D. REID has made a fresh approach. The problem of cardiologists is presented initially as the determination of the presence or absence of organic disease. Given the existence of a cardiopathy, what is its nature and degree, remedy and outlook? There follows a consideration of the history and an assessment of the important factors of age, symptoms, and predisposing diseases. In this vein the author has pursued the routine and orthodox technique of physical and special examinations, and has explained the principles of prognosis and treatment. We need scarcely say that one hundred pages suffice to give only a bare outline of facts, methods, and accumulated experience, but a manual of this kind must be short if it is to achieve its object and preserve perspective. Cardiologists reading this book will appreciate the sensible exposition and the stress laid upon fundamental facts. It may be said that the only unorthodox features of the work are the somewhat colloquial style, and the marginal lines indicating salient paragraphs and sentences.

This is a book which could greatly profit those general clinicians who find difficulty in the diagnosis and treatment of cardiovascular disease. Among other things, it would help to prevent the commonest error of cardiologists—namely, the discovery of organic disease which does not exist. It would also make clear to many the relative unimportance of percussion of the heart, the fallacies attaching to the discovery of "weak heart sounds," the significance of murmurs, and a hundred and one other points of which clinicians seem still too often unaware. This is a little book, but one that is careful and valuable within its own sphere.

FABRICIUS AB AQUAPENDENTE

Fabricius *stat nominis umbra* for most medical men; for the mere anatomist he is an Italian teacher who shares with Canano the honour of calling attention to the valves in the veins of men and animals; for physiologists he was the first of those who begat Harvey and Lower and Hales and the experimental school which still flourishes amongst us. Dr. K. J. FRANKLIN, the university demonstrator of pharmacology at Oxford, has reproduced in facsimile with an English translation the *De Venarum Ostiis*, a little pamphlet of twenty-three folio pages published by Fabricius late in his life, which set Harvey thinking and experimenting until some eighteen years later he lectured and taught that the blood moves in a circle. Dr. Franklin, as an introduction, has written a very charming little biography of Fabricius, bringing him back from the shades and showing him as a man with like passions as ourselves. A teacher of renown, for it is said that he had ten thousand

pupils; no lecturer but a good demonstrator of practical anatomy; more a man of research than of theory; so highly respected that his fellow citizens at Venice and Padua gradually increased his salary as professor of anatomy from a beggarly 100 florins, perhaps £5, a year until it reached 1,100 florins, and he retired on an allowance of a thousand scudi. But anatomy was only a part of the life work of Fabricius. He was well known and equally respected as a surgeon; Galileo was more than once among his patients. All this and much more that is interesting about Fabricius has been collected by Dr. Franklin, who adds plans of the Anatomical Theatre at Padua made by Professor Castiglioni at the suggestion of Dr. Charles Singer. As a good historian, too, Dr. Franklin has been at pains to work out the somewhat difficult bibliography of the various publications issued by Fabricius, and he adds reduced copies of the illustrative plates, being careful to give the exact measurements of the originals. Altogether a most satisfactory piece of work, creditable alike to the author, to the Carnegie Corporation, who appropriated a sum of money to the History of Science to defray the cost of production, and to the publisher, Charles C. Thomas, who adds, as a colophon, an account of the printing and binding. The book is appropriately dedicated to Dr. J. F. Fulton, a fellow Oxonian, now Sterling professor of physiology at the Yale University School of Medicine.

ORTHOPAEDIC SURGERY

The Vienna school of orthopaedic surgery, with which the name of Adolf Lorenz was for so long and so honourably associated, is now well represented by Professor JULIUS HASS, whose book on *Conservative and Operative Orthopaedics* is now before us. It is not possible in the limits allowable to a review to discuss critically all the subjects treated of in the 360 pages of this textbook. Briefly, we would say, that Professor Hass's work may be taken as a representative treatise, fulfilling the professions with which the author set out. In particular it may be noted that operations on tendons are much favoured and consequently fully described, while the treatment of paralytic affections by such means is fully discussed and illustrated. In this connexion the 333 figures reproduced from original drawings should not be allowed to pass without notice and commendation.

The first forty-eight pages are concerned with orthopaedic technique, and are followed by sections on the general consideration of orthopaedic treatment of a conservative nature. Other sections of the work deal seriatim with various regions of the body and their maladies. Tuberculosis, which looms so large in some modern works on orthopaedics, does not occupy a great deal of Professor Hass's pages. Congenital deformities and paralytic affections are allotted much more space. As might be expected of the school of Lorenz, the treatment of congenital dislocation of the hip receives a due, but not too full, amount of attention.

We anticipated that, with the increase of athletic sports on the Continent, the subject of internal derangement of the knee-joint and other sprains would receive full attention, but a search of the index as well as the pages of the book has not revealed any reference to the semilunar cartilages. Possibly this is intentional, and as recent fractures are also unmentioned it may be that they are not covered by the term "Orthopaedic" as used by Dr. Hass. An appendix deals with artificial limbs in a rather perfunctory manner.

Notes on Books

The July issue of *Arquivos de Medicina Legal e Identificação*,⁴ the official organ of the Institute of Identification at Rio de Janeiro, founded in 1931, contains, among others, original papers and clinical lectures on the following subjects: the state of criminality at the present day; the evolution of criminology in Cuba; hymenolatry; prison psychoses; the mental character in epilepsy; dactyloscopic identification of corpses; epileptiform convulsions and mythomania; and the psychopathology of passion and its medico-legal aspects.

Under the stimulating title of *Real Adventure*⁵ is gathered together eleven travel tales from various parts of the world. Contributors include Sir Ernest Shackleton, Sir Francis Younghusband, A. J. Evans ("We Escape"), Mary Kingsley and F. S. Smythe. An attempt has been made to select accounts of personal adventure which will be recognized as the real thing by anyone who has encountered similar perils. It may well succeed.

The eighty-seventh annual issue of *Who's Who* includes over forty thousand brief biographies, and is arranged on the plan that must by now be familiar to all our readers. More than a thousand entries have been deleted on account of death since the publication of the 1934 edition, and approximately fifteen hundred new names appear. Every entry in the book has been submitted to its subject for revision during the past few months, and details for nearly all the new biographies have been supplied direct. As a work of reference *Who's Who* is indispensable in modern life. The 1935 edition contains nearly 3,700 pages, but the price remains at 60s. in buckram, or 63s. in leather-backed binding. It is published by A. and C. Black, Ltd., Soho Square, W.1, and is obtainable at all booksellers.

⁴ *Arquivos de Medicina Legal e Identificação*. Edited by Leonidio Ribeiro. Rio de Janeiro: Imprensa Nacional. 1934. (Pp. xvi + 415; illustrated.)

⁵ *Real Adventure*. Selected by E. W. Parker, M.C. Edited by W. F. Hutchins, M.A. London, New York, and Toronto: Longmans, Green and Co. 1934. (Pp. 175; illustrated. 2s. 6d. net.)

Preparations and Appliances

AN IMPROVED HEADLAMP

Mr. B. H. Pincock, F.R.C.S. (Winchester), writes:

Notwithstanding the convenience of modern self-illuminating instruments, an efficient headlamp still holds an important place in the surgeon's armamentarium.

In the vast majority of cases the part requiring intensive illumination is small in area, whether it be a vessel in the tonsillar fossa or part of a cavity from which the prostate has been removed. Any extraneous illumination not only

detracts from the concentration of light on the required spot, but is likely to be reflected by specula or other instruments, to the discomfort of the surgeon.

The ideal headlamp should be light and comfortable, and must not slip on the head held in any position. It must throw a powerful beam of even illumination over a field of approximately half an inch, at a distance

of one foot from the projector lens. The projector should be mounted on a ball joint in the same horizontal plane as the surgeon's eyes, the beam thus almost coinciding with his line of sight. The projector must be kept within reasonable dimensions.

Having failed to find a headlamp on the market fulfilling these conditions, Messrs. F. Davidson and Co., 143, Great Portland Street, have made one for me complying with the above requirements, and I have found it ideal in examinations of and operations on the ear, nose, and throat, as well as in all cases where a powerful local illumination is necessary.

APPLIANCE FOR RHEUMATOID ARTHRITIS

Dr. FRANK HOWITT (London) writes:

The apparatus depicted below is a modification of one designed by Dr. Gunnar Kahlmeter of Stockholm, and fully described by him in *Acta Rheumatologica* (No. 18, September, 1933). Its purpose is to correct the deformities characteristic of atrophic arthritis of either primary (rheumatoid) or secondary (infective) forms, which occur in the wrist and hands. These deformities consist of a flexion-fixation of the wrist, and of the metacarpo-phalangeal joints with ulnar deviation of the fingers.

It is important that correction should be gradual, but this is difficult to obtain in these cases by ordinary splinting,

because the individual joints may be involved in varying degree, and must therefore be treated separately. On the other hand, forcible manipulation of contractures in atrophic arthritis is contraindicated on the following grounds:

1. Because not only are the intra- and peri-articular adhesions in these cases extremely firm, but the bones are decalcified, and there is a consequent risk of fracture.
2. Considerable reaction follows manipulation of joints the subject of atrophic arthritis, resulting in pain and increased stiffness.
3. Improvement in alignment obtained by force is always gained at the expense of loss of strength. A misshapen but strong hand is more useful than a straight but weakened one.

This apparatus is held by the forearm, both below the elbow and above the wrist, by wide leather straps (A). Gradual extension of the wrist is obtained by means of the ratchet screw (B). The fingers are held in extension by plated finger-stalls (C), which can be easily applied, and are stretched by means of rubber tubes (D). The latter are fitted with hooks which can be inserted into a series of slots in the aluminium frame (E). In this way the fingers can gradually be pulled towards the radial side, thus correcting the ulnar deviation. Pressure is meanwhile maintained on the metacarpo-phalangeal joints by means of a padded strap (F), in order to correct the flexion-fixation of these joints.

The apparatus is light, and can be held in any position. It should be applied daily, at first for short intervals, according to the tolerance of the patient. Later the length of application can be increased, and the apparatus adjusted to meet the response of the individual joints. It is made by Messrs. Allen and Hanburys Ltd., 48, Wigmore Street, W.1.

NASAL DROPS

Anaquinine nasal drops contain ephedrine, volatile oils, and benzoates dissolved in oil. The drops have a decongestive and antiseptic action. A profuse watery secretion also is produced for a short time, and this washes the nasal mucous membrane. The drops are recommended for coryza, etc. They are marketed in this country by the Anglo-French Drug Company, 11, Guilford Street, W.C.1.

DALTOSE

Daltose (Cow and Gate Ltd., Guildford) is a mixture of carbohydrates which has been worked out on scientific principles to provide a satisfactory carbohydrate reinforcement of milk in infant feeding. The mixture contains maltose, dextrose, and dextrins, with calcium lactate and vitamin D in addition. The rationale of the mixture is to provide carbohydrates which will be absorbed at a uniform and suitable rate by the infant, thus minimizing the danger of microbial fermentation of sugar. The mixture is designed according to sound physiological principles, and represents the intelligent application of modern knowledge of infant dietetics.

DEC. 29, 1934]

FAMILY ALLOWANCES

FAMILY ALLOWANCES

MEMORANDUM BY THE CHILDREN'S MINIMUM COMMITTEE

The following comments on the proposed regulations of the Unemployment Assistance Board have been received for publication from the Children's Minimum Committee (116, Thames House, Milbank, S.W.1):

The scale on which the Unemployment Assistance Board proposes to base its grants in respect of dependent children will be welcomed as a considerable advance on the practice of most public assistance committees. The Children's Minimum Committee for adults the total income under the proposed scales for families with two or more children will be appreciably larger than the notoriously inadequate amounts previously allowed to such families under transitional or statutory regulations which appreciate also the elasticity of the high rents will permit additional allowances to cover the high rents with two or more children the proposed scale will not even now permit an expenditure sufficient to satisfy the standards laid down for food by the British Medical Association Committee on Nutrition, and for clothing and other necessities. The following table (A) compares the children's allowances at different ages with the estimated cost of food on the B.M.A. standard plus the bare minimum of 1s. 2d. per child for clothing, cleaning, and light allowed in the Merseyside survey.

Age of Child	U.A.B. Scale	B.M.A. Food, plus 12d. for Clothing, Cleaning, and Light.	Deficit
2	3/-	4/3d.	1/3d.
4	3/-	4/7d.	1/7d.
6	3/6d.	5/1d.	1/5d.
8	4/-	5/12d.	1/12d.
10	4/-	6/6d.	2/6d.
11	4/6d.		

Table B compares the scale for families of various composition with estimated minimum needs, taking the B.M.A. scale for food and the Merseyside estimates for clothing, cleaning, light, and fuel.

Scale	Man and Wife	1 Child, 2 Years	2 Children, 4-9 Years	3 Children, 10-14 Years	5 Children, 14-17 Years
B.M.A. and Merseyside Unemployment Ass. Board	21/3d.	27/3d.	31/3d.	43/3d.	51/3d.
Both the above scales assuming the following "basic rents" allowed by the Board are the actual rents:	7/3d.	7/3d.	7/3d.	7/3d.	7/3d.
Unemployment Benefit	15/-	22/-	25/-	32/-	37/-

The physiological estimate of "needs" allows nothing for any expenditure above the bare necessities of living, nothing for fares, clubs, trade union subscriptions, or personal and household sundries. Even so, it will be seen that the margin between the minimum needs scale and unemployment assistance widens in the table from 3s. 5d. where there are two children to 10s. 10d. where there are five. If higher ages had been taken for children the deficit would have been still greater. It has been suggested that the Board, in failing to lay down a scale which would be adequate for the larger families,

may have been influenced by two considerations: (1) that the scale should not exceed the normal rate of wages; and (2) that the cost of more generous allowances would be too heavy a burden on the Exchequer. As to point (1) the committee recognizes the difficulty of giving assistance on a needs basis which would in the case of large families exceed the rate of wages in agricultural and other low-paid occupations; but it submits that, if the intention of the Board is that assistance to the individual applicant should not exceed his normal rate of wages, that point is already definitely stipulated in the regulations. If, however, it is meant that the individual should never receive more than employed workers in some of the worst-paid occupations, since they already exceed wage rates in some of the worst-paid occupations, the other hand, they fall far below the earnings of the mass of industrial workers. Special investigations by the Ministry of Labour, covering 2,759,548 adult males—less than 2 per cent. of the total number of workers covered. To fix the average earnings of adult males in a very large number of industries in 1931, showed that the industries in which employed only 45,794 adult males were less than 45s. of the total number of workers covered. To fix the scales at their present level is therefore neither logical nor compatible with the assurances given by the Government before the Act was passed, that the whole needs (excluding medical needs) of applicants and their dependants should be met. As to point (2), the additional cost of a more generous assessment in the case of the larger families is easily exaggerated. Although a considerable proportion of families have at some time or other more than three dependent children the number of such families at any one time is relatively small. In the 1921 Census only 6.7 per cent. of adult males had more than three children under 14 years, and it is probable that with the fall in the birth rate the percentage to-day is even smaller.

THE COMMITTEE'S RECOMMENDATION.

The committee would therefore urge that the upward revision of the scales should be considered at the earliest possible date. It notes that where there is only one child the children's allowance is to be 4s., and that where a household consists of more than five members (for example, man, wife, and four children) the allowance for each member in excess of five is to be reduced by 1s. It is generally admitted that with an increase in the size of the household there is a saving in the overhead costs per head, and if the allowances were in themselves adequate this latter provision might be regarded as reasonable; but it is indefensible when the basic rates per child already fall below the minimum of subsistence. It must be remembered, moreover, that under unemployment assistance it will no longer be possible, as it used to be, for any additional relief.

No instructions are contained in the regulations with regard to the assessment of meals or milk. The committee very strongly urges that until the scales themselves are adequate they should be supplemented by free meals and milk, which should not be taken into account in assessing the family resources; that where free meals and milk are not yet available at schools and maternity and child welfare centres the appropriate Government departments should immediately bring them for families living below a minimum subsistence scale. It further urges that until such provision is made its lack should be accounted a "special circumstance" under Regulation 11 (2), which would entitle the family to obtain an additional money allowance in lieu of the school meals to which the children would otherwise be entitled. Another point which seems to require elucidation is the position of sick members of the household. While the regulations provide for persons under health insurance, they do not appear to deal with dependants who may receive help from the Poor Law in respect of medical needs. The committee hopes it will be made clear that in such cases any excess in the amount given over that which the dependant would have been entitled under the Board will not be reckoned in calculating family resources.

OVERCROWDING IN SCHOOLS

An uncompromising attack has recently been made by Dr. E. Kaye Le Fleming¹ on hygienic conditions in English boarding schools in general, and public schools and their preparatory schools in particular. He deliberately commits himself to the challenge that "all schools, with very, very few exceptions, are overcrowded to the detriment of the health of the pupils," and is confident that this statement could be substantiated with ease before an unprejudiced medical tribunal. While crowding may perhaps be inevitable in classrooms, dining halls, and common-rooms, it is not inevitable in dormitories, and it is in arrangements for sleeping that he considers that most of the mischief is done. The Board of Education, he points out, makes recommendations as to floor space, air space, and the distance between beds in dormitories. How often, he asks, is the three-foot space between beds a real three feet, that will allow a rod of that length to pass without contact? How often is the air space "vital" and not a dead air space without circulation? How often are air-space requirements met by excess of height over floor area? Few schools, he suggests, which profess to conform to recognized standards remember that these standards are minima, and that the moment sickness arises in school a much more liberal standard is required. If epidemics are to be controlled, arrangements for expansion of sleeping accommodation are absolutely necessary. Further, the more efficient the arrangements for early isolation of the sick, the less not only the danger of spread of infection, but also the risk of such serious complications as pneumonia and secondary infection of the ears.

The causes of overcrowding at school are, says Dr. Le Fleming, largely economic. Schools are not charitable institutions, and the more pupils that can be accommodated in a given building the greater the profit. He finds it difficult to avoid the conclusion that financial considerations override all others in the minds of a school authority. Either, he says, they are ignorant of the dangers of overcrowding or they refuse to face an awkward problem. In matters of health the head master, though free to take any advice he thinks fit, is the sole and final arbiter. As a human being he shares the common failing of mankind of thinking that he knows a good deal about medical questions. Sometimes he is responsible to a board of governors on which medical opinion is not represented, and sometimes the

kind of medical advice at the disposal of the board is not the best on such a technical question as accommodation. The school doctor is often criticized for not recognizing that his duty is to take care that the boys remain in good health; but before he can practise preventive medicine he must have some control of the conditions which govern the conduct of his patients while in good health. It is difficult, observes Dr. Le Fleming, to imagine a more suitable field for preventive medicine than a school community, where the conditions of living can be modified to a great extent by a stroke of the head master's pen. But the dead weight of tradition, he declares, too often induces in the medical officer an acquiescence in a state of affairs of which he disapproves but which he cannot control. He has learned by bitter experience that it is easier to obtain the expenditure of ten shillings on a boy for almost any other object than that of health.

By way of remedy, Dr. Le Fleming suggests that the method of fixing school fees should be revised. These are at present arranged to provide education of the mind on the assumption that all boys are healthy and will remain so. Medical charges are "extra," and if there is one thing more than another that irritates parents it is the additional payments associated with school fees. In a well-organized school with experience of a period of years it should be possible, he thinks, to estimate the charges entailed by all necessary medical services. In a large school the expenses of sanatorium, nurses, consultations, and everything else could be covered by a fixed sum included in the regular school fee. This sum would be ear-marked for a special fund, which would constitute an insurance of the whole school against sickness. Part of the money could with advantage be spent on preventing overcrowding in dormitories and providing fresh air in the scientific sense. He points out that eight hours or so of the twenty-four can be made relatively free from the risk of infection instead of a period of incubation. Slowly but surely, he foresees, the advantages of open-air dormitories will become recognized, and those schools which have adopted the system will provide an object-lesson alike to education authorities and parents. There are, meanwhile, many schools which can at small cost give facilities for a limited number of boys to sleep in the open air under shelter.

Dr. Le Fleming's indictment, backed by his great experience, cannot be disregarded by any school medical officer or head master. Not all head masters, happily, are obstinate and indifferent, and a surprisingly large number would probably put their schools in order once they grasped the necessity for doing so and were properly advised on the steps which they should take. The school medical officer, like Agag of old, is constrained to walk delicately lest evil befall. Dr. Le Fleming's bold example may well encourage medical officers who hitherto have refrained from speaking their minds to make a stand for what they consider indispensable to the welfare of their charge.

DIET DURING PREGNANCY AND LACTATION

The awakened interest in the dietetic problems peculiar to pregnancy and lactation is expressed in the rapidly increasing number of papers dealing with different aspects of the question. The foetus is a parasite, and during pregnancy the mother has to provide it with food and at the same time lay up a reserve of supplies for lactation. Too often the woman at the beginning of pregnancy is more fitted to go to a convalescent home than to undergo the readjustments necessary to enable her to entertain a hungry guest. Macy and Hunscher¹ conclude, as the result of an analysis of quantitative chemical and physiological data, that the daily diet during pregnancy should contain 70 to 100 grams of protein, 1.6 grams of calcium, 2 grams of phosphorus, 0.3 gram of manganese, and 20 mg. of iron. It may be stated in parenthesis that the average diet in this country contains from 5 to 10 mg. of iron. They also stress the need for including a sufficient amount of vitamins in the diet, and point out that lactation requires a greater amount of all food nutrients than does pregnancy. Macomber² places the daily protein requirement during pregnancy at the still higher figure of from 100 to 125 grams, and agrees that an increased amount is necessary during lactation. Working with white rats he found that on a diet containing 2.9 grams of protein, or 20 per cent. of the daily diet, fertility was optimum. Progressive reduction in the daily protein intake to a minimum of 0.83 gram reduced fertility but did not affect pregnancy. He further found that a low protein intake resulted in a diminished secretion of milk; so that a smaller number of young of a lower average weight were weaned. Moreover, the mothers suffered a greater loss of weight.

The relevance of these results and the justification for the estimate the author has made of the amount of protein required by a woman during pregnancy may be questioned when it is remembered that millions of women in Southern China and India subsist on an excessively low protein diet, are extremely fertile, and nourish their young until the next arrival claims the breasts. Turning to the question of calcium it was found by Mendenhall and Drake,³ as the result of clinical observations, that a somewhat high percentage of pregnant and lactating women suffer from symptoms due to calcium deficiency, and that most of the symptoms can be relieved by the proper administration of calcium and vitamin D. They also concluded that calcium may help to prevent the toxæmias of pregnancy, and that this therapy can be used with absolute safety. Nicholas, Johnson, and Johnstone⁴ found that while the maternal serum calcium decreases during the

latter months of pregnancy, reaching a low concentration at delivery and then increasing during the puerperium, the diffusible calcium increases both relatively and absolutely during the latter months of pregnancy, reaches a high level at delivery, and then decreases during the puerperium. Blood taken from the umbilical cord had a higher calcium content than that of the mother, although the diffusible fraction was lower. Abnormal pregnancies showed variations in the total and diffusible calcium contents of both maternal and foetal blood, and the authors are disposed to think that there is a connexion between a low serum calcium and the presence of toxic amines in the blood of eclamptic women, suggesting a disturbance of parathyroid function.

Lastly, reference may be made to the observations of Donaldson and Macy⁵ that the biological potency of breast milk may be enhanced by the addition of a concentrated source of vitamin B to the diet, while the mothers themselves experience less fatigue. All these papers stress the need for an adequate diet during pregnancy and lactation, but whereas a greater demand for protein, carbohydrate, and fat is made by the child on the breast than by the foetus *in utero*, the demand for iron almost ceases, and that for calcium is greatly lessened with delivery.

INFLUENZA

A recent issue of a German contemporary⁶ contains a series of four papers on the subject of influenza. Three of these—by Hegler, Baernsner, and Pette respectively—deal with the complications of the disease, its effect on pre-existent lung conditions, and its effects on the nervous system. Perhaps the most interesting is the remaining paper by Gundel, entitled "Influenza Problems." This is concerned in part in defining what influenza is, and more particularly what is an influenzal pneumonia. Anyone who has attempted any investigation of this disease, even during a mild epidemic, is aware of this difficulty in certain diagnosis, especially at an early stage. In cases of bronchopneumonia the history, certain clinical features, and the state of the trachea and the histology of the lung post mortem may all afford indications which are generally accepted as evidence of influenzal origin; Gundel maintains that the bacteriology is also characteristic. He is, in fact, largely concerned to maintain the claim of Pfeiffer's bacillus to be regarded as the cause of influenza, only granting the possibility that a virus infection may coexist. If this is a common view in Germany to-day it affords another example of Teutonic isolation, since, apart from the true merits of the question altogether, it is indisputable that the adherents of Pfeiffer's bacillus in this country and in the United States are few and far between; the virus hypothesis almost fills the whole picture. In the course of an argument which seeks to reconcile the distribution of Pfeiffer's bacillus with his hypothesis, Gundel suggests that the epidemic type

² Macomber, D.: *Ibid.*, 1934, xxvii, 483.

³ Mendenhall, A. M., and Drake, J. C.: *Ibid.*, 1934, xxvii, 860.

⁴ Nicholas, H. O., Johnson, H. W., and Johnstone, R. A.: *Ibid.*, 1934, xxvii, 504.

⁵ Donaldson, E. G., and Macy, I. G.: *Journ. of Nutrition*, 1934, vii, 231.

⁶ *Deut. med. Woch.*, 1934, ix, 1575.

differs from those found in unaffected individuals. This might well be so, but several distinct types of this micro-organism are in fact recognized, and it should be the business of those who offer this suggestion to substantiate it by detailed studies of strains isolated from epidemic and other sources. With one of Gundel's conclusions no one will disagree: that every future opportunity should be taken for thorough bacteriological study of the disease. No one knows from one winter to another what it will bring forth, and another great pandemic may well occur within the next twenty years. Against this we are unprepared with any means of prevention or specific treatment in which there is general confidence. When an epidemic begins it is too late to organize a system of research and a team to execute it; if an organization and a plan were brought into being at leisure beforehand much might be hoped from its concerted efforts when the time came. If any such attempt as this is made to ascertain finally the microbic cause of influenza, it should approach the problem from every angle. Investigators in the past have either sought to demonstrate a virus or studied bacterial flora: these two methods of investigation have rarely, if ever, by satisfactory methods and in adequate detail, been applied together to the same cases. That this should be done is an obvious necessity so long as both these beliefs exist, and it may require some sacrifice of prejudice; carried out on an adequate scale, it would certainly demand the services of a considerable number of investigators. Provided that the duties of each were defined and suitable transport facilities were available, it would not be necessary that all should work in the same institution. Co-ordination of effort in this direction might present difficulties, but it is worth a trial when the isolated efforts of individuals in dealing with a problem of this magnitude have in so many years furnished such meagre results.

WATER POLLUTION

The report of the Water Pollution Research Board for the year ending June 30th, which has just been issued,¹ states that the long spell of dry weather not only caused difficulties in the provision of ample quantities of water, but had a serious detrimental effect on the quality in the rivers and streams into which sewage and trade effluents are discharged. At the present time many undertakings use polluted river water, after treatment, for domestic and industrial supplies, and there is no doubt that other polluted rivers will have to be drawn upon in the future to meet growing demands. It is important, therefore, that further efforts should be made to prevent the fouling of rivers and streams and other water supplies if expensive methods of treatment and danger to public health are alike to be avoided. This calls for intensive systematic research, because entirely satisfactory methods of treatment and disposal of many trade effluents at a reasonable cost are not known. Further, as industry develops new processes of manufacture are devised and new methods of dealing with the waste waters will be required. Experiments have been made to ascertain the effects of various factors on the treatment of water by the

base-exchange process of softening. In this process the calcium and magnesium salts, which cause the hardness, are removed and replaced by sodium salts by passing the water through granules of material consisting of complex sodium aluminium silicates. The softening materials are either treated minerals or clays, which are imported. During the past two years experiments have been carried out on British clays with the object of preparing base-exchange material. Many samples have been employed, and clays have been produced with water-softening capacities greater than those of some imported materials at present in use. Research has been continued on methods of treatment of the waste waters discharged from dairies and milk products factories. In the year under review many cases of serious difficulty and pollution of streams by such effluents have arisen. The experiments indicate that there are methods whereby the effluent can be satisfactorily purified before disposal, and a stage has been reached at which the processes suggested should be tested on a large scale. The industry has been offered the opportunity of co-operating both technically and financially in these further investigations. Considerable progress has been made on the biology and chemistry of methods of purification of sewage, but further research of the kind initiated by the Board is necessary for improving methods of purification of water.

THE CAUSE OF MONGOLISM

The occurrence of mongolism in one twin or in both has provided the starting-point for another attempt to explain the aetiology of this curious condition. A. J. Rosanoff and L. M. Handy¹ of Los Angeles report several new instances, and analyse the total sixty-four cases found by them in the literature. Of the twelve examples in which both twins were affected either they were definitely monozygotic or (in four) the type was unascertained. Out of the remaining fifty-two cases in which one twin was a mongol and the other normal eleven were also in the unascertained group, together with five where the sex of the twins was not stated. This leaves thirty-six definitely dizygotic twins—twenty-three of opposite sex—in which only one was a mongol. The authors assert that the family histories in cases of mongolism definitely exclude hereditary—that is, pre-germinal—factors in its aetiology, and their analysis of the twin material seems to narrow down the aetiological factors to those at work some time prior to that moment in the early part of the embryonic period of development at which, in the case of monozygotic twins, the division into two takes place. The theory of "uterine exhaustion" can scarcely be maintained when one of the twins alone is affected, but since all studies of mongolism agree in finding some correlation between an advanced maternal age and the chances of an affected offspring, the authors deal with this in some detail; they conclude that the size of family and order of birth, equally with "uterine exhaustion," play no real part in the causation of mongolism, but stand out only because of their relation with one real factor—the age of the mother. What cause, then, could be present which would increase the hazard as the mother grows

¹ H.M. Stationery Office (ed.)

¹ *Amer. Journ. Dis. Child.*, 1934, *Alvin*, 764.

older? The answer to this, they suggest, is to be found in postulated changes in the ovary. The authors speculate on what they term circumstantial evidence, that in the ovary of a woman who has given birth to a mongol there will be areas of tissue change, perhaps scars, marking the sites of possible damage to the ovum. The changes they suggest will not be gross, but small discrete foci, probably of scar tissue, which, occurring to a certain extent in all women, will by hazard cause damage to an ovum in some instances—a chance effect which is more likely to arise the more often ovulation has taken place. While by this theory all the blame is attributed to the mother, the authors add a suggestion which prevents the father from being completely exonerated. Why, they ask, is the sex distribution so uneven, and an excess of nearly 50 per cent. of boys agreed upon by all authors who have written on the subject? This excess was also apparent in their collected material among the opposite sex twins, and they suggest that in some cases fertilization of an ovum by a spermatozoon bearing the female-producing chromosome may prevent the development of a mongol which would have resulted had the spermatozoon contained the male-producing chromosome. They quote, also, in support of this that mongolism when it does appear in girls is relatively milder than in boys. Beginning with facts the present authors, like many before them dealing with this subject, end with speculation. The new theory, while it is of interest, does not stand much chance of acceptance till more direct evidence is available. It would be a relatively simple matter to ask gynaecologists and pathologists to secure the ovaries from a mongol's mother and to have this material submitted to a detailed histological examination.

HOSPITAL ADVERTISING

If ages past were fairly described as the Stone Age, the Bronze Age, and so on, this age may be described as the age of advertisement. There is no escaping attacks upon our senses, particularly through the eye and the ear, by our would-be benefactors. Even in the depth of the country some cynic will assure us that the blaze of colour on the heath and in our garden, or the perfume of the rose, is but another and more successful and most ancient display of advertisement. Last week, when leaving London, with its posters, for the country, with its more subtle attractions, we were assailed in a traffic block by a host of modern footpads; from car to car they leapt, taking toll of the passengers. They were a lot of handsome young men (particularly one whose eye we knew!) decked in a variety of incongruous garments, with a make-up and "adjustments" of features that did not come from Clarkson's. They made a splash of colour in the drab morning, and certainly drew attention to the claims of — Hospital. Should such things be done? Should earnest students of medicine leave their books, their dissections, and their wards for a gay carnival of collecting-boxes? Some have taunted the voluntary hospitals with these "unworthy" practices. Others have justified them, and maintained that the voluntary hospitals win a place in our hearts by being known. Those who are troubled on this matter would do well to read a book that has been published by Captain J. E. Stone, the secretary

of the Birmingham Hospital Centre. He has already made a mark with his excellent writings on hospital accounts and financial control. Now he puts us further in his debt by this well-considered book, *Appeals for Funds and Hospital Publicity*.¹ There is no aspect of the problem which he has not well considered, and his findings are of real value. He deals with the importance of publicity, the psychology of this appeal to human nature, the various channels open for such appeals; the necessity for the business management of such appeals; and he goes into details of the preparation and make-up of literature and the drafting of letters. He discusses the varying values of newspaper and poster advertisement, and the more subtle forms of publicity given by hospital reports and subscription lists. Nor does he forget the advertising value of hospital days, and of ceremonies such as royal opening of new wings, dedication services, and addresses of welcome. Here is a book to be read by everyone who has any responsibility for the collection of hospital funds. There are hints on how to do it and how not to do it, and there is some lesson of value on every page.

PROBLEMS OF BECONTREE

Twelve years ago the population of the London County Council estate at Becontree was just over 2,000; at the last census (1931) it was over 91,000; to-day, when the building may be regarded as completed, it is estimated as approximately 118,000. The whole estate was planned and built by the County Council, who now manage it as the landlord. The Council conceived it as an entity, and wished, and perhaps expected, that it would remain one—a town in itself. It is, however, situated in the county of Essex, and neither the council of that county nor those of any of the county districts concerned were in any sense partners in the enterprise. It was thrust upon them, and has indeed caused them many embarrassments. The estate cuts across the boundaries of three such authorities—Ilford, Barking, and Dagenham. When the development began Dagenham was merely a small village in the Romford rural district, with a local parish council. The London County Council therefore was not responsible for providing for the health, education, or other local government necessities or amenities for the rapidly growing population, which had to be met by the four local authorities. Each of these, being concerned with only a portion of the estate, has those powers only which are limited by its status. For example, Ilford and Barking are local education authorities, autonomous as far as elementary education is concerned; Dagenham is not. For that part of the estate within the boundaries of this last, the Essex County Council is the authority, as it is for higher education over the whole area. Similarly, there are divisions and limitations with regard to libraries, and with regard to several public health services. Even as to nomenclature there is a common misunderstanding that the estate is not one, but two—Becontree and Dagenham. Such are the problems of Becontree. They have not yet been solved, but an impartial and comprehensive survey of them has been

¹ *Appeals for Funds and Hospital Publicity*. By Captain J. E. Stone, M.C., F.S.A., F.S.S., Birmingham: Barbeck and Sons, Ltd. 1934 (21 ls., postage 9d.)

made for the Pilgrim Trust by Mr. Terence Young,¹ with an introduction by Mr. Stanley Baldwin, the chairman of the Trust. It should prove of value both to those interested in local government and housing, and to those more immediately concerned with the social, industrial, or religious problems which are raised by the special circumstances of the case. Mr. Young gives a short account of the early history of the area. This is followed by a review of the three stages of the development of the estate, and this by the main survey of the conditions of the estate and their effect upon those who live there. A glance into the future, the formulation of a number of questions which the survey raises, and several valuable appendices, mainly statistical, conclude the volume. Of particular interest to our readers will be the sections dealing with public health, with hospital services, and with the application of the findings of the British Medical Association's Report on Nutrition to the particular economic circumstances of the area. All these are adequately dealt with.

THE STOMACH AND BLOOD FORMATION

A few years ago it would have seemed strange to associate the stomach with the formation of blood. Recent work on pernicious anaemia has shown that there is indeed a close relationship. It has been proved that the stomach secretes a substance which, acting on some portions of the food, produces a stimulus to the bone marrow. The parts of the food forming the so-called extrinsic factor are not exactly known, but are attached to muscle proteins. The intrinsic factor, which Castle showed to be secreted by the stomach, is of the nature of a ferment, not a hormone. It is present in normal stomach secretion and is absent from that of people with pernicious anaemia. Patients who have had a large amount of stomach removed at operation are known to develop pernicious anaemia sometimes. Observations of pig's stomach show that both the proximal and the distal parts of the stomach produce the Castle ferment, but not the intermediate part. Healthy pig's stomach dried at low temperatures is a full remedy for pernicious anaemia, since it contains both the ferment and the stomach muscle, and consequently both constituents of the stimulus to bone marrow. This substance passes through the liver, where it is stored, and the lungs, which contain it in smaller concentration, before reaching the general circulation and the bone marrow. Extracts of these organs and of the kidney are effective in producing remissions in the course of pernicious anaemia. A second disease, achylic chloranaemia, shows the close relation of the stomach to blood formation. This is a hypochromic anaemia, with a gross reduction in the number of red blood corpuscles and an even greater reduction of their haemoglobin content, which is associated regularly with achylia gastrica. In this disease the Castle ferment is present, and the essential factor is not lack of hydrochloric acid but of iron for haemoglobin formation. These patients benefit greatly when iron is administered in large quantities. Patients who have lost much blood—for instance, after childbirth or accident—usually regenerate blood quickly; those who do not are often

found to have anacidity; in the latter large doses of iron will often bring about satisfactory blood regeneration. Reinmann suggested the name "sideroses" for these conditions of deficient iron metabolism, and they may be due to disturbance of gastric function. Treatment consists not so much in supplying the absent hydrochloric acid, as in giving iron in excess, since this cannot so readily be taken up from the food in the absence of hydrochloric acid. The Castle ferment does not run parallel with the hydrochloric acid secretion, but the recent discovery that a reticulocyte response in rats can be used as an index of the presence and amount of Castle ferment has enabled further researches to be pursued. Workers in Eppinger's clinic have been led to consider that, as well as a deficiency of Castle ferment, there may be in some cases an excess produced; and some interesting developments on these lines are described by Hitzenger.¹ It is recognized that cases of duodenal ulcer have usually a high blood count, and after haemorrhage regenerate blood quickly. In cases of duodenal ulcer it was found that there was an increase of total oxygen capacity above normal—that is, a greater haemoglobin quantity for taking up oxygen. This has been regarded as due to an increased density of the blood owing to hypersecretion. Hitzenger suggests that it may rather be due to an increased production of Castle ferment in these cases or to a better utilization of iron; thus producing a disease entity which is the exact opposite of pernicious anaemia or achylic chloranaemia. A further step is the suggestion that an increase in Castle ferment production may be responsible for the increased formation of red blood corpuscles in polycythaemia rubra. Naturally a distinction must be drawn between a true polycythaemia and one secondary to emphysema or congenital heart disease. In the literature a number of cases of polycythaemia are recorded in which the complication of duodenal or gastric ulcer occurred. The crucial test would be the demonstration that in cases of polycythaemia there is over-production of Castle ferment, and this may be possible now that the rat reticulocyte test is available. So far no conclusive results have appeared in the literature. If Hitzenger's contention is correct, it would seem that cases of polycythaemia vera should be treated by systematic drawing off of the gastric juice by stomach sound, or preferably by x-ray therapy of the stomach rather than the long bones, or even, in recalcitrant cases, by resection of two-thirds of the stomach itself.

INTERNATIONAL UNION FOR COMBATING CANCER

A meeting was held in London on December 13th for the purpose of electing the two national delegates to represent Great Britain on the Conseil de Direction of the Union Internationale contre le Cancer. The meeting was attended by representatives of all those organizations proposing to join the International Union, together with the original British delegates to the preparatory conference. Mr. Cecil Rowntree, member of the executive committee of the British Empire Cancer Campaign and surgeon to the Cancer Hospital, and Dr. W. Cramer of the Imperial Cancer Research Fund, were elected to represent Great Britain.

TREATMENT IN GENERAL PRACTICE

This article is one of a series on the management of some of the major medical disorders met with in general practice

THE TREATMENT OF PLEURISY

F. G. CHANDLER, M.D., F.R.C.P.

Pleurisy, dry or with effusion, has many causes: tuberculosis of lung or mediastinal glands, military tuberculosis, injury, pneumonia, new growth, lymphadenoma, any suppurative affection in the lung or below the diaphragm (especially perinephric abscess), infarction, local thrombosis. It may be what is called "primary." There are some who believe in a rheumatic pleurisy, but I have never convinced myself of the truth of this. I believe, however, that herpes zoster may cause pleurisy. The commonest, if not the only, cause of so-called primary, or idiopathic, pleurisy is tuberculosis. Obviously this cannot occur primarily on the pleura. The infection travels there either from the lung or by lymphatics from the mediastinal glands. That this latter is possible is proved, I think, by the existence of carbon pigment on the parietal pleura, even though adhesions between the two layers of the pleura are absent. I propose to deal only with primary, or idiopathic, pleurisy.

Dry Pleurisy

Our first consideration is usually the relief of pain; this will be dealt with later.

The systemic disturbance may be very slight indeed—so much so that dry pleurisy is frequently ignored and the patient is allowed up and about in a few days' time. This, in my opinion, is absolutely wrong. Complete rest in bed should be insisted upon for at least two weeks; if there is fever, then bed until the temperature has been normal for at least a fortnight. If there is any sputum this should be examined for tubercle bacilli. At the first opportunity an x-ray photograph of the chest should be taken. A careful temperature record—especially of the temperature at 6.30 p.m.—should be kept.

Relief of Pain

The simplest method of relieving pain is by the application of heat or of some counter-irritant: a linseed poultice; antiphlogistine; a hot-water bottle; hot-salt bags; a mustard plaster; a belladonna plaster; a firm bandage or strapping of the chest in position of full expiration, binding the hemithorax from spine to sternum with one of the excellent modern adhesive strappings. Aspirin alone, or aspirin 10 grains, phenacetin 5 grains, caffeine citrate 4 grains, in a mucilaginous mixture, may be given. If these measures do not suffice then recourse to some form of opium may be necessary: hypodermically—morphine 1/4 grain, heroin 1/12 or 1/6 grain, omnipon 1/6 or 1/3 grain; or by mouth—pil. saponis co., or 15 grains of Dover's powder. Any of these can be repeated if necessary. If these measures do not suffice, four to seven leeches applied to the painful spot may give magical relief. Another method is carefully to infiltrate the parietal pleura over the most painful area with 1 per cent. novocain, using as much as 10 or even 20 c.cm. The technique for doing this will be the same as that to be described later for exploratory puncture or paracentesis.

As in all acute febrile illnesses it is necessary to ensure complete evacuation of the bowels. This may be done by a good dose of Epsom salts in hot water, say 2 to 4 drachms for an adult, flavoured with lemon juice, or by castor oil, or by a vegetable laxative, followed, if it does not act well, by an enema. In any case, if the aperient does not act well an enema should be given. The next consideration is diet. In the first few days the patient may feel disinclined for food, and nourishment need not be pressed upon him. Later it is important to maintain the nourishment of the patient in the highest possible degree.

Convalescence

The after-treatment consists of very careful convalescence, with rest, not exercise, all the fresh air possible, and abundant nourishment. The patient should be kept under observation for at least two years. Sputum examinations should be made if any expectoration is available, and x-ray photographs should be taken, say, every three months. It is as dangerous to ignore a mild attack of dry pleurisy as it is to ignore a haemoptysis. Occasionally we meet with cases of widespread recurrent dry pleurisy, accompanied by fever, with no impairment of resonance, no tubercle bacilli in the sputum, and a negative x-ray picture. Such cases are extremely refractory to treatment. There is little doubt that they are of tuberculous origin, and should be treated as such, preferably at a sanatorium.

Pleurisy with Effusion (Idiopathic)

The effusion may begin insidiously without the patient being aware of anything except malaise and perhaps an increasing dyspnoea; or it may begin with urgent symptoms. An acute pleurisy with effusion most commonly runs a course of about three weeks, and during this period the patient may be and look very ill. The measures to be adopted for the relief of pain have been described above. With the formation of fluid pain as a rule disappears.

Exploratory Puncture

Exploration may be necessary in order to make sure that the effusion is clear and not purulent. It should be performed in the following manner.

First choose the exact spot for the puncture. The best sites are the fifth space in the mid-axillary line, or more posteriorly in the space below the angle of the scapula. It is a mistake to go too low. The skin is rubbed with tinct. iodi. A 5 c.cm. syringe is filled with sterile 2 per cent. novocain solution. This may be boiled before use or kept in a rubber-capped bottle in chloroform water 0.25 per cent., so preventing the growth of the delicate fungus which otherwise occurs. The finest hypodermic needle is used. With two fingers the intercostal space is carefully determined. The needle is inserted horizontally just beneath the epidermis and a bleb of novocain made. The needle is withdrawn, and a long fine hypodermic needle is then attached to the syringe. With the fingers marking the intercostal space as before, this needle is inserted vertically through the bleb of novocain, and is gently and slowly pushed through the insensitive intercostal structures. When the slightest pain is felt thoroughly infiltrate with novocain, and continue infiltration millimetre

by millimetre, attempting to withdraw the piston. Soon the lessened resistance will show that the parietal pleura has been passed; withdrawal of the piston will show the presence of fluid and its nature. Done thus there is no danger in the procedure. The syringe and needle must be perfectly air-tight. The needle must never be pushed in right up to the hilt, for it is at this point that breakage occurs.

Paracentesis: Indications and Dangers

The next question that will arise if the effusion increases is: Shou'd it be tapped or not? It should not be so treated as a routine. There are fairly definite indications for paracentesis:

1. If the effusion is causing distress, cyanosis, or dyspnoea.
2. If causing great displacement of the mediastinum.
3. If it will not absorb within a reasonable time—that is, within three or four weeks.
4. If it is increasing progressively under treatment.
5. If it appears to be keeping up the temperature.
6. If there are tubercle bacilli in the sputum and there is no skiagraphic evidence of disease on the other side, when the effusion should be replaced by air and the artificial pneumothorax so produced subsequently maintained.

If the effusion is left too long the pleura may become greatly thickened and the lung consequently may not re-expand.

The dangers of paracentesis are: (1) cough, discomfort, or pain; (2) dyspnoea; (3) haemoptysis; (4) acute oedema of the lung; and (5) syncope, or even sudden death. These are caused by a too high negative pressure in the pleural cavity, which produces a strain on the lung, with its capillaries and lymphatics, and on the mediastinum.

Technique of Paracentesis

The initial anaesthetization is exactly the same as that for exploration. The track having been thoroughly anaesthetized, a large needle or a trocar and cannula can be inserted without pain. Removal of fluid can be carried out in the following ways.

SIPHONAGE

The simplest method is ordinary siphonage. All that is required is a needle and a bottle containing some 1 in 100 carbolic solution. The needle is put into the chest with the tube attached, and the distal end of the latter is placed under the fluid in the bottle, which stands on a chair by the bedside or on the floor. A cough will usually drive fluid out of the tube and siphonage will take place.

NEGATIVE PRESSURE ASPIRATORS

Potain's aspirator is somewhat clumsy, and apt to go wrong or be out of order unless in constant use. Dieulafoy's aspirator is more handy. It is portable, can be used for replacement, and the tube is less likely to be blocked by lymph, or, if blocked, can be cleared by reversing the action; it should be of a type without washers. Care must be taken not to exert too much force, as too high a negative pressure may be created in the pleural cavity, with the unpleasant or alarming results mentioned above. These can all be prevented by the replacement method described below.

REPLACEMENT BY AIR OR OXYGEN

The fluid, instead of being drawn off by the force of aspiration or of gravity, is replaced by sterile air or oxygen, so that a pneumothorax is left. This soon becomes absorbed, resulting in a steady and gentle traction on the lung, helping it to expand. By this method no pressure changes are produced, no negative pressure is caused, and no strain is put upon the lung.

In fact, if during an aspiration pain or discomfort is experienced, the symptoms can at once be relieved by removing the tube from the needle or cannula, covering the aperture of the cannula with gauze, and allowing the patient to take a few breaths; this draws air through the cannula into the pleural cavity, and all discomfort at once ceases. This is the simplest and crudest method of air replacement, but it may be most effective; it not infrequently comes to pass accidentally owing to a leak in the instruments employed.

The best and most scientific method of replacement is the two-needle method, using an artificial pneumothorax apparatus. In this way the amount of air admitted can be measured and the intrapleural pressure controlled by the manometer. The aspirating needle is inserted in one space, and the artificial pneumothorax needle in a space or two above. After aspiration has begun this second needle is inserted, care being taken to avoid fluid running up the tubing: air is then allowed to flow, and an air space will soon be created and manometric readings can be taken. If oxygen replacement is intended, the air bottle is previously filled with oxygen.

The method of "automatic air replacement" may be employed: instead of using an artificial pneumothorax apparatus a hypodermic needle is inserted in an interspace well above the site of aspiration—say in the second or third space, in the mid-clavicular line. This is covered with gauze, and air is automatically drawn into the pleural cavity as the fluid is aspirated. It is the simplest possible method, and quite effective.

Usually it is not necessary to withdraw all the fluid. One to three pints are generally sufficient; sometimes even less than one pint may be enough, after which the temperature will fall and the remaining fluid be rapidly absorbed. After withdrawing the instrument, put firm pressure over the puncture and seal with gauze soaked in collodion. Brandy, sal volatile, or a cup of tea or coffee may be given afterwards. If there is any pain or distress, give morphine.

Other Methods

Other methods designed to disperse the fluid have been employed—for example, blistering, cupping—but their value is doubtful. Salyrgan has been given to induce a profuse diuresis, but I cannot help thinking that this, though more subtle in application, is just as crude in principle as the older methods of purging, bleeding, and sweating (which have been abandoned), and just as ineffective.

After-treatment

The after-treatment of pleurisy is as important as its immediate management. When I hear of a patient who has had pleurisy going back to work in three weeks I know that one of two things was wrong—the diagnosis or the treatment.

Idiopathic pleurisy, it must be emphasized again, is tuberculous, whether tubercle bacilli are found in the effusion or not. It means a long convalescence, with rest, fresh air, abundant food, malt and cod-liver oil, a careful temperature and weight record, bacteriological examinations of the sputum, and serial skiagrams of the chest. Actually, to go to a sanatorium is the safest thing in some cases, unless ideal conditions can be found elsewhere. The high altitudes are very beneficial in these cases. Sea voyages are not ideal, for the nights are usually passed in stuffy cabins; the weather may prevent the restful enjoyment of fresh air in the daytime, which is so essential; the diet will not be well balanced; and should complications occur no skilled help is, as a rule, available. For at least two years the patient should be kept under careful observation.

INTERNATIONAL PUBLIC HEALTH

QUARANTINE PROCEDURE

The official summary of the October session of the Permanent Committee of the *Office International d'Hygiène Publique*, which has just been published,¹ gives an account of the work of the committee on the chief international sanitary conventions and agreements and on various problems of plague, yellow fever, cholera, small-pox, typhus fever, and other infectious diseases that are liable to be carried from country to country by maritime or aerial traffic. Although every country with seaports has not as yet ratified the International Sanitary Convention of 1926, its application in practice is almost universal, and few difficulties arise. Some difficulties are being met satisfactorily by agreements between individual countries for facilitating and expediting the procedure called (for want of a better term) "quarantine operations." The arrangement by which a number of countries have agreed to dispense with "bills of health" or, alternatively, with Consular visas on bills of health is an example.

In connexion with the difficulties and delays arising from measures for freeing ships from rats the committee devoted much attention to an important report by a group of British shipowners on the rat-proofing of ships which was published in the *Bulletin Mensuel de l'Office International d'Hygiène Publique* for 1934. It is evident that in proportion as shipbuilders comply with the recommendations of that report the routine procedure of "deratization" will become less and less necessary.

SPREAD OF INFECTION BY AIRCRAFT

The International Sanitary Convention for Aerial Navigation (1933) awaits ratification by six more countries before coming into force, but the committee has received information that the required number of signatories will soon be obtained. In the meantime the committee is endeavouring to arrange that countries over which air traffic passes will make uniform regulations under the Convention as soon as possible, particularly with regard to the measures to be taken for preventing the spread of yellow fever, plague, cholera, and small-pox.

Concerning the measures applicable to yellow fever, the committee examined particularly the difficult problem arising from the discovery that in the interior of Africa and South America there are vast areas in which inquiry by means of "the mouse-protection test" indicates that yellow fever is endemic, but in which, up to the present, no case of yellow fever has ever been reported either among the indigenous population or among travellers, traders, and officials. An area in the southern part of the Anglo-Egyptian Sudan was included in the list of these so-called silent areas, but in 1934, following the occurrence of a fatal case diagnosed as yellow fever, the authorities decided to take all the precautions which the Convention prescribes for areas in which that fever exists. Intensive search for clinical cases is being made in other "silent areas" in Africa, and the committee decided to recommend that the histological examination of specimens of liver tissue obtained by viscerotomy or necropsy on persons dying from fevers of less than ten days' duration was a useful aid in this task. The committee also gave consideration to the problem of the destruction of mosquitoes in aircraft. Information on this subject is being collected with a view to indicating the measures which special inquiry and experience may show to be effective and practicable.

As regards measures for preventing the spread of plague the committee insisted that at present it is impossible to rely on vaccination for the protection of individuals, and that anti-plague inoculation could not, therefore, be included in the category of quarantine measures.

The International Agreement of Brussels, 1924, which provides for the treatment of merchant seamen suffering from venereal diseases, received further attention, particularly for the purpose of defining and obtaining general

agreement to schemes of treatment which are most suited to the circumstances of a seaman's life.

YELLOW FEVER VACCINATION

As usual a large part of the work of the session was devoted to communications on the epidemiology and prevention of the particular infectious diseases which are the subject of international sanitary conventions. There was a discussion on the advantages and disadvantages of different methods of protective vaccination against yellow fever. At present two methods are being tried "in the field"—namely, that in which living neurotropic virus fixed for mice is used in combination with immune serum, and that in which the same living virus is used in different stages of attenuation without the additional inoculation of immune serum. Following the discussion the committee adopted the report of its expert Commission, to the effect that vaccination against yellow fever was to be recommended, but that in the present state of knowledge the use of a vaccine composed of living virus without the supplementary precaution of inoculating immune serum seemed to involve certain risks that called for caution.

IDENTIFICATION OF CHOLERA VIBRIO

The problem of finding a bacteriological method of identifying the cholera vibrio which will give the same results when employed by workers in any part of the world continues to occupy the attention of the committee. On this subject note was taken of a communication by the delegate of Great Britain on work that was being undertaken in England in association with workers in India for the preparation of a standard "O" antigen, which could be used for the preparation of high titre diagnostic sera. These workers have come to the conclusion that "O" agglutination is the method of serological identification upon which most reliance can be placed, and are engaged in studying the preparation of an "O" antigen in a dried form in which the "H" fraction has been destroyed by heat. It is believed that the use of such an antigen would make it possible for workers in any part of the world to obtain precisely comparable results, and so obviate the difficulties arising from the use of strains of vibrio which are liable to variation. The subject is particularly important in view of the discovery that, even in the absence of clinical cases of cholera, agglutinable and non-agglutinable vibrios are sometimes found in pilgrims returning from Mecca who are subject to routine examination at the quarantine station of El Tor, and that there is a difference of opinion whether these vibrios are to be regarded as the true cholera vibrio or not.

MISCELLANEOUS COMMUNICATIONS

The committee discussed communications from the delegates for Great Britain, the United States of America, Poland, and Germany on the new procedure for preparing small-pox vaccine by cultivation on the allantoic membrane of the incubated hen's egg. The lymph obtained by this procedure seems to be identical in its effects with ordinary calf lymph, but trials on a large scale will be necessary before a considered opinion on the merits of the new practice can be given.

Among general subjects the committee received reports on "terminal disinfection," the safeguarding of milk supplies, the endemic incidence of goitre in various countries, psittacosis, Weil's disease, undulant fever, and leishmaniasis in Europe.

King Edward's Hospital Fund for London is making a further six-monthly issue of the time-table prepared recently by its out-patient arrangements committee. The object of the time-table is to minimize the waiting, with possible hardship, which results from patients attending hospital out-patient departments at the wrong hour or even sometimes on the wrong day. The present issue, revised to November, 1934, is being distributed to all doctors in the London area. Copies may be obtained free on request from the publishers, Messrs. Geo. Barber and Son, Ltd., Fumival Street, E.C.4.

¹ It can be obtained from 195, Boulevard St. Germain, Paris.

England and Wales

Medical Society of London

The programme has now been issued for the second half of the 162nd session of the Medical Society of London. On January 14th there will be a pathological evening (8 o'clock), followed by discussions, on January 28th, on the treatment of minor maladies of the foot; February 11th, on body weight in relation to disease; February 25th, on the value and limitations of radium therapy; March 11th, on the surgical treatment of syringomyelia; March 25th, on the future of diagnostic radiology. All these discussions begin at 8.30 p.m., at 11, Chandos Street, W. The Lettsomian Lectures, on the surgery of pleural and pulmonary infections, will be delivered by Mr. J. E. H. Roberts on February 18th and 27th, and March 4th, at 9 p.m. The annual general meeting of the society will be held on May 13th, when the annual oration, by Sir William Willcox, on "Toxic Drugs, their Use and Misuse," at 8.30 p.m., will be followed by a conversazione.

Campaign for Safer Milk

At the annual general meeting of The People's League of Health, held at 12, Stratford Place, W., on December 12th, Dr. C. O. Hawthorne, chairman of the council, said that a very useful addition to the machinery of the League had been created during the past year in the shape of a veterinary council. He referred also to the endeavours of the League to secure not only a clean, but a safe milk supply. An important part of its policy had been to urge on the Government that if consumers desired to obtain a milk which, in addition to being from tuberculin-tested cows, had been pasteurized to render it safe from other organisms, they should have that provision. It had pressed forward the various points set out in its classical report on bovine tuberculosis, published in 1932, and had supplemented this by an authoritative memorandum which had been presented by deputation to the Ministers of Health and Agriculture in the same year, and again in April of the present year, immediately preceding the discussion of the Government's Milk Bill in the House of Commons. To one proposal of the Milk Marketing Board the League had taken the strongest exception: this was the accredited herd and producers milk scheme. The grounds upon which the League, in its memorandum on "A Safe Milk Supply," published in August last, had criticized the scheme were that they doubted the general cleanliness of milk would be improved by the proposal to offer a bonus to selected producers—to be known as accredited producers—who attained a standard of cleanliness which was within the reach of, and should be made compulsory on, all producers. "Accredited" milk (as it would assuredly be called) would no doubt appeal to the public as milk guaranteed to be satisfactory. Yet it would not be obtained from tuberculin-tested herds; the cows yielding it would undergo a general veterinary examination only once in six months; and the protective necessity for pasteurization or boiling would be ignored. "Accredited" milk, in short, might claim to be "clean"; it certainly could not claim to be "safe."

The Hospital for Sick Children

The Princess Royal was present on December 11th at the Mansion House, when the Lord Mayor of London presided over a large and influential meeting in support of the appeal for £400,000 for reconstruction of the Hospital for Sick Children, Great Ormond Street. Her Royal Highness announced two generous gifts: one of £10,000 from Mr. Charles P. Johnson of Sevenoaks, and the other of £50,000 from the deputy-chairman of the hospital,

Lieut.-Colonel Stanley G. Cohen. The Archbishop of Canterbury, in the course of a moving address, recalled that the hospital began eighty-two years ago in a small private house, with ten beds. Now, after many years of great work, it asked London and England that it might be enabled adequately to fulfil its great task. The doctors, surgeons, and nurses who were continually giving themselves to the service of Great Ormond Street had to do their work under the most crippling conditions. It was not their fault; it was not the fault of the hospital: it was the fault of circumstances. During a recent visit he was impressed by the way in which the expansion, not only of the hospital, but of the methods of treating children, had involved the erection of new buildings piecemeal around the old one. The connexions between the old and new buildings were most defective. Children being taken either to the one operating theatre above or to the one x-ray room below very often had to be carried up and down by the nurses. He was perplexed by the passages through which he was hurried. There was a serious lack of sunlight and freshness of air, and a great difficulty in securing a balcony for open-air treatment. The wards were bright and clean and cheerful, but were much too large, and ought to be divided for different classes of patients. The rooms for the nurses at the end of the wards were most inadequate. There was nothing for it but that the buildings, however wonderful their associations might be, must be pulled down and reconstructed from top to bottom.

Tuberculosis in Sheffield

Part of the annual report on the health of Sheffield for the year 1933 is devoted to a survey, by Dr. H. Midgley Turner, clinical tuberculosis officer, of the prevention and treatment of this disease in the city. In the year under review the death rate from all forms of tuberculosis was 838 per million living, a slight increase over the figure for 1932, but considerably less than the other large towns in England and Wales, with the exception of Croydon and Portsmouth. This favourable position is attributed to five factors: (1) There is said to be complete co-operation on the part of general practitioners with the tuberculosis scheme. (2) Adequate sanatorium and hospital accommodation has now been provided for all citizens who are suffering, or even suspected to be suffering, from tuberculosis. (3) A large number of early cases are undergoing treatment subsequent to discovery by means of the examination of contacts of notified cases. (4) Intensive work has been in progress with regard to the isolation of infectious cases either in hospitals or in their own homes. (5) Finally, the intensification of the rehousing scheme has included the provision of accommodation for tuberculous patients who had previously been living under conditions where isolation was impossible. Notification rates were low in 1933, both as regards tuberculosis and general sickness, but Dr. Turner points out that it is not desirable that this tuberculosis rate should fall consistently until, hand in hand with the steady fall in the death rate from tuberculosis, there shall be a decrease in the number of new infectious cases. He stigmatizes the policy of delaying notification until tubercle bacilli are found in the sputum as quite wrong, since it is now known that the percentage of cases which show permanent arrest when the disease has reached this stage is exceedingly small. The total number of notified cases on the register on December 31st, 1933, was 6,560, of which 1,400 (including fourteen children under the age of 15) had had tubercle bacilli found in their sputum at some time. No case which has at any time been found to be infectious has so far been cancelled. The dispensary staff examined 92.1 per cent. of the cases of pulmonary tuberculosis notified during the year, showing how

desirous the patients are of availing themselves of the services provided by the municipality. Of the remaining 111 cases, thirty-seven were receiving treatment in institutions not under the control of the corporation at the time of notification; of the other seventy-seven patients, forty-two did not desire treatment; and thirty-five died before, or within fourteen days of, notification. The slight increase in the death rate for 1933 over that for 1932 is associated by Dr. Turner with the economic depression which was widespread in the city. The percentage of patients dying within a year of notification is still large, but it is admitted that in a certain number the disease ran a very rapid course. Three cases occurred in milk handlers during the year. The large figure of 2,403 sent to the dispensary for diagnosis indicates that medical practitioners are making full use of its services. Of patients notified during life 88.16 per cent. had been sent to the dispensary prior to notification. The ultimate diagnosis of suspicious cases often entails observation for long periods, and in many cases residence in the observation beds in sanatoria. There were 2,912 contacts examined from the homes of notified cases, and of these it was found desirable to retain 40.38 per cent. for observation and treatment. It is recognized that this is one of the most valuable activities of the department, since it is among this section of the population that tuberculosis is most likely to occur in the future.

Food Inspection at the Port of Manchester

The inspection of imported joints of meat through the Port of Manchester involves the exercise of great vigilance, owing to the operation of what is known as the "direct traffic" system. A special rate is quoted by the Manchester Ship Canal Company for all goods landed direct to road transport vehicles, railway vehicles, or barges, and the importers take every opportunity of securing this facility. All frozen meat is handled in this manner, and, although refrigerator space is provided at one berth, it has not for a great number of years been used for meat storage. Only a cursory examination of such imported meat is therefore possible, and the finding of any damage or disease generally entails transferring the full inspection from the port sanitary authority to the local authority of the district to which the particular consignment is to be delivered. In his annual report for 1933 Dr. E. H. Walker, medical officer of health to the Port of Manchester Sanitary Authority, finds that the importation of joints and other small portions of carcasses militates against efficient inspection at this port, owing to the lack of accommodation and facilities for "defrosting" before examination and rehardening afterwards. It is therefore essential that permitted imports should be thoroughly inspected at the time of slaughter, and bear evidence of this on each particular part. He adds that it is of the utmost importance that the certificate from the country of origin shall be trustworthy. An illustration of checking, both as regards quantity and quality, is provided by the catalogues issued by the various fruit brokers. All food and vegetables sold by such firms are graded according to soundness or otherwise, and a catalogue issued before each sale gives full details of the amounts and condition of the various articles offered for purchase. Copies of these catalogues are obtained each day when there is a sale, and an inspector can ascertain from these the condition of any consignment. It is agreed between the brokers and the port sanitary authority that any consignments which show 50 per cent. of unsound fruit shall be sorted on the quay by the buyers, under supervision by the inspector. A list of the various seizures on the dock quays during 1933 includes seventy-three tons of wheat, fifty-seven tons of maize, thirty-six tons of apples, eight tons of oranges, and six tons of tinned beef.

Scotland

Undulant Fever Investigations in Aberdeen

In his report for 1933, Dr. H. J. Rae, medical officer of health for Aberdeen, includes a summary by Dr. J. Smith, the regional bacteriologist, of examinations undertaken to ascertain the possible sources of infection in undulant fever, and the incidence of *Brucella abortus* in the milk of individual cows. No samples of butter from local or English farms or Colonial or foreign sources contained this organism, but five out of the fifty-one locally prepared butters contained tubercle bacilli. No margarine or cheese samples contained *Brucella*, but two out of six locally prepared cheeses were found to be infected with tubercle bacilli. No ice-cream samples were so infected, but the inquiry was hampered by the fact that in some cases the ice-cream was contaminated with various anaerobes which produced intense infections in the experimental animals. Arrangements were made to examine the blood of practically every man engaged in the slaughtering and meat trade business. Out of 106 sera examined fifteen agglutinated *Br. abortus* to a dilution of 1 in 25 or more, eleven positive reactions occurred in sera from actual slaughtermen, and four in sera obtained from men in the meat trade. From the slaughtermen five sera agglutinated the organism to a dilution of 1 in 25, five to 1 in 50, and one to 1 in 100. Sera from the men engaged in working with carcasses, hides, and offal agglutinated *Br. abortus* to a dilution of 1 in 25 in three cases, and in one to 1 in 50. All the eleven with agglutinins of 1 in 25 or more in their sera were engaged in killing all the three types of animals—sheep, cattle, and pigs. It was also found that in slaughtermen the positive reactions occurred in those who had been thus employed for eleven years or more, whereas in those engaged in handling hides, carcasses, and offal, three out of four positive reactions were found in men who had been employed for less than ten years. Furthermore, when the relation of agglutinins in age groups in the abattoir workers was compared with the agglutinins in the sera of normal individuals in the same age groups, a greater incidence emerged in the slaughtermen and other workers with animal products. Thus 16.1 per cent. of sera from slaughtermen and 10.3 per cent. of sera from men working in allied trades agglutinated *Br. abortus* to a dilution of 1 in 25 or more, as compared with only 6.8 per cent. of sera from normal men. When the men who showed agglutinins in the blood were questioned as to a history of previous illness, no evidence was obtained that any of them had suffered from an illness suggesting undulant fever. Dr. Smith presumes, therefore, that latent infections must have occurred in some to give rise to the higher incidence of agglutinins. Bovine infections by this organism are very prevalent, but there is so far very little evidence that sheep or swine are similarly attacked. Examination of samples of blood from sheep and swine only showed agglutinins present in 0.9 per cent., and then only to a dilution of 1 in 25, which can scarcely be regarded as significant. Specimens of porcine uteri, bladders, and spleens were entirely negative to *Br. abortus*, but 12.5 per cent. were infected with tuberculosis. A herd of eighty-four cows which had been vaccinated against *Br. abortus* were examined. Of thirty-one with serum agglutinin titres of 1 in 400 or more, ten (32 per cent.) were excreting this organism in their milk, and 60 per cent. of those with titres of 1 in 800 or more were found to be excreting it. It was noted that, despite vaccination and contact with infection, four out of this herd failed to show agglutinins in the blood in a dilution of 1 in 25, while 95.2 per cent. gave positive agglutination reactions in dilutions ranging from 1 in 25 to 1 in 12,800. No

indication was found that the whey agglutinins had been formed locally. Presumably their appearance was due to damage of the secretory apparatus previously by infection, this damage allowing the serum agglutinins to percolate into the milk. Two out of the ten strains of the organism which were isolated were found to grow in the normal atmosphere without the addition of carbon dioxide. It is held that these strains were probably established in the udder as a result of vaccination with a living strain having the same cultural peculiarity. Out of 203 random samples of milk from cows *Br. abortus* was recovered by guinea-pig inoculation in twenty-three (11.3 per cent.)—a figure comparable with that obtained from the herd of vaccinated cows.

New Zealand

[FROM OUR CORRESPONDENT IN WELLINGTON]

Medical Practice and the Law

An important judgement of the Supreme Court has been given in a claim against the Waitaki Hospital Board for £2,000 damages for injuries alleged to be due to negligent treatment by nurses. The plaintiff, who was injured at a hydro-electric works, was in a state of collapse after operation, and the house-surgeon ordered the use of a radiant heat cradle, during the application of which one of his knees was burned. Some time after discharge septic infection necessitated amputation of the leg. The judge held that in some unobserved period the patient was burned on the knee, and that such injury would not have occurred had the nurse in charge properly applied her professional skill. His Honour said, however, that in her professional treatment as apart from her ministerial treatment of a patient a nurse was bound to apply her professional skill and training subject to the orders of the doctor, not of the board. The proper inference was that the board could not interfere by rule or superintend her work. In such circumstances and in such treatment under the doctor she was not the board's servant. The neglect was not in the matter of mere ward duty or routine, but in the discharge of professional duty, and judgement was therefore given for the defendant board with costs.

In another recent case in the magistrate's court a chiropractor was sued by a woman for damages amounting to £48 for pretending to cure a neck injury by treatment extending over six months, and thereby causing her great pain and suffering. The chiropractor said that he had made a diagnosis of insomnia and neuralgia, the symptoms coming from the region of the neck as shown by x-ray photograph. Medical evidence, however, was to the effect that the treatment administered was unsuitable and aggravated the complaint, and x-ray examination showed nothing abnormal. The magistrate gave judgement for the full amount claimed and costs.

Restricted Entry of Medical Students

There is one medical school in New Zealand, at the University of Dunedin, but mild attempts have occasionally been made to obtain authority to establish another at Auckland. There is no doubt that the number of hospital beds in Dunedin available for clinical teaching is rather limited, but this difficulty has been partly overcome in an agreement whereby in the student's final year part of his clinical work may be done at the hospitals at Wellington, Auckland, or Christchurch. Furthermore, owing to the comparatively large number of public hospitals in New Zealand requiring house-surgeons, a larger supply of medical graduates is needed for junior resident appointments than can later be absorbed in private prac-

tice. Some lay critics do not hesitate to express the opinion that, as regards the number of young doctors starting private practice, the more the better, and the survival of the fittest will best serve the public. Medical practice will thus become a struggle for existence, of economic as well as of biological interest. The problem in New Zealand is further complicated by the necessity for young medical graduates of this Dominion to proceed to Great Britain for further experience, post-graduate study, or the taking of higher diplomas. However, the university authorities have, temporarily at least, removed the problem from Parliament, the people, and the Press by authorizing a definite restriction in the number of medical students, and at the stage of the beginning of the second academical year. The test is to be based purely on scholarship, or, as some might say, on a transitory retentiveness of memory, and not also on heredity and environment, as birth, upbringing, character, and manners, all of which are considered in the admission of students to the older medical schools of the United States of America. The University Council has decided that sixty students are to be accepted at the beginning of the second academical year, and an order of precedence is established, whereby first opportunity is given to candidates who are already graduates of another faculty, and second opportunity to students who have taken a year's science course beyond the requirements of the first professional examination, and the third category consists of those, in order of merit, who have passed the first professional examination (still called the "intermediate" in Dunedin). The experiment of setting up a hurdle at the end of the first year has something in its favour, and the results will be watched with interest.

Causes of Mortality

"Although the total number of deaths registered in 1933 (11,701) was eighteen more than in the previous year, the death rate shows a slight increase—7.98 as against 8.02 for 1932—and sets a new low record," states the report on vital statistics of New Zealand for 1933. The rate of deaths in the first year per thousand of live births was 31.64 compared with 31.22 the previous year—a slight increase. The report points out that the greatest success in combating the infant mortality problem has been attained between the ages of one and twelve months. During the last ten years the death rate in this group has been almost cut in half, but little success has attended the efforts to reduce the mortality at much younger ages in recent years. The rates for deaths occurring within one week of birth have shown but little response, and indeed for 1933 indicate on the whole a slight retrogression. The nearer the moment of birth the less is the decline in the rate observed. Judged on the basis of total death rate alone, it may be said that the health record for New Zealand for 1933 was even more satisfactory than for the previous year. An examination of some of the principal causes of death, however, tends to detract somewhat from that pronouncement. Outstanding among the increases noted is that for cancer, which with 1,624 deaths not only reached the peak for New Zealand but also registered an increase of 152 over the previous year. The largest upward move, however, goes to heart disease, deaths from which advanced by 163 in comparison with 1932. Then cerebral haemorrhage, another of the degenerative diseases, increased by sixty-six, and it would appear that, generally speaking, the greater part of the increased loss of population by death during 1933 may be attributed to diseases of later life and those associated with the degeneration or wearing out of the human structure. In striking contrast to the white races, the death rate from cancer among Maoris is remarkably low, although the

experience is similar as far as the upward movement of the rate is concerned. It is probable that the exceedingly high death rate from tuberculosis is exerting a certain influence towards keeping the cancer death rate fairly low among Maoris.

India

A Public Health Textbook

When a medical practitioner has been born and brought up in a small Punjab village, has studied in Indian schools, qualified in Edinburgh and Cambridge, practised for some twenty years as M.O.H. in two Lancashire towns, and returned to work in India, he is well equipped for writing a useful outline of public health as applied to the conditions to his own country. This Dr. N. R. Dharmavir has done, and his book *Public Health in India*¹ can hardly fail to be of service to those to whom it is addressed—namely, to health and welfare workers, nurses, teachers, and the rulers of municipalities. It deals fearlessly with the public health conditions as he finds them, particularly with the ignorance that still permits preventable diseases to spread, infant mortality to persist, and many Indian women to live unhealthy as well as hopeless lives. Some of the revelations made will help Europeans to understand how difficult it is to promote health—for example, the unpleasant personal habits of some otherwise most respectable Indians, the unsatisfactory dietaries of the urban populations, and the insanitary dwellings and unhealthy villages. Dr. Dharmavir expounds simply and lucidly the principles of right living from the public and private health standpoint. He describes the nature of the more prevalent infectious diseases, emphasizing the possibilities of prevention as capable of being practised by laymen. He fully appreciates the importance of climatic considerations, and gives sound advice about the necessary modifications of life which the Indian sun and rainfall impose.

Urban Sanitation in the Punjab

New sanitary projects are being brought into being in the Punjab as fast as funds will permit. In 1932 they numbered twenty-two, and were a response to urgent needs in respect of schemes for water supply, drainage, sewerage, which could not be left unregarded. The Government and local bodies were alive for the most part to their duties of providing the necessary sanitary amenities within the areas of their respective jurisdiction, but it has to be recorded by the director of public health for the Punjab in his report for 1932 that in some cases the local bodies neglected to keep and maintain such works in proper repair. Major Malhotra, I.M.S., states that the inspection reports of the officers of the public health department, especially on waterworks, revealed many examples of such neglect, but that repeated urgent representations to the authorities concerned had resulted in bringing about a better state of things. In the forty-three towns supplied with a piped water supply the expenditure exceeded the income, except in the case of seven. This will involve the levying of a water tax and the metering of all public and private connexions. Such measures will prevent the waste and extravagant use of water, and will also bring in money for the extension, maintenance, and improvement of waterworks. Experience has shown, however, that very little effort is made by urban authorities to enforce the metering of water supplies, owing to their unwillingness to incur local odium, but until this is done, Major Malhotra insists, no progress is possible. There is need also for a complete overhauling

of the conservancy arrangements. The problem of water-flushed latrines and urinals in towns is becoming more urgent, as is also that of sewerage schemes. At present no town in the Punjab is completely sewered, and accordingly, owing to the lack of proper arrangements for the disposal of effluents from these installations, the danger of contamination of the water supply and the consequent rise in the incidence of water-borne diseases is bound to occur. As regards religious fairs, the incineration of night-soil has now become the recognized policy of the public health department, the burial system which was previously in vogue having been completely discarded. At all fairs, whether of local or provincial importance, this policy was advocated persistently and persuasively until the local authorities were converted to incineration. The result is that at almost all fair sites permanent latrines, urinals, and incinerators are being constructed. This method of disposal of human excreta is not only safer, but it is at the same time cheaper, since the maintenance charges incurred are merely nominal. No deaths from cholera were reported at any of the fairs.

The Bombay Small-pox Epidemic

Small-pox is rarely absent from Bombay, and sporadic cases occur through the year. Dr. J. S. Nerurker, the executive health officer of the city, gives in his report for 1933 an account of one of the severest epidemics that have ever occurred there. In October, 1932, there were twenty-nine cases, and fifty-one in the following month. A sudden rise occurred in December, fifty-eight cases being notified for the week ending December 17th, an indication of the coming of a severe epidemic which lasted until the beginning of June, 1933, causing 4,487 attacks with 2,676 deaths. The two worst months were February and March. As soon as the disease was officially declared to be an epidemic in December, 1932, the usual preventive measures were put into force. Notices were issued in the public press and posters were put up in various parts of the city instructing the public in methods of precaution. Letters were addressed to mills, schools, colleges, banks, and various other similar institutions, offering vaccination at their premises free of charge, an offer widely and gratefully accepted. Small-pox slides were shown in most of the cinemas, advising people to be vaccinated or re-vaccinated. Letters were also written to general practitioners urging them to co-operate in instructing the community, and offering free supplies of lymph for mass revaccinations. Besides the twenty-one permanent vaccination stations, twenty-one temporary ones were opened. The number of primary vaccinations during the year was 33,439 as against 23,783 in 1932, and that of revaccinations 243,102 as compared with 12,436 in the previous year. The proportion of primary vaccinations in children under the age of 1 to the total number of births reached the high percentage of 72, while the numbers of primary vaccinations and of revaccinations were the highest on record. The accommodation supplied by the 160 beds in the Arthur Road Hospital proved sadly inadequate. All the available space, including that in the general unit, had to be devoted to receiving small-pox cases. A record number of cases were admitted, the highest number on one day being 436 on March 12th, 1933. Dr. Nerurker argues that, whatever precautions are taken and preventive measures adopted, Bombay can never be made free from small-pox. Experience has shown that the only effective measure to control it is revaccination. The Bombay Vaccination Act unfortunately does not provide for compulsory revaccination, which Dr. Nerurker maintains it should do, since periodical compulsory vaccination of the community would secure a considerable degree of immunity.

Reports of Societies

EXERCISES AND MANIPULATIONS IN SPINAL CONDITIONS

At a meeting of the Section of Physical Medicine of the Royal Society of Medicine on December 21st, Dr. J. B. Burr presiding, two demonstrations were given, the first by Dr. T. Stacey Wilson of Birmingham on the value of rapid rhythmical exercises as an alternative to osteopathic manipulations for the cure of back pain, and the other by Dr. J. B. Menzell on joint manipulation as applied to the sacro-iliac joints and the joints of the spinal column. Both were assisted by living models, on whom the movements were demonstrated, and Dr. Jeffery gave an appendix to Dr. Menzell's address with some ingenious anatomical puppets.

RHYTHMICAL EXERCISES FOR BACK PAIN

Dr. STACEY WILSON said that he fully believed in the value of osteopathic manipulations; what he had to bring forward was an alternative method of treatment for those who, owing to distance or want of means, could not get into touch with a trained manipulator. The back pain which was curable by osteopathic manipulations appeared to be due to fixation of intervertebral joints by involuntary muscular activity. Once involuntary muscular activity had originated it was liable to persist as a habit phenomenon for months or even years, and the fixation of the joint might prevent other structures from returning to their normal relationships. He had himself suffered for a long time from a subluxation of vertebrae, with pain in the back, due to a badly judged jump from a diving-board, and one day it was suddenly and entirely cured when he jarred his spine by stepping from the pavement into the gutter. The exercises which had been found useful consisted of rhythmical to-and-fro muscular movements having a rapidity of about eight complete movements in five seconds. Such simple exercises were capable of dominating involuntary muscular activity and counteracting habit-fixation of joints.

During the war he had under his care three soldiers who were incapacitated by back pain resulting from strain after being blown into the air by shell explosions. He devised a series of exercises which he made them practise three or four times a day, and within two or three weeks they were completely cured. He mentioned another case, a woman of nearly 70, with back pain due to extensive fixation of the dorsal vertebrae. The pain had been attributed to gastric disturbances, although it was bilateral, but it cleared up under exercises, with perfect restoration of mobility. Another case was in a woman of 36, in whom neck pain following strain had been recurring for nine years. It was cured in a few minutes, and when later it made fugitive reappearances due to habit fixation immediate relief was found in the exercises.

Dr. Wilson then gave a demonstration of the movements. In the case of the spine rotatory movements were made, the patient sitting upright and swinging the whole body and the head first to the right and then to the left, making eight such movements in five seconds. The movement was a kind of purposeful throwing of the body. It called into play the muscles which were fixing the vertebral joints, and if of sufficient rapidity it caused relaxation of the spinal muscles as complete as could be done by osteopathic manipulations. The patient repeated aloud the figures 1 to 8, partly because it assisted the rhythm, and partly because it gave definiteness to the movements. It was not usually possible to carry them on beyond eight, owing to giddiness. If the pain was in the lower part of the dorsal region the patient bent forwards, with the spine almost horizontal, and worked round an axis as far as possible, first to right and then to left. The manipulative method was preferable, especially with a somewhat neurotic patient who would not carry through the exercises, but the exercises had a very real value, and should be commended especially to the country doctor, whose patients might not be able to get manipulative treatment.

JOINT MANIPULATION AS APPLIED TO THE SPINE

Dr. J. B. MENZELL first showed a number of x-ray photographs to illustrate the movements of the sacro-iliac joints and of the joints of the spinal column, showing the ordinary limits of movement in any healthy young adult. He then proceeded to a demonstration of treatment by manipulation to show how fixation could be secured at each level, so that a mobilizing strain might be placed upon the joints in each section of the spine, with a minimum expenditure of force, of exertion, of discomfort to the patient, and a maximum of control, while at the same time securing the relaxation which is an essential part of mobilization treatment. The movements in the different areas of the spine, he said, must be different in each section. It was quite out of the question that they should have been given such differently shaped articular processes if they were not meant for different movements. There was no sudden jump from a lumbar vertebra to a thoracic, or from a thoracic to a cervical; there must be transition from the one to the other, where the vertebrae and their articular facets were altering in shape, and, where there was movement, in function. Relative instability was likely to be chiefly noticed where the vertebrae were not typical—that is to say, in the transitional portions—and this in practice was actually found. Weakness, for example, was most common at the lumbosacral junction. Again, where there was an area of limited movement, as in the upper thoracic vertebrae, which were anchored down by the short and very substantial first rib, liability to disturbance of function was greater than where a wide range of movement was in any way possible.

He had never been able to understand why the same symptomatology was denied to the joints of the spine as was conceded to the joints of the extremities. Yet few of them had been bold enough to write down in black-and-white that a patient was suffering from traumatic arthritis with fluid present in the joint between the second and the third lumbar vertebrae. But why not? The condition must occur. An irritable joint in the spinal column, as elsewhere, was liable to be splinted with the patient's own muscles, with results well known to them all. Just as it was now generally agreed that it was not unwise to manipulate a knee that showed in the x-ray photograph a few bony and cartilaginous changes, so one was justified in freeing the joints of the spine by manipulation. He mentioned that, under an anaesthetic, he had manipulated the necks of two ladies, both of them well over 80, one for sheer pain, and the other for a spasmodic torticollis, with very gratifying results in both. If an anaesthetic was required on account of acuteness of symptoms the same technique which he had demonstrated for securing a mobilizing strain on each section of the spine was generally available. The movements which he showed were, for the most part, not under voluntary control; these, therefore, could not be performed by ordinary active exercises.

Dr. Menzell next considered the possibility of symptoms being referred from the joints to distal parts. The possibility of referred pain must be borne in mind. On an injury to the wrist, for example, pain shot up the arm. The extraordinary distance over which pain might be referred was exemplified by the use of the hypodermic needle when it began to get blunt. The fact of this referred pain accounted for many of the much-acclaimed successes of the unqualified osteopath. The patient came forward with a story of pain in the breast, and perhaps a lump was felt. Mastitis was immediately diagnosed; or it might be pain over the heart region, and nothing would persuade the patient that it was not an angina, and afterwards the manipulator was declared to have cured an incipient cancer or a heart disease, as the case might be, when actually what was wrong was in the chest wall, and relief was obtained by manipulation of the bone and joint structures. It was similar with supposed cases of gall-stones or gastric trouble. Pain in the abdominal wall over the region of the gall-bladder or of the stomach had been cured by manipulation. Often, therefore, the osteopath rode off with the credit of having cured a whole set of conditions which had never existed at all.

ANTI-STREPTOCOCCAL SERUM FOR "RHEUMATIC" AFFECTIONS

At a meeting of the Liverpool Medical Institution held on December 6th, with the president, Dr. J. MURRAY BLIGH, in the chair, Dr. ROBERT COOPE and Dr. F. PYGOTT presented a short paper on "The Use of Anti-streptococcal Serum in certain 'Rheumatic' Affections."

The authors prefaced their remarks by a quotation from one of Trousseau's clinical lectures: "When a patient runs an imminent risk it is justifiable, or at least it is excusable, to use every remedy, as in such a case we cannot make bad worse. Still, even in such cases, our therapeutic action must be defensible in theory and by an appeal to analogy." They presented for consideration a series of nine recent cases in which they had felt driven by clinical necessity to try the effect of anti-streptococcal serum.

One patient, a middle-aged man, had a post-scarlatinal non-suppurative arthritis of the hip-joint, which did not improve with immobilization and heavy dosage with salicylate; intramuscular injection of 20 c.cm. of scarlatinal antitoxic serum was followed by rapid recovery.

The remaining eight patients, all adults, were seriously ill with acute polyarthritis, and in all but one there was a clear history some nine to twelve days previously of severe "sore throat." In four of them the illness was associated with erythematous nodules in the skin; they were patients whose ages varied from 43 to 52 years, and there was no evidence of active tuberculous infection. Their erythema nodosum was but an incident in a generalized severe "acute rheumatism," which did not improve on intensive treatment by salicylate. They all responded quite dramatically to one or two doses of serum (in two cases scarlatinal antitoxin was used, in the other two polyvalent streptococcal antitoxin). Of the other cases, one was desperately ill and incontinent, but after the injection of 20 c.cm. of the polyvalent serum on two successive days he was greatly improved and went on to full recovery.

In another patient, a woman of 35 years, who at the time she fell ill was actually waiting to be admitted for removal of unhealthy tonsils, the acute polyarthritis was complicated first by a toxic nephritis and later by double basal pneumonia. Blood culture revealed a non-haemolytic streptococcus, and two doses of 20 c.cm. polyvalent anti-streptococcal serum were given. The general condition improved, but she then developed an intense urticaria and serum sickness, and nearly died. After that, however, the temperature fell to normal and she slowly recovered.

The remaining two patients were not quite so gravely ill. One young man, in spite of treatment and the disappearance of his fever, had a series of relapses of the arthritis. Three days after a single injection of 20 c.cm. of scarlatinal antitoxin the pain and swelling of the joints subsided, and there were no further relapses. Another patient, seriously ill with polyarthritis and pericarditis, improved temporarily after 30 c.cm. of serum, but later had a series of relapses, involving the throat and joints.

Looking back on the last case, Drs. Coope and Pygott felt that at the time they lacked confidence to repeat the injection, and should have done so. In all the cases treatment by large doses of salicylate was ineffective. In the light of these experiences they suggested that whatever may be the effective mechanism of recovery, whether specific or non-specific, the use of serum treatment in similar cases was worthy of trial.

Sterility with Ovarian Dysfunction

Mr. T. N. A. JEFFCOATE read a paper on "Sterility due to Ovarian Dysfunction," based on the records of 654 patients complaining of sterility of at least two years' duration. A classification of the aetiology of sterility revealed the fact that no abnormality of any kind was present in 17.3 per cent. of cases. Of the patients 12.3 per cent. had no gross lesion, but complained of some menstrual upset—in addition to sterility. The view was put forward that the poor results attending treatment of this condition are due to failure in the diagnosis of the underlying cause. The cause lies frequently, not in any anatomical defect, but on some physiological upset in the ovary. An outline of the modern conception of the normal ovarian and uterine cycles was followed by an explanation of the various types of menstrual irregularity. It was pointed out that all menstrual disturbances, apart from epimenorrhoea, are characterized by absence of, or

infrequent, ovulation; hence the sterility encountered in patients presenting these symptoms. The results of examination of premenstrual curettings from sixty-three patients who had regular uterine haemorrhage (but did not necessarily complain of sterility) were given; these showed that 25.4 per cent. of these women exhibited anovular menstruation. It was suggested that anovular menstruation is even more prevalent in patients complaining of sterility. An appeal was made for the performance of curettage during the premenstrual or menstrual phases, as an essential part of the investigation of sterility. In this way anovular menstruation should be recognized. A method of treatment of this type of ovarian dysfunction was outlined.

Mr. M. DATNOW said there could be no doubt that insufficient stress had been laid on physiology as an aetiological factor in sterility in the past; this was especially so in the case of the ovarian cycle, as was evidenced by the common lay fallacy that a woman is most fertile just after and just before menstruation, instead of during the middle fortnight of her cycle. The fact that menstruation could occur without ovulation (anovular cycle) had been recognized (although controverted) for some considerable time. In rabbits not infrequently the follicles did not rupture and pseudo-pregnancy ensued, with all the uterine and general changes of pregnancy, terminating with lactation about seventeen days after oestrus. Mr. Datnow stressed the importance of inquiring carefully into the menstrual history of every patient who complained of sterility. The time of follicular rupture was fairly constant for any particular individual, and the speaker had frequently been told by patients that they always became pregnant on or about the same day of their cycle. This made him advise his patients who sought advice for their sterility to resort to coitus during different weeks of the cycle each month. He pointed out the importance of correlating the ovarian picture with the histological findings in the endometrium, which Mr. Jeffcoate had not stressed enough. In patients suffering from dysfunction and irregular menstruation there was no doubt that one could see histological appearances illustrative of all the phases of the endometrial cycle in any one uterus. The speaker was not convinced that curettage and examination of the curettings would be of any more value than merely to prove that there was dysfunction. He felt that it was more important to make an analysis of the hormonal content of the blood and urine in those cases of sterility with dysfunction, which really only formed a very small percentage of the total, in order to determine those hormones that were in excess or lacking, so that the appropriate treatment could be applied. It was the absence of a fertilized ovum rather than the presence of a new "hormone Z" suggested by Mr. Jeffcoate, which precipitated the menstrual flow.

INTRATRACHEAL ANAESTHESIA

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland, held on November 23rd, with the president, Mr. SETON PRINGLE, in the chair, Dr. R. W. SHAW read a paper on "The Intratracheal Method of Anaesthesia."

Dr. Shaw said that this method was first practised about the year 1886. The apparatus used was a modification of that designed by Fell and O'Dwyer for the treatment of laryngeal diphtheria by intubation. The great advantage of the method in those days was that it permitted, for the first time, operative surgery in the thoracic cavity. One of the first operations of this kind was performed in 1898 by Parham of New Orleans. Improvements in the technique continued to take place between the years 1900 and 1910, but the intervention of the war somewhat retarded its development. Up to 1920 the method in use was known as "insufflation endotracheal anaesthesia," but in that year Rowbottom and Magill reported their experiences in surgery of the head and neck, using the method of to-and-fro breathing through a laryngeal tube, calling the method "inhalation endotracheal anaesthesia." The essential difference between these two methods was

that with insufflation the anaesthetic vapour was delivered into the trachea under pressure through a catheter which was not large enough to fill the rima glottidis; expiration then took place around this catheter. With the inhalation technique the catheter used was of such a size as nearly to occlude the laryngeal cleft. Inspiration and expiration took place through this tube, and no pressure, or very low pressure, was used. This method had now completely displaced the older method of insufflation. It was simple to use once skill and facility in the introduction of the catheter had been achieved. The catheter might be introduced (a) through the nose, and (b) through the mouth. If introduced through the nose the "blind" method, as described by Magill, could be adopted, or a laryngoscope and special forceps might be necessary. When introduced through the mouth the catheter was always passed by direct vision with a laryngoscope. Any efficient gas-oxygen-ether machine could be used for maintenance of anaesthesia, and a minimum of ether was required. The patient must first be anaesthetized by N_2O -ether sequence, or basal anaesthesia combined with cocaineization of the larynx might be found more convenient. In an experience of over forty cases the method had proved entirely satisfactory, more especially for the surgery of the head and neck.

The PRESIDENT said that there were many cases in which intratracheal anaesthesia was of the greatest possible service, but he did not think it would ever come into any very widespread use. He did not believe it was necessary for cases of non-toxic goitre, and in these he personally had found the block method very satisfactory.

Mr R. ATKINSON STONEY referred to the amazing change which had taken place in the giving of anaesthetics in the last thirty years; he felt, however, that in spite of the improvements there had also been an increase in the complications of anaesthesia. Mr T. J. D. LANE said he thought intratracheal anaesthesia was the best method in many cases, and that for some operations the only apparatus necessary could be carried in the pocket. Mr W. DOOLIN thought that in the last five years anaesthesia had developed even more quickly than surgery, and had developed in response to the surgeon. He was convinced that intratracheal anaesthesia was the method of choice in facial surgery, especially in cases of cleft palate.

Mr A. CHANCE said that he felt very confident regarding this method of anaesthesia. A number of the cases quoted by Dr. Shaw were cases of his, and in all of them the result had been most satisfactory. The method was of great use in thoracic surgery. Dr J. J. FITZSIMONS said that he had not used gas and oxygen intratracheally, but he had used McKesson's apparatus, very similar to Walton's. On getting the laryngoscope at the side of the mouth it was possible to see the epiglottis more easily. Dr T. G. WILSON referred to the favourable results of intratracheal anaesthesia in laryngology. He felt that the method was the safest and best for operations on the upper air passages. It dispensed with the nasopharyngeal plug, which was such a nuisance.

At a meeting of the Medical Society of Individual Psychology held on December 13th with Dr. JAMES YOUNG in the chair, Dr. FRANK BODMAN read a paper in which he dealt with the psychological background of patients suffering from colitis. In a series of cases he demonstrated the gradation in the series—functional diarrhoea, mucous colitis, and finally ulcerative colitis. He showed how the ideas of bowel function were associated in the child's mind by training with ideas of good and evil, and how the child learnt to exercise its power over its relations by controlling the action of its bowels. After describing a series of cases of colitis in young women starting to earn their living, of colitis in pregnancy, and, finally, of colitis in women whom he described as "rolling stones," he showed how colitis might be a "flight into illness," and that many of these patients had a family background of a father's home and a widowed mother with a strong personality.

CORRESPONDENCE

Endowment of Clinical Science

SIR,—In your leading article on this topic in the *Journal* of December 15th (p. 1106) you say that there are some who consider that too big a proportion of the funds provided out of public sources for medical research goes to subjects whose medical aspect is somewhat remote. Can you not inform us, roughly, what the annual amounts of these funds are, and how they are apportioned? I think you would do a public service if you would, and that future discussion on this topic would be clarified.

No one would wish to belittle all the aid to the progress of medicine that the ancillary sciences have given. All praise to such men as Sir Gowland Hopkins for the great work they have accomplished. But is it not well to remember what is the original derivation and meaning of the word "clinical," and that there is still room for encouraging purely clinical observation by endowment? Sir Gowland Hopkins, you say, suspects that some clinicians fear that the introduction of multitudinous laboratory methods into the domain of diagnosis is tending to destroy the true clinical art. This suspicion has good foundations, and its causes are not unconnected with many of the present-day difficulties of medical education.

Fifty-three years have gone by since Professor T. H. Huxley (before the seventh International Medical Congress of 1881) said: "We are apt to forget that there is such a thing as a pure science of medicine, which has no more necessary subservience to practical ends than has zoology and botany." Since then James Mackenzie has blazed the path along which medicine can go without endangering a serious divergence between the science and art of medicine. William Osler, in an address given in 1899, said: "To cover the vast field of medicine in four years is an impossible task. We can only instil principles, put the student on the right path, give him methods, teach him how to study and early to discern between essentials and non-essentials." But how can such paths be followed so long as only a small proportion of the sums spent annually upon medical research goes to aid those who are following in the footsteps of such keen-minded scientists as Thomas Addison, William Jenner, and Hughlings Jackson? Their great achievements were based upon the employment of truly clinical methods of research. They advanced medicine by painstaking bedside observation, controlled by morbid anatomy and purposeful laboratory experiments; but in that order.

There is a danger of losing sight of the proper perspective in these things. More money spent on true clinical research would tend to readjust the balance between laboratory and clinical methods, would help to direct medicine back to principles. Medicine can never be a science until the causes of *dis-ease* in human beings are so fully unravelled that broad principles and sure rules of practice can be laid down. It still has far to go to reach such a condition, though the writings of Mackenzie, and much work along such lines before and since his time, are bringing it gradually to that state.—I am, etc.,

Mandeville, Dec. 17th.

S. VERE PEARSON.

London University and its Medical Schools

SIR,—A strange statement appears in Professor F. J. Brown's letter in the *Journal* of December 15th. He suggests that forensic medicine and public health are academic subjects with little relation to daily experience in general practice, and that the examinations in these subjects should be taken, say, at the end of the fourth year. I cannot speak for forensic medicine, although I

should have thought it a highly practical subject, affecting the daily work of many practitioners. But it is the reference to public health which surprises me, for it would be hard to think of a subject which is less academic. It is usually taught, both in London and in the provinces, by men engaged in the public health service; and the teaching puts emphasis not only upon the application of scientific knowledge to the prevention of disease, a matter surely of great practical importance to every medical man and woman, but also upon the machinery afforded by central and local governing bodies for securing that such knowledge is applied in an organized way. With these bodies the general practitioner has to work in the closest co-operation to an ever-increasing extent. To relegate this part of the student's training to a stage of the curriculum when he is hardly capable of understanding the terms used, and, by inference, to suggest that the knowledge imparted has little or no bearing upon his future work, would be a peculiar act in these post-war days of State medicine.—I am, etc.,

Cardiff, Dec. 17th.

RALPH M. F. PICKEN.

Treatment of Ruptured Spleen

SIR,—I was very much interested in Mr. Harold Dodd's article on rupture of the spleen, but I cannot concur with him in his advocacy of the transverse abdominal incision for urgent splenectomy. This incision, although a most excellent one in many set operations, appears to me to be out of place in an emergency. First, even after considerable familiarity with it, the transverse incision takes at least three times longer to close securely than the midline incision—an important factor where speed is a consideration. Secondly, as is well known, the tail of the pancreas is sometimes damaged at the time of the injury; consequently, by reason of digestion by escaped pancreatic ferments, any patient recovering from splenectomy for rupture is liable to the unpleasant complication of burst abdomen. A burst transverse incision is more dangerous and far more difficult to repair than a burst midline incision. I have removed a ruptured spleen through a midline upper abdominal incision on seven occasions; all the patients recovered.

For the above reasons, and others I have detailed elsewhere, I feel confident that in the treatment of this catastrophe the midline upper abdominal incision is the incision of choice.—I am, etc.,

London, W.1, Dec. 15th.

HAMILTON BAILEY.

Epilepsy and Nasal Sinusitis

SIR,—In your issue of December 15th (p. 1101) Mr. D. Y. Richardson called attention to two cases of Jacksonian epilepsy in which the associations with acute nasal sinus disease were so intimate as to leave no doubt of the causal relationship to the epilepsy. Having published in your columns and elsewhere¹ cases of recent mental disorder with epilepsy in which intracranial bacterial invasions from nasal sinusitis were demonstrated, and being interested in these cases from the point of view of the study of the aetiology of mental disorder, I should be glad if your readers would write to me regarding any further similar cases which have or may come to their notice.—I am, etc.,

F. A. PICKWORTH,

Director, Joint Board of Research for
Mental Disease, City and University
of Birmingham.

Hollymoor, Northfield, Birmingham,

Trichlorethylene

SIR,—I should like, through your columns, to draw attention to the use of trichlorethylene as a surgical skin cleanser. It is a powerful "degreaser," and as a wound cleanser is, in my opinion, greatly superior to the better-known preparations such as surgical spirit, methylated ether, etc. It is non-inflammable, non-irritating, and has a Chick-Martin coefficient of 0.9. As it is also a good solvent for tar, it is particularly useful in the treatment of tar burns, as illustrated by the following case, which also bears out the fact of its non-absorption through the skin.

On September 21st, 1934, a boy aged 9 was playing with a tar-spraying machine when he fell beneath the tap, which was turned on by a companion, with the result that boiling tar ran out over the patient. He was admitted to the General Hospital, Birmingham, at 10.30 p.m., with several tar burns on the face, neck, chest, parts of both arms and forearms, areas of the abdomen, back, both thighs, both legs, and the left foot. The tar burns were cleaned with trichlorethylene under a general anaesthetic, and subsequently coagulated with tannasavine. The following morning the boy's condition was good and he was free from pain. He has made an uninterrupted recovery, except for a little mild sepsis on the seventh day.

It is interesting to observe that the boy's urine remained normal throughout, whereas in tar burns it is usual to find albuminuria due to absorption of phenol. I personally have seen death occur from an acute kidney damage by a tar burn the size of a saucer. I am indebted to Mr. H. H. Sampson, honorary surgeon to the Birmingham General Hospital, for permission to publish this case.—I am, etc.,

Witton, Birmingham,
Dec. 6th.

H. B. TRUMPER,
Regional Medical Officer, Imperial
Chemical Industries.

SIR,—My attention has been directed to the following paragraph on page 2 in *Industrial Maladies*, by the late Sir Thomas Legge (Oxford Medical Publications):

"Again, the rapidity of absorption is important, for, with some poisonous gases in sufficient amount, it is so quick as to cause instantaneous unconsciousness (carbon monoxide, sulphuretted hydrogen gas, trichlorethylene)."

I have had very considerable experience of the effects of chemicals and the measures of protection. It is well recognized that the effect of carbon monoxide and sulphuretted hydrogen of sufficient quantity is dangerous, because of the rapidity of the onset of the symptoms of poisoning, and in some cases sudden unconsciousness.

In the case of trichlorethylene, however, my experience of the effects of this substance is at variance with the above paragraph. Trichlorethylene is similar to other chlorinated hydrocarbons such as dichlorethylene, perchlorethylene, and chloroform in that it is a narcotic, and it is similar to chloroform in that it does not produce sudden unconsciousness.

In these circumstances, the classification of trichlorethylene with carbon monoxide and sulphuretted hydrogen appears to me not to be in accordance with fact.—I am, etc.,

THOMAS E. A. STOWELL, M.D., F.R.C.S.,
Chief Medical Officer, Imperial Chemical
Industries, Ltd.

London, S.W.1, Dec. 17th.

** Trichlorethylene (C₂HCl₃) has been used for relief of trigeminal neuralgia (Glaser, 1931, *Journ. Amer. Med. Assoc.*, xcvi, 916), and the drug is included in *New and Non-official Remedies*, where the maximum daily dose for inhalation is given as 60 minims. This dose does not appear to produce toxic effects. The toxicity of trichlor-

ethylene as compared with carbon tetrachloride is a matter of dispute (*Journ. Amer. Med. Assoc.*, 1934, cii, 1250). McCord (*ibid.*, 1932, xcix, 409) says that the toxicity of these two compounds is equal. He found that application to the skin of rabbits of 1.2 c.cm. trichloroethylene per kilo daily made the animal ill but was not fatal in seven days, whereas 3.8 c.cm. per kilo a day killed in five days.—ED. B.M.J.

Fractures of the Neck of the Femur

SIR,—Mr. Maurice Sinclair does me the injustice of condemning me unheard (December 8th, p. 1072). On the basis of nothing more than one phrase in a very brief report of my paper he attributes to me a series of opinions which I do not hold, and then proceeds to attack them. I have never doubted the value of the Thomas splint in first-aid treatment; the fact is that first-aid treatment was not under discussion. The treatment of gunshot wounds with compound fractures was not under discussion; the treatment of spontaneous fractures in malignant disease was not under discussion, and a considerable part of Mr. Sinclair's letter is a criticism of views which have never been expressed.

The only fracture to which reference was made was the simple subcapital fracture of the femur in elderly patients. I made two observations on the use of the Thomas calliper and knee-splint in this injury: (1) That many patients are so old and feeble that the treatment of the general condition is of greater importance than the immobilization of the fracture, and that in such cases early ambulation in a Thomas calliper is advisable. (2) That if the patient's general condition is so good as to justify operative fixation of the fragments with a Smith-Petersen nail, the Thomas knee-splint or calliper is dangerous, and is not to be recommended at any stage of such treatment; if in any case the operator feels that external fixation is advisable in addition to the nail, a plaster spica should be employed and not a Thomas splint.

The Thomas knee-splint does not, and cannot, immobilize the hip-joint. It was never intended to do so, and even Hugh Owen Thomas himself designed a different splint to immobilize the hip. In the course of my paper I brought forward clinical and radiographic evidence to prove that even a plaster spica does not always prevent rotation movement of the trunk and pelvis, and therefore of the detached head of the femur. It is obvious that a splint which does not even extend beyond the level of the fracture is still less capable of preventing movement of the pelvis. In this fracture the proportion of cases uniting by bone varies directly with the degree of immobility. If there is no immobilization none unite by bone; if immobility is absolute all unite by bone; between these two limits there is every degree of fixation, with a corresponding percentage of cases of bony union. The fact, as reported by Mr. Sinclair himself, that only a proportion of his cases unite by bone is proof that the method he employs does not immobilize every case perfectly.

Not only is the Thomas splint and calliper an inadequate means of immobilizing the fracture of the femoral neck, but it is actually dangerous, and may be responsible for refracture if it is employed as part of the after-treatment of operative fixation. The calliper fixes the ankle and knee, and converts the limb into one long rigid lever, with its fulcrum at the level of fracture. Every movement of the limb, even slight twisting movement of the feet, is directly transmitted to the neck of the femur.

If the object of our treatment is nothing more than, in Mr. Sinclair's words, "patients leaving hospital walking—some united, others not—in calliper splints," then

the treatment advocated by Mr. Sinclair is adequate. If, on the other hand, the object of our treatment is bony union of the fracture with no shortening of the femoral neck and with full movement of the knee- and hip-joint, then his treatment is not adequate.—I am, etc.,

Liverpool, Dec. 14th.

R. WATSON JONES.

Uveo-parotid Tuberculosis

SIR,—The letter from Dr. Garland in your issue of December 15th last, commenting on our article on "Uveo-parotid Tuberculosis," requires an answer from us.

In the first place, we should like to make it quite clear that our paper was written some considerable time before the appearance of Garland and Thomson's in the *Lancet* on October 6th. It was submitted to you, Sir, on August 10th, and you will recollect that, on the appearance of theirs, one of us wrote to you pointing out this fact and asking your advice on the desirability of proceeding any further with the publication of our account of Case II. Had we known that Dr. Garland intended publishing an account of this patient we would willingly have supplied him with clinical notes showing her progress whilst under our care.

With regard to our statement about the finding of tubercle bacilli in the sections of the parotid gland of this case, we base it upon a later report of the pathologist, who, after a further painstaking and exhaustive search, was able to demonstrate them to us. There were only a few present, but neither he nor the assistant pathologist had any doubts about them.—We are, etc.,

Leicester, Dec. 17th.

S. E. TANNER,
ARTHUR MCCURRY.

** The paper by Drs. Tanner and McCurry was submitted for publication on August 10th, 1934; and Dr. Tanner wrote to us, as he says, in October, after the appearance of the paper by Drs. Garland and Thomson.—ED., B.M.J.

SIR,—There are one or two points raised in Dr. A. D. Macdonald's letter (December 15th, p. 1123) which require some explanation. He says that "a story of discharging neck glands in youth is often obtainable from patients." I wonder which patients. When Dr. Thomson and I reviewed all the available literature on this subject¹ we were only able to find one case (that of Kaitz) with such a history. Again he says: "One of the most constant physical signs is that of enlargement at the root glands of the lungs, demonstrable in skiagrams," but this has only been noted in two or three cases. He then refers to "a recent investigation which I had occasion to make into cases of this malady." Are we to gather that Dr. Macdonald has seen several cases of uveo-parotid tuberculosis which have not yet been recorded in the literature? He next mentions "the conception of tuberculous infection . . . of familial origin"; surely the word familial usually connotes inheritance, more especially recessive inheritance.

With regard to the association between uveo-parotid tuberculosis and Mikulicz's syndrome there can be no doubt that some cases of the latter are examples of the former condition with associated involvement of the lachrymal glands, and several such cases are on record, the last being that of Dr. Esmond Rees.²—I am, etc.,

Leeds, Dec. 17th.

HUGH G. GARLAND.

² *Lancet*, October 6th, 1934, p. 749.

Early Diagnosis of Whooping-cough

SIR,—Whilst appreciating the value of the clinical signs and symptoms enumerated by Dr. P. R. Evans (*Journal*, December 8th, p. 1043), one would like to emphasize the importance and simplicity of the lymphocytic count in the early stages of whooping-cough before the whoop. A simple film stained with Leishman's stain will often show such a high relative percentage of small lymphocytes (in the neighbourhood frequently of 70 per cent.) that a full differential count is rarely necessary. The importance of this is that it transforms what is at the best a suspicion into a diagnosis.—I am, etc.,

London, N.7, Dec. 15th.

W. LEES TEMPLETON.

Obstetric Methods at St. Mary Abbots

SIR,—Dr. Theobald says he is delighted to have my "categorical assurance" that for the last quarter of a century general practitioners have

"always worn gloves, shaved the pubic hair, used more than a gallon of antiseptic solution, and a corresponding number of swabs for each confinement; have dispensed with vaginal examinations in normal cases; have not touched the perineum during delivery; have dispensed with induction of labour and Caesarean section, and kept the forceps rate below 4 per cent.; have used adequate amounts of anti-streptococcal serum in possibly infected cases; have insisted on adequate drainage and purgation; and have kept the urine alkaline during the puerperium."

Now my categorical assurance was never intended to cover all the measures that Dr. Theobald thinks needful to secure the excellent results he does in St. Mary Abbots. But general practitioners have for over a quarter of a century used antiseptic and swabs. They do not share Dr. Theobald's faith in the magic of a gallon or more, and have not had reason to regret either that some cases took only three-quarters of a gallon and some three or four gallons. As for not touching the perineum during labour, they certainly reduce such a practice to the minimum. General practitioners have not a plenitude of helpers in these cases as Dr. Theobald has. They have left Caesarean section to the specialists and also left them to condole with each other on the results. They have induced labour, when necessary, with entirely satisfactory results. They have not bound themselves down to any artificial percentage minimum of forceps applications, but have applied these when they thought them indicated, and both they and the patient have continued to be grateful for an instrument which wisely and properly used has done so much to alleviate and to save. Anti-streptococcal serum, of course, is a comparatively late comer into the obstetric field, but the general practitioner uses it if he thinks the patient requires such support. The general practitioner gets his patients to sit up twenty-four hours after delivery, and as for purgation, he secures that invariably and sufficiently, but not heroically. As for keeping the urine alkaline, the general practitioner does not think himself cleverer than Nature, and if Nature shows an acid urine and all is otherwise well he leaves her alone. If, however, the urine shows signs of infection, he gives ample fluid and pot. cit. Incidentally, how does Dr. Theobald secure clean urine in the puerperium? It must be contaminated by discharges unless it is got by catheter. If contaminated, it will be alkaline, as the discharges will make it so. To catheterize is a dangerous practice, and only justifiable in retention; it involves touching the parts.

When I said that the general practitioner carried out many of Dr. Theobald's ideas I meant that he sees that the breasts are kept clean and the nipples toughened up and developed long prior to confinement. He attends to the bowels and diet. He does not wear masks, as he

shares Dr. Theobald's beliefs on this point. He has known for years that antiseptics, not aseptics, is the key to safe midwifery. These and many more points were in my mind when I congratulated Dr. Theobald on his rediscoveries.

His criticism led me to re-read his article. I should like to say a few words thereon; and to ask a few questions. How did it come that with such efficient ante-natal care a case came to labour a breech, and another a face? Why is it such a dangerous procedure to insert a finger even once into the vulva in a normal and physiological state like labour but a perfectly right thing to do, again and again, in an abnormal state like abortion? Had that case with the retraction ring, in which both mother and child were lost, been a general practitioner case might it not have been thought that zeal for a low forceps rate was at the bottom of the disaster? It also makes strange reading that some infants were born dead after easy labour with no post-mortem signs of any cause of death. I should like to know if these were first cases, and the length of labour in each case? We are not told the length of the labour in any case in the series. Judged by general practitioner standards the infant mortality is high. Why put on forceps when the head was on the perineum? Was it for exhaustion of the mother or child? How did he manage to put them on without touching the perineum? Were they put on with the tongue forceps? How did he dilate the cervix—manually, without touching the perineum? If the estimation of the ability of the head to pass through the pelvis is done under chloroform a false idea is conveyed to the observer; if not attempted under chloroform, Dr. Theobald's manoeuvre is impossible in a primipara. The abdominal muscles are too tight to get behind the uterus, and the primiparae are the cases that really matter. No mortal man can tell certainly in these borderline cases whether the head will pass or not. It depends on so many factors and their interaction. It is not a mere pelvic problem. With so much washing out and purging, one would not expect faeces on a glove after a rectal examination. Lastly, if there is dystocia how does Dr. Theobald secure a fruitful and comfortable labour without resort to Caesarean section, induction, or forceps? As Coleridge asked of Mont Blanc, "Hast thou a charm to stay the morning star?"—I am, etc.,

Glasgow, Dec. 12th.

JAMES COOK, M.D.

The Practice of Midwifery

SIR,—The recent correspondence in your columns revealing the differences of opinion amongst obstetric teachers must be very interesting to the general practitioner. It would seem that pelvimetry has had its day, and it is now suggested that it is almost malpraxis not to hand over our ante-natal work to the radiologist. Will not this add to the anxiety of the mother, who merely wants to know if it is safe to have her baby at home, not to mention the expense?

A short while ago we were asked to take with us to our confinements an anaesthetist with a complicated and cumbersome gas apparatus which made the drop-bottle which our fathers used to take in their pockets look foolishly simple. If the biochemist and physiotherapist want to join the party we may have to buy trailers for our cars. It will be no joke carrying apparatus over ploughed fields in the small hours.

The fact remains that most babies will continue to be born at home under the care of midwives or general practitioners so long as most babies are born for under two guineas instead of at Harley Street prices.—I am, etc.,

WALTER RADCLIFFE, M.B., B.CHIR.

Wivenhoe, Essex, Dec. 18th.

Chloroform Analgesia in Maternity Cases

SIR.—With reference to the letter by "G. D. G." on anaesthesia in maternity cases in the *Journal* of December 15th, I should like to express my agreement as to the efficiency of chloroform used as an anaesthetic in midwifery cases. I would go further and say that the use of the brisettes or crushable chloroform capsules of 20 minims each, as tried out in the maternity hospitals in London and throughout the United Kingdom, has proved a success. The trial was made under the auspices and by the aid of the National Birthday Trust Fund, and the tabulated results bear out the safety and usefulness of chloroform used in that way as an analgesic in labour.—I am, etc.,

London, W 2, Dec. 18th.

W. D. HAYWARD, M.B.

Viewing the Pelvis

SIR.—Perhaps some of our friends have seen the simple x-ray apparatus used to show if a boot or shoe fits. That is what we need in obstetrics. The apparatus is usually stamped with the name Gaiffe Pilon et Cie, for it was invented by the Compagnie Générale de Radiologie, whose headquarters are in Paris.

As I could not get anyone in England to be sufficiently interested in what happens to the pelvis when a patient squats, I spent over a year in France, and, by the kindness of that very company, who gave me introductions to x-ray specialists and assisted me with the work, I found that in squatting or crouching the top of the sacrum goes back, while the subpubic angle opens and the pubic arch is widened, the pubic symphysis diminished in depth, thus facilitating the passage of the foetal head. In a well-shaped pelvis this movement converts it into a cylindrical tube (see Testut—*Anatomie*), and easiness of birth, as I have pointed out before, depends upon three factors:

- 1 Shape of the pelvic brim (the more nearly it approaches the circle the greater is its capacity).
2. Mobility of pelvic joints, which enable the movements described above to be carried out. This mobility is much increased by appropriate exercises.
3. Position adopted for delivery, which should be such that the top of the sacrum can rotate backwards and forwards freely, for the antero-posterior diameter of the pelvis is increased in the squatting position, which necessitates movement and expansion of the pelvic joints.

I therefore asked the Compagnie Générale de Radiologie if they could design a simple apparatus in which, by pressing a button, the pelvis could be viewed. With such an appliance one would not only see the shape of the pelvic brim and judge of its capacity, one could also measure its mobility and what amplitude of movement the pelvic joints possessed. More important than the usual measurements are pelvic mobility, and this can be judged by the difference in the external conjugate when standing compared with the same measurement when squatting.—I am, etc.,

London, W 1, Dec. 18th.

KATHLEEN VAUGHAN.

Alkaline Treatment of Coryza

SIR.—It was with much interest that I read Dr. Bernard Potter's letter in the *Journal* of November 17th, confirming my experience that sodium bicarbonate cures the common cold.

For about ten years I suffered from recurring corneal ulcers—often lasting me off work for six weeks. These were treated by tests in different parts of the world, and I was in London with Dr. Rosa Ford, four

If the object of our treatment was the pertinent question, in Mr. Sinclair's words, "to cure the ulcer" and after making the usual—some united, others supplied the answer by informing

me that I had a nasal sinusitis. This, at the time, seemed to me incredible, as there were no symptoms to suggest this—no pain, tenderness, or discharge, etc. However, after carrying out the treatment prescribed, this diagnosis proved to be right, and I have had no eye trouble of any kind since. About two years ago someone wrote in the *Journal* advising alkalinizing the tissues for such infective conditions by taking sodium bicarbonate—half a teaspoonful three times daily—explaining that infective germs flourish most readily in an acid medium. I adopted this treatment one winter, carrying it out for several months, and it was remarkable that during this time I never had a cold. Usually I suffered from at least three heavy colds in the year, one or more of which appeared in the winter. Thinking that this happy state of things must be due to the alkali, and arguing that those who were liable to infections were those with a lowered alkalinity, it seemed sound treatment to correct this, so I have continued taking half a teaspoonful of sodium bicarbonate at bedtime ever since. The result has been that I have not had a cold since I adopted this prophylactic dose. Occasionally, when I had run much risk of infection, I have felt the familiar symptoms of the commencing cold, but pushing the dose to half a teaspoonful three times a day has immediately nipped it in the bud.

Dr. Potter says the treatment is an old one, but, if so, I think it is so little known that if one were called to a patient suffering from nasal catarrh with chest symptoms and prescribed a teaspoonful of sodium bicarbonate the result would be a letter asking one not to call again. However, I have tried it out on friends with uniform success. One of these never passed a winter without several colds with chest symptoms, each attack laying her up for about a fortnight. She adopted the prophylactic dose and got through last winter without one attack. Others have taken it when the cold was commencing, with the result that it was arrested.

The alkaline treatment may only act with people who have a lowered alkaline reserve, but then probably these are the ones who suffer readily from infections.

Some years ago I had an American patient suffering from severe influenza with cardiac complications. She was astonished that she personally should have caught influenza, as she thought she was immune. She had nursed her husband repeatedly through attacks of it, but she herself had never contracted it. She told me that when she expressed the fear that she might be attacked her American doctor had said, "Don't be afraid; take a teaspoonful of sodium bicarbonate at bedtime and you will be all right."

This leaves one wondering if the alkaline treatment has a wider field of usefulness than in preventing or curing the common cold. At least it suggests that it would be worth trying during an influenza epidemic.—I am, etc.,

San Remo, Dec. 15th.

LOUISE FRASER.

Economic Aspects of Suicide

SIR.—Under the heading "A Practical Note on Suicide" Dr. Frederick Dillon (*Journal*, December 15th) stated that "speaking generally, we may say that suicide is a way of escape from a situation that has become intolerable," and also that "worry from external circumstances, unless the latter are of an extraordinary or exceptionally disturbing character, cannot be said to be sufficient in itself to arouse a suicidal attitude of mind."

In the *Listener* of December 5th, in an article which was broadcast by Major C. H. Douglas, the originator of the Douglas Social Credit Scheme, in the "Causes of War" series, entitled "Is our Monetary System to Blame," there appears a graphic representation of the suicides and bankruptcies in Great Britain since 1910. This startling graph shows a remarkable parallelism between suicides and bankruptcies. During the war both diminished in frequency, to be followed by a rapid rise after the war. The graph indicates that worry from

external circumstances of an extraordinary and exceptionally disturbing character was operative before the war, diminished during the war, when money was more plentiful and greater economic security existed for the individual in spite of the enemy at our gates, and has been and is operative more than ever since the war, during a period of great financial stringency decreed by sound finance.

It is clear that with increasing irritations of an economic nature an increasing number of people will go bankrupt and will commit suicide. This is an argument against the irritations rather than against human nature. At a public meeting convened by the Committee against Malnutrition Sir F. Gowland Hopkins remarked on the now generally accepted fact that through the success of scientific methods the repetition of the miracle of the loaves and fishes had become possible. This possibility is true literally and metaphorically, and yet bankruptcies and suicides have been, and are, increasing. Life itself, including medicine, is being frustrated.

The close association between bankruptcies and suicides suggests a financial basis for them both, and for much of the present frustration of life. Major Douglas's graph is a very practical note on suicide, introduces a realistic touch to a psychological study, and points the accusing finger unflinchingly at the false god of High Finance. This is an aspect of the subject of great moral and practical importance which calls for consideration.—I am, etc.,

Barnard Castle, Dec. 17th.

JOHN LEISHMAN.

Obituary

Dr. FREDERICK GOULBURN GIBSON died suddenly at his home in Christchurch, New Zealand, on November 5th, at the age of 63. He was born in New Zealand and was at school in Christchurch, and subsequently took his M.A. in the University of New Zealand. He studied medicine at Guy's Hospital, taking the M.R.C.S. in 1930 and the M.D.Lond. in 1903. Keen in all sports, he particularly excelled at Rugby football, playing for Guy's Hospital. For the last thirty years he had practised in Christchurch, New Zealand, where he was one of the leading practitioners. He enjoyed particularly the old type of family practice, perhaps less common in new countries than in England, where the general practitioner becomes the friend and counsellor of his patients, as well as merely their medical adviser, and is able to follow the same patients and families through more than a generation. He was also an energetic member of the Christchurch Division of the British Medical Association, and was President of the New Zealand Branch in 1923. During the war he served as a major in the N.Z.M.C., part of his active service being spent on the hospital ship *Marama*. He leaves a widow, two daughters, and a son.

We regret to announce the death, on December 12th, of Dr. ARCHIBALD CAMBELL, medical officer in charge of the venereal clinic of the Royal Hospital, Portsmouth. Born in 1880, he received his medical education at Owens College, Manchester, graduating M.B., Ch.B.Vict. in 1905. After some post-graduate study he joined a partnership in Portsmouth. In 1914 he received a commission and went to France, where he developed great ability in the treatment of venereal diseases. He was later appointed to specialist work at Hilsa Military Hospital, and in 1917, when the new venereal diseases clinic was opened in Portsmouth, he was placed in charge of it, continuing to work there until just before his death, with conspicuous success. As a specialist he was widely known. He invented an aero-urethroscope, and contributed articles on treatment to the *British Medical Journal* and elsewhere. A keen member of the British Medical Association, he was

vice-president of the Section of Venereal Diseases at the Annual Meeting at Edinburgh in 1927. Dr. Cambell was a great organizer; he built up the present venereal diseases department of the city of Portsmouth, which has been widely acclaimed as a model scheme. He took whole-hearted interest in the work of diminishing these diseases, and in 1931 he had the satisfaction of seeing the city rank as the third lowest of the twenty largest towns in the country in respect of the attack rate. He devoted himself particularly to children suffering from transmitted disease, saving very many from permanent blindness, and restoring a large number to health. Quiet and unassuming, he shunned anything that seemed to savour of advertisement. He was imbued with a strong sense of duty, which was evident in the punctilious care given to every detail of his work. He endeared himself to everyone with whom he came into contact by his kindness and charm of manner. Dr. Cambell leaves a widow, three sons, and a daughter.

The following well-known foreign medical men have recently died: Hofrat Dr. MAXIMILIAN STERNBERG, professor of internal and social medicine at Vienna; Dr. HUGO WINTERNITZ, professor of internal medicine at Halle, aged 66; and Dr. G. FARKAS, professor of physiology at Budapest, aged 63.

The Services

ROYAL ARMY MEDICAL COLLEGE

The War Office announces that Brevet Colonel H. M. J. Perry, O.B.E., Honorary Surgeon to the King, has been selected for promotion to colonel and for appointment as Director and Professor of Pathology at the Royal Army Medical College, Millbank, London, with effect from December 28th, 1934, in succession to Colonel A. C. H. Gray, O.B.E., M.B., Honorary Surgeon to the King, who is retiring on retired pay.

Colonel Gray has served for more than thirty-one years in the Army, during which, in addition to the appointment he is now vacating, he has held the appointments of Assistant Professor of Pathology and Professor of Pathology at the Royal Army Medical College as well as that of Director of Pathology at the War Office. He also served for over five years (while seconded) in Uganda with Sir David Bruce as a member of the Royal Society's Commission on Sleeping Sickness, and received the thanks of the Secretary of State for the Colonies for his very valuable work.

Medico-Legal

PUNISHMENT FOR LIBELLING A DOCTOR

At the last Manchester Assizes, before the Commissioner, Mrs. Nelly Mills of Marple pleaded not guilty to publishing defamatory libels on Dr. Garth ApThomas of Stockport, in anonymous letters sent to Dr. ApThomas, his daughter, and his partner. The indictment consisted of six charges, three of them under the Post Office Act.

Mr. A. E. Jalland, for the prosecution, said that the letters imputed immorality by Dr. ApThomas, who, in fact, apart from attending Mrs. Mills for a fortnight in September, 1929, had spoken to her on two or three occasions only. Counsel submitted that all the letters were written in the same disguised handwriting, and there was not a word of truth in the allegations. The letters had been arriving since 1930. Counsel, describing the events leading up to the arrest of the prisoner, said that post-office officials watched her post a letter and then dropped a newspaper into the letter-box. When the pillar-box was opened, a letter addressed to Miss ApThomas was immediately underneath the newspaper. Mr. J. E. Greenwood, a handwriting expert of Manchester, identified the handwriting on this and other letters as that of the prisoner.

In sentencing Mrs. Mills to twelve months' imprisonment the Commissioner described the offence as abominable.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons spent three days last week debating the new regulations for Unemployment Relief. The adjournment of the House was arranged for from December 21st to January 28th.

On December 18th Mr. Isaac Foot presented a petition, signed by 5,102 persons, which stated that, believing vivisection to be morally unjustifiable, scientifically useless, and dangerous and demoralizing to the community, the signatories earnestly prayed the House to pass a Bill withdrawing the sanction of the law to this practice.

The National Health Insurance (Arrears) Amendment Regulations (No. 3), 1934, were laid on the table of the House of Commons on December 20th.

The Housing Bill and the Housing (Scotland) Bill were introduced in the House of Commons on December 20th by Sir Hilton Young and Sir Godfrey Collins respectively. The text of the former will be issued on January 16th. Its purpose is "to make further and better provision for the abatement and prevention of overcrowding, the redevelopment of areas in large towns in connexion with the provision of housing accommodation therein, and the reconditioning of buildings, to make provision for the establishment of a housing advisory committee and of commissions for the management of local authorities' houses, to amend the enactments relating to the housing operations of public utility societies and other bodies, to provide for the consolidation of housing accounts, and to amend the enactments relating to housing." The long title of the Scottish Bill is similar, save that "large towns" are not specified. The second reading of the English Bill is set down for January 30th and 31st.

The Government of India Bill was presented in the House of Commons by Sir Samuel Hoare on December 19th. Sir Francis Fremantle has made representations to the Secretary of State upon its medical aspects.

A motion praying for the annulment of the Traffic Signs (Pedestrian Crossings) Provisional Regulations, 1934, which authorize "beacons," was moved in the House of Commons on December 18th, but withdrawn.

In the House of Lords the Depressed Areas Development and Improvement Bill was read a second time on December 19th, and passed through committee and remaining stages on December 20th, "special areas" being substituted in the title for "depressed areas." The Supreme Court of Judicature Amendment Bill was read a third time on December 20th. The Royal Assent to the former Bill was arranged for December 21st.

The House of Lords, on December 18th, approved by 239 votes to 62 the proposals on Indian government made by the Joint Select Committee.

Revised figures for the division on the second reading of the Osteopaths Bill in the House of Lords show it passed that stage by 37 to 20.

Unemployment Assistance

In the House of Commons, on December 17th, Mr. OLIVER STANLEY moved that the draft Unemployment Assistance (Determination of Need and Assessment of Needs) Regulations, 1934, should be approved. He said that the scales proposed were the result of a very careful survey by the Board of the primary needs of the people for whom they had been responsible. There were very great differences in the results which had been arrived at by the different social surveys, but in deciding whether the Board had succeeded in its task or not it was not fair to pick out the best bits from each of those scales and put them into one scale with which to compare the Board's to the great disadvantage of the latter. In the spring of this year there was a hotly contested debate, and even a

closely contested division, whether a child should receive 2s. or 3s. In the new scale the minimum for any child under 5 was 3s., and that amount increased with age, which was a new principle. This was the first time, he thought, that the distinction had been made on the proper basis—that the older the child the more it needed and the more it should receive. Members would agree that in comparison with the old scale, under which the vast majority of those on transitional payment had been dealt with, this new scale for the family with children was an immense improvement. He had received that day from the Children's Minimum Committee certain criticisms on the subject of the scale for children. The committee frankly admitted, with all the criticism it had to make, that the new scale represented a great advance on what had gone before. However, the committee attempted to make out a case for a higher rate, said that the scale was still inadequate, and gave figures to form a comparison between the British Medical Association's scale for food and the Merseyside scale for such things as fuel, light, and clothing, and the scale adopted by the Board. It would have been possible to take the Merseyside survey as a basis for the whole of the need, including food. Were that done, it would be found that the Board's scale for a man and wife and three children was higher than that of the survey. With regard to the British Medical Association's scale he did not pretend to be able to say whether that scale or the scale produced by three or four other surveys was theoretically correct. It did happen that the British Medical Association's scale, which had been selected for comparison, was very much the highest in the matter of food. One of the reasons for this was the very large provision which the B.M.A. scale made for milk. The latter scale, and the costing of it, were drawn up before the scheme for the provision of cheap milk in schools came into operation, and required revision in view of the fact that the milk, which formed such a large part of it, could now be obtained elsewhere.

Dealing with the question of the treatment of resources other than earnings, he said that with regard to milk and school meals the basis which the Unemployment Assistance Board was going to adopt in the first instance was as follows. All meals given on a doctor's certificate that a child was suffering from a specific physiological condition and required extra nourishment were to be set off against the personal medical requirements of the children, and ignored. The next provision dealt specifically with milk or other special items, such as cod-liver oil, which was to be entirely ignored. Meals up to two per day for a single child in a household, or one meal for two children, would be ignored as constituting a negligible saving to the family. That was to say, twelve meals in the week in the household were free. After that, some deduction was to be made in respect of those meals, which worked out at roughly one penny a meal. As regards medical relief, maternity and child welfare, and tuberculosis services, any payments or allowances in kind under those services would be regarded as being set-off by the special needs, and would therefore be ignored. In the case of pensions for old age, widows and orphans; and blind pensions under the Blind Persons Act, 1920, any balance after providing for the pensioners' needs at the scale rate would be allowed for personal requirements where there were no other resources. In other words, in those cases it would be ignored.

The B.M.A.'s Nutrition Scale

Mr. GREENWOOD moved an amendment to the effect that the regulations would be inadequate to ensure the maintenance of unemployed persons and their dependants in health and physical efficiency. Referring to the adequacy of the scale, he said that Mr. Stanley tried to dispute the validity of any kind of comparisons. The right hon. gentleman said: "Of course, if you accept the British Medical Association's scale you should accept it for everything. If you accept the scale of the Merseyside Social Survey Committee you should accept it for everything." His reply was that on the question of ascertaining the food values and human needs as regards food, it was far better to place reliance on the British Medical Association than on a non-medical body like the Merseyside Survey Committee. While he complained about the price that the British Medical Association put on its food values, as regards food needs there was no higher authority they could accept. As regards other needs, he was prepared to

accept the Merseyside Survey Committee's report, because the committee was dealing with things within its knowledge, and that would not apply to the other elements in the cost of living if the British Medical Association had tried to elaborate the scale. The first point in the British Medical Association scale was that examinations which had been made by working-class women of experience, who could be relied on to, buy in the best possible market, showed that it was impossible to buy the amount of food laid down in the Association's scale at the price that scale suggested. The medical officer of health for the Lancashire town of Middleton said that the prices were higher within that area than in the British Medical Association's scale. He estimated that it would need 24s. in the town of Middleton to buy the food which the B.M.A. said could be bought for £1. That meant that the estimate of the B.M.A., not in terms of food value but of the money needed to buy that food, was about 20 per cent. wrong. He was not blaming the B.M.A. for not being able to change calories into pounds, shillings, and pence, but he could give the House a list of places showing that the Association's scale as measured in money was hopelessly below what would actually be possible. In some towns it would need 25s., 26s., or 27s. to buy the amount of food it was suggested could be bought for £1. That made any disparity between the Unemployment Assistance Board's scale and the British Medical Association's scale all the greater. It was clear to those who had examined the regulations and gone through the scales and tried out various sizes of families, which he spent part of his week-end doing, that there was a very considerable disparity in many cases. He was certain if the British Medical Association's scale was examined as it stood, not subject to a 20 per cent. increase in costs, it would be found that there was a serious disparity between that scale and a reasonable allowance for the barest physical needs of life, which meant that the Government was not meeting the minimum physical requirements of the people. He could not understand the attempts of supporters of the Government to prove that malnutrition did not exist. He was not going to pretend that we were on the whole a C 3 nation, and that there was evidence of malnutrition everywhere; but he said that when people tried to belittle the effects of malnutrition they were not acting in the public interest. It was the Chief Medical Officer of the Ministry of Health who said that malnutrition should be judged objectively; he did not see the cases, but the Labour Party had a certain volume of evidence that under the existing standards of unemployment insurance benefit or transitional payments, numbers of people, especially young people, were suffering from malnutrition, and, unless the scheme was sufficiently generous to meet all reasonable physical needs, the amount of malnutrition which existed to-day would increase.

In the House of Lords, on December 20th, the same Draft Unemployment Assistance (Determination of Need and Assessment of Needs) Regulations were considered. Lord MARLEY said that figures printed in the *Times* on December 17th (p. 14) showed the deficiency of the Unemployment Board's scale of allowances per child compared with the scale laid down by the British Medical Association and the Merseyside survey. The scales laid down in the regulations were likely to affect the heads of the families which came under them. They were inadequate for building up healthy, strong, and capable future citizens. They were shillings per week below the British Medical Association's scale, which was itself founded on a price level which few of their lordships would be able to put into effect if they had the spending of the money. Lord ROCHESTER said that with reference to the difference between the scale of the Unemployment Assistance Board and the British Medical Association, the question had been considered at a conference attended by representatives of the Ministry of Health and the British Medical Association. The conference had deplored the exaggerated importance that had been attached to the alleged disagreement between the two committees which had drawn up scales. It had stated that there was no fundamental disagreement between the two bodies on any matter of scientific importance. The Board scale, taken as a whole, compared very favourably with the average of those other scales to which reference had been made. The regulations were at least a distinct advance on anything which had previously been enacted. The House then agreed to the draft regulations.

Sickness Benefit.—In reply to Mr. West on December 13th, Sir HILTON YOUNG said it was estimated that the sum expended on sickness and disablement benefits by approved societies in England and Wales in the years 1932 and 1933 represented 164,000,000 and 174,000,000 working days respectively.

The Water Survey.—On December 17th Mr. SHAKESPEARE informed Major Hills that the inland water survey which he was instituting was to collect and correlate reliable records of available water supplies, particularly of river flows, including flood flows, and of underground water levels. The information for the survey would be obtained from catchment boards, which were primarily responsible in England and Wales for flood prevention, and other qualified bodies and persons, as well as from water undertakers. The survey would be of value to those concerned with all aspects of inland water administration.

Battersea Power Station.—Mr. ALAN TODD asked the Minister of Transport, on December 17th, if he could make a report on the emission of smoke and noxious fumes from the new Battersea power station. Captain A. U. M. HUDSON, who replied, said a further report by the Government Chemists' Committee was being printed.

Ante-natal Clinics.—Replying, on December 18th, to Viscountess Astor, Mr. SHAKESPEARE said that, according to the latest information available, four of the 422 maternity and child welfare authorities in England and Wales had not yet set up maternity or child welfare centres, and forty-six others which had provided welfare centres had not yet set up separate ante-natal clinics. In some of these areas voluntary clinics worked in harmony with the local authorities, and in others of a rural character arrangements were made by the local authorities for ante-natal supervision by general practitioners. Viscountess Astor asked if the Minister could do anything to make authorities which had not taken advantage of the Act of 1918 set up clinics. Mr. SHAKESPEARE said the Ministry had sent out a circular of reminder to every one of these authorities.

Conservative Housing Committee.—In the absence of Sir Francis Fremantle, who was awaiting his turn to speak on the Unemployment Assistance Regulations, Sir WALTER WOMERSLEY presided, on December 19th, at a meeting of the Conservative Health and Housing Committee. Mr. A. C. BOSSOM opened a discussion on rehousing and slum clearance schemes. He estimated that with the best organization it would take ten years to complete the Government's programme. The first step should be to estimate the total requirements in materials. The Ministry should divide the country into, say, ten areas, each with its building schedule; and each assured of a steady supply of materials. Mr. BOSSOM mentioned as one hindrance to economic efficient organization of building schemes the varying regulations enforced by local authorities. This threatened failure to the proposals of the Government. Mr. H. R. SELBY followed with suggestions in reference to Improvement Area Procedure. The meetings of this committee are of increasing interest in view of the overcrowding legislation to be introduced after Christmas. Its secretary is Captain G. S. Elliston.

Battersea Factory's Fumes.—Mr. SHAKESPEARE, on December 18th, informed Mr. Todd that the attention of the Minister of Health had been drawn to the nuisance caused to residents in West Chelsea by the emission of fumes from the factory owned by the Morgan Crucible Company, Ltd. The Minister's alkali inspectors had taken up the matter with the company, and had conferred with officers of the Battersea Borough Council. The company had very recently completed the installation of remedial plant which, the Minister was advised, had effected a definite improvement. The inspectors would continue to watch the situation. In the circumstances the Minister had not thought it necessary to press the local authority to take action.

Reconditioning of Rural Dwellings.—Mr. SHAKESPEARE informed Captain Heiglers, on December 18th, that the number of dwellings in England and Wales which were reconditioned or improved under the Housing (Rural Workers) Acts during the year ended September 30th last was 1,215. Work was in progress at that date on a further 1,020. During the same period 3,860 houses were built by rural district councils.

Education of Partially Sighted Children.—Mr. RAMSBOTHAM informed Mr. Ernest Evans, on December 20th, that a large number of local education authorities were considering the recommendations contained in the report of the Committee on Partially Sighted Children. He could not say how many of them had already decided to adopt any of those recommendations. The Board of Education was in general agreement with the recommendation of the committee on the advantages of educating partially sighted children in classes which formed part of ordinary elementary schools. A proposal to make provision in one area on lines indicated in the report had recently been approved. The Board of Education took steps as opportunity arose to give effect to the committee's recommendations.

Nursery Schools and Cheap Milk.—Mr. RAMSBOTHAM told Mr. David Grenfell, on December 20th, that it was not the policy of the Board of Education to refuse to sanction any expenditure on nursery schools. Those schools were not debarred from participating in the scheme for cheap milk. An increasing number of grant-earning nursery schools were eligible to participate in the scheme, but it did not apply to schools of any type not recognized for grant.

Answering Lord Strachie in the House of Lords on December 18th, Lord HALFAX said that so far as he was aware the milk supplied to school children in Somerset was not limited to pasteurized or tuberculin-tested milk.

Universities and Colleges

UNIVERSITY OF OXFORD

The following candidates have passed in the examination indicated:

FINAL B.M.F., B.Ch. (Medicine, Surgery, and Midwifery).—H. A. Broadbent, R. Clark, A. Fearnley, P. R. Greaves, C. A. Hinds Howell, A. H. Hunt, T. G. Lowden, R. McDonald, R. Passmore, N. K. Stott, T. M. Williams.

UNIVERSITY OF CAMBRIDGE

At a congregation held on December 19th, the following medical degrees were conferred:

M.D.—J. St. C. Elkington, J. H. L. Easton, D. Aserman, E. A. Nicoll, L. E. Houghton

M.B., B.Ch.—A. C. de B. Helme, A. Lister, A. Willcox, C. S. Hall-Smith, C. H. D. Bartley, F. J. Curtis, R. S. Handley, A. M. Lester.

M.B.—R. H. Dobbs, W. A. Elliott, C. P. F. Boulden, A. R. R. Mears, F. W. Holdsworth.

B.Ch.—R. W. D. Turner, F. B. Turner.

* By proxy.

UNIVERSITY OF BIRMINGHAM

The following degrees were conferred at a congregation on December 14th:

M.B., Ch.B.—H. T. D. Bocking, J. D. Cruikshank, Brenda Fife, R. N. Jones

UNIVERSITY OF BRISTOL

Dr. H. J. Drew Smythe has been appointed to succeed Dr. R. S. Statham as professor of obstetrics.

The Council has decided to establish a full-time chair of medicine. Subject to the concurrence of the Bristol General Hospital, the first holder of the new chair will be Dr. C. Bruce Perry.

The following appointments have also been made: Dr. Charles Cornfield, lecturer in charge of the Department of Anaesthetics, in succession to Mr. Stuart Stock; Dr. C. E. K. Harpath, clinical dean at Bristol Royal Infirmary; Dr. L. A. Moore, clinical lecturer in anaesthetics; Mr. R. Gordon Paul, F.R.C.S.Ed., clinical lecturer in surgery; Dr. H. J. Orr-Ewing, F.R.C.P., clinical lecturer in medicine; Dr. G. E. F. Sutton, M.R.C.P., clinical lecturer in medicine.

VICTORIA UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examinations indicated:

FINAL M.B. AND CH.B.—Part II: J. Barkman, J. Curry, F. G. Dribbough, A. Harris, B. P. Hild, J. A. Holton, R. H. Johnson, S. H. O. Jones, Fred H. Knight, Winifred Potter, W. K. Street, Maryne Susan, A. McN. Tomlinson. **Part I:** J. Cohen, A. J. F. Crosby, H. A. Reutz, B. Thornley, G. W. Ward.

TURO M.B., Ch.B.—Pathology and Bacteriology: S. G. Abelson, Beryl A. Barlow, Muriel J. Brayshaw, J. C. Brundret, P. J. Burke, J. H. B. Cantley, Caroline J. Chalmers, Violet Cohen, D. L. Cooke, G. D. Dawson, B. Flacks, J. Goldman, D. Halpern, A. B. Humer, A. Hargreaves, B. P. R. Hartley, J. A. Herd, I. Hesford, J. Hilton, C. B. Holland, G. M. Komrower, V. T. Lees, J. Meynell, Evelyn N. A. Milligan, Eleanor M. Mills, E. J. Mitchell, W. S. Parker, *B. Portnay, D. A. Richmond, A. L. Robertshaw, E. N. Rowlands, A. Shashoua, R. M. Shaw, Nina Shetstern, H. B. Slater, A. M. L. Smith, F. W. Smith, N. Taylor, D. J. Walker, E. P. Whitaker. **Pharmacology:** L. S. Anderson, J. C. Rabbage, I. W. Ball, L. Ballon, T. E. Barlow, R. S. A. Beckett, G. H. H. Benham, Muriel L. Bennett, Gretel Berghheimer, G. Berry, M. J. Blank, T. Dinsdale, J. H. Ferguson, J. H. France, Rosaline Green, Edith A. Greenhalgh, R. S. P. Hawkins, T. Holme, W. Ingman, R. Jackson, Monica M. Job, T. H. Lawton, Katherine I. Liebert, H. N. O'borne, *Nydia E. Panton, A. F. Pearson, W. A. Robson, Mary A. Rogerson, J. K. Rowson, R. N. Stansfield, T. S. Stewart, F. Stratton, N. Whalley, *A. B. White.

*With distinction.

NATIONAL UNIVERSITY OF IRELAND

UNIVERSITY COLLEGE, CORK

The following candidates have been approved at the examinations indicated:

M.D.—J. J. Healy.
M.B., B.Ch., B.A.O.—D. J. Burgess, J. J. Glynn, M. D. Hegarty, J. J. Hurley, J. F. MacCarthy, T. J. Mullins, T. P. O'Brien, T. P. O'Connor, D. G. O'Driscoll, P. Powell, T. Sutton. **Part I:** J. P. Corcoran, Mary P. Quinlan, J. N. McCarthy. **Part II:** D. C. Lawton. **Exempt in Pathology:** V. Bennett, Brendan Buckley.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

A meeting of the Royal College of Surgeons of Edinburgh was held on December 18th, when Dr. A. H. H. Sinclair, President, was in the chair. The following candidates, having passed the requisite examinations, were admitted Fellows:

C. D. G. Williams, T. J. Eason, G. C. Ferguson, B. B. Frishwater, M. Gaffney, C. J. K. Hamilton, J. A. Inrie, J. G. Irving, J. M. Jackson, O. V. Jones, I. D. Kitchen, A. D. Koutin, J. Lowe, C. C. McCallum, M. MacCulloch, C. A. P. d'A. Martins, P. H. Merfin, D. C. Monro, W. I. C. Morris, I. Newton, E. A. Nicoll, H. L. Rees, Naomi Reuben, D. N. R. Jones, I. M. Rutherford, R. G. A. Savage, P. Shannon, P. K. Thiagarajah, W. E. Thompson, J. H. Wilson.

Medical News

The annual dinner of the London (Royal Free Hospital) School of Medicine for Women, postponed on account of the death of Lord Riddell, will be held on Thursday, January 24th, at the Savoy Hotel (Embankment entrance), at 7 for 7.30 p.m.

Mr. Kenneth Gray will open a discussion on "The Improvement of Drainage and Water Pipes by the Use of Lead Alloys" at a meeting of the Royal Sanitary Institute at 90, Buckingham Palace Road, S.W., on Tuesday, January 8th, at 5.15 p.m.

The next meeting of the Society for the Study of Inebriety will be held at 11, Chandos Street, W., on Tuesday, January 8th, at 4 p.m., when Dr. Percy E. Turner will open a discussion on "Methylated Spirit Drinking."

The fifteenth International Congress of Physiology will be held in Moscow in 1935, according to the decision of the fourteenth congress, which was recently held in Rome, under the presidency of Professor Pavlov, with Professor L. N. Federoff of the Pan-Russian Institute of Experimental Medicine as general secretary.

The Seventh Imperial Social Hygiene Congress will be held at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C.1, from July 8th to 12th, 1935. Further particulars will be issued later.

The King George V Merchant Seamen's Memorial Hospital, Malta, was opened in 1922, and is now in need of extension, which it is hoped may be possible soon. During 1933 the equipment of the x-ray department was considerably augmented, thanks largely to the Royal Naval Benevolent Trust. The in-patients numbered 343, while there were 3,042 out-patients. An appeal is made for financial support, since there is a bank overdraft of £290.

The Physical Society's twenty-fifth annual exhibition of scientific instruments and apparatus will be held at the Imperial College of Science and Technology, Kensington, S.W., on January 1st, 2nd, and 3rd. Admission is free without ticket on Thursday, January 3rd, from 3 to 6 and 7 to 10 p.m. Admission on the first two days is by ticket only. Tickets may be obtained from the exhibition secretary, Physical Society, 1, Lowther Gardens, Exhibition Road, S.W.7, who will also supply copies of the catalogue (price 1s., post free).

The Minister of Health has now arranged to exercise through the Welsh Board of Health his functions in relation to the welfare of the blind, so far as concerns Wales and Monmouthshire, except matters relating to old age pensions for the blind under Section 1 of the Blind Persons Act, 1920, which will continue to be dealt with by the Ministry in Whitehall direct. The transfer will take effect on January 1st, 1935. Local authorities and voluntary associations for the blind should address all correspondence relating to the matters in question to the Welsh Board of Health, City Hall, Cardiff.

The new ward in the Hospital for Sick Children, Great Ormond Street, towards which Mr. Charles Johnson, a member of the committee of management, has given £10,000, is to be named after the Princess Royal, who worked at the hospital during the war.

Sir G. Lenthal Cheatle, K.C.B., C.V.O., has been appointed a Chevalier of the Legion of Honour.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Offensive Breath

"J. B. F." writes: I have as patient a girl of 8; good general physique, but suffering chronically from "bad breath." The following possible causes have been eliminated: constipation, bad teeth, tonsils and adenoids, antrum, and accessory sinuses. I should be grateful for suggestions.

Circumcision

Mr. S. F. MARGRAM-MÖLLER (15, Melville Street, Edinburgh) writes: I am preparing a pamphlet on circumcision, and would feel very grateful if any of your readers would let me have their experiences regarding the spread of non-ritual circumcision within recent years. Statistics from school medical inspection, etc., would be of special interest.

Income Tax

Payment for Guaranteeing a Loan

"A. N. M." refers to a reply in our issue of December 8th, and states that in similar circumstances the deduction was refused in his case. He would like the former reply to be amplified.

** In the case of *Ryall v. Hoare*, [1923] 2 K.B. 447, two directors guaranteed the bank overdraft of their company and were paid a commission for so doing. The deduction was refused to the company, but allowed on appeal to the special commissioners; the High Court case decided that the directors were directly assessable on the sums received for their guarantee. So far as the statement of the case discloses the facts the company was finally permitted to treat the payments as allowable. So far, therefore, the case supports "A. N. M.'s" claim, but it has to be admitted that the facts were somewhat different—for instance, the overdraft was an incident of trading; it was not obtained to purchase the business. That difference is of some importance, and tends to support the contention that in "A. N. M.'s" case, and similar ones, the payment is made to obtain the practice rather than as a part of the expense of working it. At the same time, the point is worth pressing, as the case referred to above might be cited in support.

"ACCOUNTANT" writes to point out that the case of *Ryall v. Hoare* related to excess profits duty, not income tax.

** The general principles of the income-tax code relating to the distinction between capital and revenue expenditure applied to excess profits duty—the special allowance for the use of additional capital in the business was merely to exclude from the "excess" the natural result of that addition. If, therefore, the expense was allowable for the purpose of excess profits duty it is, in our opinion, allowable for income-tax purposes. In the case of *Ryall v. Hoare* the point was not argued before the court, but it seems clear that the deduction was allowed, and to that extent the case can be quoted in support of the allowance claimed. Apart from that case we are very doubtful whether the claim can be established, seeing that the payments are made not so much as expenses of carrying on the practice as arising out of its purchase by a particular person.

Proportion of Residential Expenses

"D. M. O." asks, in the case of a medical practitioner who resides and carries on practice in one district and has a surgery and consulting rooms in another district, what proportion of expenses would be reasonable for the residence.

** The proportion depends on how the accommodation at the residence is allotted, as between professional and private use; the fact that there are professional rooms elsewhere affects the matter only if it reduces the professional use of the residence. If, therefore, the residential premises cover almost exclusive professional use of two rooms on the ground floor and of the garage "D. M. O." might reasonably claim one-half, though that would seem to be the most he could expect to be allowed.

Beginning of Appointment

"T. M." qualified in October, 1933, and was employed as from December, 1933. His earnings for the period to April 5th, 1934, were £90, and for the year to April 5th, 1935, say, £200. What is his liability to assessment?

** The rule as to assessment on the basis of the previous year does not apply to the year following the one in which the employment commenced. Consequently the assessment for 1934-5 will be on the amount of the earnings of that year—that is, £200. "T. M." was presumably exempt for 1933-4. There is no real inequity in the position, as the person to be assessed is charged on his actual earnings; it of course follows that when an employment ceases the employee does not continue to be assessed on the previous year's earnings.

LETTERS, NOTES, ETC.

Psychology and Religion

Dr. IRENE N. CLOUGH (Glasgow) writes: I was disappointed to find, in Dr. Forsyth's article on the above subject (*Journal*, November 24th, p. 958), that religious ideas were treated mainly on the level of Browning's *Caliban upon Setebos*. All the great religions transcend Caliban's theology; though all their adherents do not, no religion could persist which did not transcend Caliban's theology. As this is not a point which can be settled by argument, I should like to consider another point which admits of more objective evidence. "Conversion," says the report, "was essentially a phenomenon of adolescence, and psychologically was no other than the new strong tide of sexual feeling being deflected into religion. The check to its usual course was the outcome of undue strictness in early training." On looking at history, we find that neither religion nor sex exhibits a proper sense of its psychological barriers. Dante formed a life-long passion for Beatrice when he was nine; St. Catherine of Siena devoted herself to the religious life at the age of 7; while Joan of Arc was about 13 when she first heard her "voices." If we take the adolescent period to be roughly the years between 14 and 25, we find some leaders of great religious movements experienced "conversion" during this period, and a good many more did not. If Dr. Forsyth cares to study the history of Protestant Missions, he will find a large percentage of entirely normal husbands and fathers among the men who were unquestionably moved by a stronger religious impulse than are most men.

Influence of Decubitus on Vertex Presentation

Miss MINA B. WALKER (Matron, Crayford Hospital and Barnes Cray Nursing Home) writes: As a midwife, may I be allowed to put forward the following suggestion? I submit that there is a factor which, during the latter part of pregnancy, largely determines the respective incidence of right and left vertex presentations. The child's back will almost always be found to be directed towards the side on which the expectant mother is in the habit of sleeping during the last eight or ten weeks of pregnancy. It does not appear unreasonable that this should be brought about by ordinary gravitation combined with the known tendency of the foetus *in utero* to kick away from resistance. Practical interest rests on the general statistics of vertex presentations. With a left position an occipito-posterior presentation is of rare occurrence. With a right position, however, an occipito-posterior presentation is very common, and the frequency with which this leads to various degrees of delay and difficulty in primigravidae is worth bearing in mind. For several months I have been experimenting on these very simple lines at the Crayford Hospital ante-natal clinic. Patients have been instructed to sleep on their left side from about the seventh month of pregnancy. The number of left occipito-anterior presentations has increased so markedly during this period that it is difficult to put the results down to mere coincidence. I suggest that anyone giving the foregoing method a trial will be surprised at the results obtained. The procedure aims at preventing the occurrence of right vertex positions, with their liability to be posterior or to become so at the onset of labour, and is based on the assumption that it is mainly from these positions that the majority of unreduced occipito-posterior presentations are derived. Later in pregnancy, where a right vertex (potentially posterior) is already established—say at thirty-eight weeks—some successful results will still be obtained.

A Cancer Library

News comes from Philadelphia of the gift of Dr. Frederick L. Hoffman's cancer library, made jointly by the Prudential Insurance Company and himself, to the Cancer Research Laboratories of the University of Pennsylvania Graduate School of Medicine. An effort is being made by the Cancer Research Laboratories to establish a central depot or clearing-house for all information about malignant disease, so that, for the North American continent at least, there will be a collection and reference library available to those interested in cancer. The Hoffman library includes many cancer books and reprints, as well as lists of the leading cancer periodicals, and a large collection of related medical works and the vital and medical statistics of practically the whole civilized world, covering at least the last ten years of recorded experience. The library includes also the original mortality data on cancer collected by Dr. Hoffman for various communities and sections of the United States and Canada, exceeding 65,000 transcripts of cancer death

certificates and some 10,000 questionnaires concerning clinical, physical, and dietary factors, as well as treatment data and family histories of living cancer patients interviewed by trained research assistants in different cities with the co-operation of local boards of health and hospitals. At the present time, Dr. Hoffman is concentrating most of his attention upon an elaborate study of cancer in relation to diet and nutrition, including the collection of data in Philadelphia, Boston, San Antonio, and St. Louis. The Hoffman Library for Cancer is open to anyone in search of information, and every possible assistance will be given in the furtherance of special methods of research in which the statistical method can be of value.

Female Bleeders

Dr. M. H. ARMSTRONG DAVISON (Darlington) writes: The recent correspondence concerning female bleeders has prompted me to intrude upon your space. It is well that such cases should be made known, and that the statement found in so many medical textbooks should be confuted. If, as is so often said, haemophilia were only a disease of males, and were only transmitted by females, obviously it would have died out at its inception, and could never have been inherited from the first sufferer. Actually the disease is inherited from male and female alike according to strict Mendelian laws, modified only by the fact that the gene in question is borne upon the X-chromosome. The gene is recessive, and thus, if a female carrier marry a normal male, the chances are (if the number of offspring be sufficient) that half the male children will be bleeders and half the female children carriers. Should a haemophilic male marry a normal female, all the male offspring will be normal and all the females carriers. If, on the other hand, a haemophilic male marry a carrier female the first filial generation will be composed of normal and haemophilic males in equal proportions, and carrier and haemophilic females, also in equal proportions. It will thus be seen that a haemophilic female is not an extraordinary phenomenon, but is the natural, though necessarily rare, outcome of the laws of heredity.

Castor Oil Vapour as a Purgative

Dr. PHILIP KEMP (Birmingham) writes: Another explanation of the phenomena recorded by Dr. Macphree (*Journal*, December 8th, p. 1045) might perhaps be given: Considerable veneration of castor oil prevailed among parents of earlier days, and consequently few children escaped experience of this repulsive liquid. A strong mental impression was likely to result from an administration, and this might become associated with the memory of subsequent purgation. Is it not possible that the "slightly nauseating odour," when experienced in adult life, might stimulate the bowel to increased action?

Unqualified Surgery

Dr. H. ELLIOTT BLAKE (London, W 1) writes: Recent events prompt those of us who are interested in plastic surgery to wonder why the law, which protects the public from being able to buy a few hypnotic tablets without a doctor's prescription, should still allow that public to be subjected to surgical operations under anaesthesia at the hands of unqualified persons.

Diary-Calendars for 1935

Messrs. William R. Warner and Co., Ltd. (300, Gray's Inn Road, W C 1) are issuing again for the forthcoming year their diary and calendar of medical history, and copies can be had gratis by doctors who apply to that address. It is a handy book for the consulting-room desk, with many eddiments of information among the blank spaces. We have also received the 1935 issue of the familiar "A.F.D." diary from the Anglo-French Drug Co., Ltd. (11 and 12, Guilford Street, W C 1) There is a "tear-off" page for each day of the year, the whole pad being encased in stiff covers with a calendar.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 34, 35, and 37 of our advertisement columns, and advertisements as to partnership, assistantships and locumtenencies at pages 36 and 37.

A short summary of vacant posts noticed in the advertisement columns appears in the Supplement at page 303.

THE JOURNAL OF THE BRITISH MEDICAL ASSOCIATION

EPITOME

OF

Current Medical Literature

JULY TO DECEMBER, 1934

London:

PRINTED AND PUBLISHED AT THE OFFICE OF THE BRITISH MEDICAL ASSOCIATION,
TAVISTOCK SQUARE, LONDON, W.C.1.

INDEX TO THE EPITOME FOR VOLUME II, 1934

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral; Heart and Cardiac; Liver and Hepatic; Renal and Kidney; Cancer and Carcinoma; Epithelioma, Malignant Disease, New Growth, Sarcoma, etc.; Child and Infant; Bronchocele, Goitre, and Thyroid; Diabetes, Glycosuria, and Sugar; Eye, Ophthalmia, and Vision, etc.

The Figures in this Index refer to the Number of the Paragraph, NOT the Page.

A.

Abdominal distension in retroperitoneal haemorrhage, 382
Abdominal operations followed by uraemia, 104
Abdominal trauma followed by peptic ulcer, 101
AHL, A. L.: Primary carcinoma of the liver, 64
Abortion: Abortive action of *Br. abortus*, 312
Abortion, contagious, immunization against, 477
Abortion in human infection by *Br. abortus* (Bang), 270
Abortion, induction of, local anaesthesia with percaline in, 434
Abortion, septic, tincture of iodine in treatment of, 415
Abscess, fixation, in asthma, 143
Abscess of lung, 235
Abscess, suppurative, 340

Acetylcholine in peripheral vessel occlusions, 179
acemia, 442

Actinomyces, abdominal, vaccine treatment of, 202

Actinomyces, formation of clubs in, 17

Addison's disease, treatment of, 120

Adhesive plaster, See Plaster

ADLERHEIM, E.: Lymphogranulomatosis, 334

Agranulocytic fatalities from amidopyrine and other drugs, 420, 421

Agranulocytic angina, allonal as a cause of, 78

ALBINGSMANN, H.: Early diagnosis of exudative tuberculosis, 314

Alcohol, intrathecal, as an analgesic in cancer, 423

ALDEN, F. H.: Apparent ocular atrophy, 206

Allergic reaction of bathers to aquatic vegetation, 463

Allergic reactions of veins, 121

Allonal as a cause of agranulocytic angina, 78

Amidopyrine and other drugs, agranulocytosis fatalities from, 420, 421

Anion and vernix caseosa, physiology of, 118

Amniotin in gonorrhoeal vaginitis of children, 355

Anoebic dysentery. See Dysentery

Amputation, Ricard's, 293

Amyloidosis, case of, 134

Anaemia from lice, 316

Anaemia, pernicious, invariable association of gastric achylia with, 412

Anaemia, pernicious, in pregnancy, 331

Anaemia, pernicious, proteolytic activity of gastric juice in, 117

Anaemia, pernicious, surgical operations in, 276

Anaemia, pernicious, yeast in, 126

Anaesthesia, avertin, and nitrous oxide, combined, 266

Anaesthesia, avertin, in oto-rhino-laryngology, 111

Anaesthesia, evipan, 410—In psychiatry, 145—In general practice, 267

Anaesthesia, local, in major abdominal surgery, 163

Anaesthesia, lumbar, with pantokain-L, 265

Anaesthesia, nitrous oxide and avertin, combined, 266

Anaesthesia, nitrous oxide, encephalography under, 243

Anaesthesia, nitrous oxide, in orthopaedics, 110

Anaesthesia, percaline, local, in induction of abortion, 434

Anaesthesia, percaline, in urology, 311—Spinal, a complication of, 412

Anaesthesia: pre-anaesthetic medication, experimental, 374

Anaesthesia, spinal, by percaline, a complication of, 412

Anaesthetic properties of cyclopropane, 109

ANDERSON, E. D.: Chloral hydrate in paediatrics, 135

Anaesthet, operative treatment of, 124

Aneurysm of subclavian artery, traumatic, 261

Angina, agranulocytic, allonal as a cause of, 78

Angioma of the kidney, 45

Anti-natal care, 473

Antibodies, heterophil, in glandular fever, 13

Antigonoecol serum in treatment of gonorrhoeal arthritis, 221

Antileprol in Boeck's sarcoid, 12

Antirhabd virus vaccine in treatment of sciatica and neuritis, 223

Antistreptococcal vaccine in treatment of herpes minor, 23

Antitoxin and convalescent scarlet fever serum, 145

Aorta, radiology of in the aged, 156

Aorta, stenotic, congenital, of, 137

Aortic stenosis, 23

Appendicitis, acute, mortality of, 42

Apples, powdered, in diarrhoea of childhood, 328

ARAOZ, J. D.: Tonsillectomy in cases of pulmonary tuberculosis, 139

ARNOLD, L.: Foods and bacterial invasion, 437

Arsenic-gold (combined) therapy in lupus erythematosus, 432

Arsphenamine reactions, serious, prevention of, 274

Arterial hypertension. See Hypertension

Arteriotomy, arteriography as a guide to, 81

Artery, subclavian, traumatic aneurysm of, 261

Artery, uterine, vaginal ligature of, 114

Arthritis, calcium ortho-iodoxybenzoate in, 203

Arthritis, gonorrhoeal, treatment by antigonoecol serum, 221

Arthritis, suppurative, of the knee, treatment of, 158

Ascaric acid in the chick embryo, 191

ASHCROFT, D. W.: Function of the sacculo, 223

Asphyxia, tongue in the production of, 400

Asthma, fixation abscess in, 143

Asylums, secondary pellagra in, 234

Atelectasis, massive, in pulmonary tuberculosis, 398

Atrophia, congenital, 184

Atropine dosage, massive, in Parkinsonism, 9

Aural vertigo. See Vertigo

Avertin anaesthesia. See Anaesthesia

Avitaminoses in pregnancy, 132

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

1 Spread of Tuberculosis in School Children

A. LARSEN and K. HALBERG (*Ugeskrift for Læger*, April 26th, 1934, p. 447) give an account of tuberculin tests conducted systematically since 1924 in the school population of the Danish town of Nakskov, with 14,000 inhabitants. The tests were repeated in some cases and included Pirquet's, Moro's, and Mantoux's. Among the 1,877 children thus tested were 361 positive reactors. A search was made for foci of infection, but in only about 17 per cent. could likely home sources of infection be found. Vague clues were discovered in about 8 per cent., and in the remaining 75 per cent. no evidence could be found incriminating the children's homes. The public health measures adopted since 1928 in connexion with the town's milk supply raised it above suspicion as a wholesale source of infection. In the face of these negative results the authors studied the possibilities of infection of one scholar by another, and by charting the places in school of each child they often found a remarkable bunching of the positive reactors. The proportion of positive reactors was much higher in some classes than in others, and when the incidence of positive reactions was studied in one class from one year to another a sudden rise was demonstrable. Thus, in a class of 11-year-old girls, only seven out of thirty-eight were tuberculin-positive in the summer of 1932. In the autumn of 1933, when the same scholars had moved a class up, as many as twenty were found to have become tuberculin-positive in the interval. An investigation of the homes of the thirty-eight children revealed only one in which there was an infectious case of tuberculosis. The tuberculin-positive child (one of the first seven reactors) coming from this home appeared to be perfectly well, and even an x-ray examination of the lungs proved negative. Three of the other children, however, were found to be suffering from pulmonary tuberculosis, and the authors are inclined to suspect intra-school infection as a not negligible factor in the spread of tuberculosis at school age, even when each child has his or her own desk.

2 Cow-pox in Man

J. A. C. SCHEPEL (*Nederl. Tijdschr. v. Geneesk.*, April 28th, 1934, p. 1855) records a case of natural cow-pox in a milkman aged 50, who was admitted to hospital with the diagnosis of whitlow of the right ring finger and cellulitis of the arm. On admission, the finger showed an ulcer with a dark necrotic centre, from which a network of painful bluish-red lymphatic cords passed up the arm. There was a large mass of inflamed glands in the axilla. The man appeared to be very ill, and the evening temperature was 104° F. for a few days, but reached normal in ten days. No pus formation took place and no scarring resulted. On inquiry it was found that he had been milking cows with diseased udders, and that four other milkmen on the farm had been similarly affected. According to Schepel the condition of cow-pox must be distinguished from streptococcal or staphylococcal infection, foot-and-mouth disease, and milkmen's nodes. Prophylaxis consists in vaccination of cattle and staff of the dairy when a case has occurred.

3 Neuritis Acquired in Turnip and Potato Fields

F. W. KROLL (*Deut. med. Woch.*, May 4th, 1934, p. 669) publishes seven cases of turnip growers' neuritis and two of neuritis in adolescent girls employed on a potato field. The cause of this neuritis, which is most liable to occur between the ages of 15 and 25, seems to be the prolonged squatting, which leads to compression of certain nerves of the lower limbs. There may also be a rheumatic element in the genesis of this condition. Only two of the patients were males, and the symptoms appeared

within the first three or four weeks of the work with turnips. A sense of numbness was promptly followed by paralyses and severe pain; and in practically every case the right leg suffered more than the left, an observation which may be correlated with the fact that the patients were right-handed. The nerves most frequently involved, but only partially, were the peroneal and tibial, and in two cases the right femoral nerve showed definite signs of injury. A spontaneous recovery was effected in one case, and the treatment which led to recovery sooner or later in the other cases included the various measures commonly employed for polyneuritis. It is well to temper prophecy with caution in the estimate of the time recovery is likely to take, and in every case a change of occupation should be recommended. An educational campaign is desirable so that persons working with turnips and potatoes may appreciate the significance of that tingling sensation in the legs which gives a foretaste of what is soon to overtake them. Though the author's nine cases were spread over a five-year period, he is inclined to consider this ailment as far from rare in farming areas.

Surgery

4 Sterilization in the Male

H. BOEMINGHAUS (*Zentralbl. f. Chir.*, April 28th, 1934, p. 996) predicts that time will show that morbid psychic reactions, such as have been feared but very occasionally found after sterilizing operations on the vasa deferentia, are practically confined to those in whom the intervention has been judicial and involuntary. Technically, it is essential to isolate the vasa completely, so that the testicular vessels and nerves are not injured. Whether the ducts are divided only or partially resected is immaterial if recanalization is effectively prevented. This is best done by suturing the peripheral end in the skin of the upper end of the scrotum. Through this end the vesiculæ seminales are washed out by a mild antiseptic, which passes through the ejaculatory ducts: the surviving secretion is thus got rid of, and the period of quarantine (segregation) shortened. An advantage of the procedure is that an abscess from a subsequent gonorrhoea, extending to the vas deferens, will point beneath the skin of the scrotum, not deep within it. The central end of the vas is returned to the scrotum without ligature, in order to avoid acute stasis in the testis and epididymis.

5 Tumours of the Salivary Glands

J. MARTIN and D. ELKIN (*Arch. of Surg.*, April, 1934, p. 727) state that the mixed cell variety of tumour is the most common type of growth of the salivary glands, although primary carcinomas may occur. Benign tumours of these glands may become malignant, and an incorrect prognosis may be made if they are seen before or during metaplasia. Mixed tumours of the salivary glands may be epithelial, fibro-endothelial, or fibro-epithelial in origin, and may occur at any age, with the greatest frequency in the fourth decade. The parotid gland is most often affected. The tumour is usually noticed as a small pea-shaped swelling near the gland, which may follow septic parotitis or trauma. At first there are no symptoms, but after some years there is increased activity, and if the growth is removed at this stage it is usually found to be benign. If the removal is incomplete recurrence occurs, in which growth is more rapid than in the original tumour. Radium and x rays alone have given unsatisfactory results, and complete surgical excision of the tumour is the treatment of choice. The danger of injury to the facial nerve is less grave than the failure to remove all the diseased tissue. In some cases where there had already been recurrence the implantation of radium seeds at the time of operation has given encouraging results. Twenty-four cases of tumour

of the salivary gland are reported, of which twenty-one were of the mixed cell variety, and of these eleven were definitely benign. A combination of surgical removal with x-ray and radium therapy prevented recurrence in seven cases. There was recurrence of the growth in ten cases, twelve patients are still living, whilst in seven instances the result is not known. The prognosis is therefore not good, recurrence having taken place in two-thirds of the cases. It was noted that with each recurrence the growth became more active, thereby making permanent cure less likely.

6 Appendicostomy and Peritonitis

E. JONES (*Ann. of Surg.*, April, 1934, p. 640) emphasizes the high mortality in cases of ruptured appendix with diffuse general peritonitis, and points out that patients who develop faecal fistulae usually recover. As a result of this observation, appendicostomy has been carried out in a series of seventy-five cases with a mortality of only 1.4 per cent. Early symptoms of a ruptured appendix, complicated by diffuse peritonitis, are abdominal distension, muscular rigidity with vomiting, pain, and restlessness. Severe toxæmia develops, and as infection progresses and spreads the intestine becomes increasingly distended. The severity of symptoms is in direct proportion to the time interval following perforation. As distension increases the arterial blood supply to the intestine is interfered with, resulting in ischaemia and death of the gut on its antimesenteric border. Infective thrombosis and extensive infarction may occur. Blood chlorides fall rapidly, and death ensues as in acute intestinal obstruction. The advantages of appendicostomy are that the caecum and ascending colon are drained, and relaxation occurs when pressure is removed from the ileo-caecal valve. The intestines are also placed at rest, peristalsis is slight or nil, there is no distension, and therefore the blood supply becomes normal. Following appendicostomy obstructive adhesions rarely occur, and the introduction of fluids and chlorides through the appendicostomy tube prevents acute systemic dehydration and rapid and severe chloride loss. The operative technique is described, and stress is laid on the necessity for post-operative treatment. Warm normal saline solution is instilled into the caecum through the tube every two hours, and nothing is given by mouth for forty-eight hours, the fasting period being extended according to the condition of the patient. The average period of hospitalization in the series was eighteen days. Six cases are reported as being typical of the series of seventy consecutive cases in which the mortality rate was 1.43 per cent.

Therapeutics

7 Injection Treatment of Haemorrhoids

M. KIRSCHEN (*Wien. med. Woch.*, May 5th, 1934, p. 527) has treated about 400 patients suffering from haemorrhoids with injections of a high concentration of quinine. The material recently used for injection was "antiphlebin," a concentrated solution of quinine put up by the *Sächsische Serumwerke*. For the preceding six weeks the authors had been working with "nodithrombin," made in Austria by the firm of Löw. The preparation has the same effect, and it is thought that the addition of glycerin and alcohol to the solution has promoted the thrombogenic action of the quinine. Though as a rule the patients were thus treated under ambulatory conditions, it was never necessary to intervene surgically. There were also no serious complications. Yet this treatment was extended to the most troublesome forms of haemorrhoids aggravated by prolapse and haemorrhage. In the four cases in which relapses occurred within a two-year period, renewal of the treatment quickly effected a cure. The treatment was preceded by a rectoscopic examination, after which the patients were instructed to avoid evacuation of the bowels during the following twelve to twenty-four hours. This injunction, aided by a suitable diet and a few drops of tincture of opium, helped to make the internal haemorrhoids more congested and easier to expel. In

opposition to the opinion of others, the author finds that in many cases it is difficult to give the injections satisfactorily without an effective preliminary aspiration by means of Bier's suction apparatus, which, after being in action for ten to fifteen minutes, draws out and gives prominence to the internal haemorrhoids. Such aspiration is helpful even when the internal haemorrhoids can be rendered visible simply by exerting pressure on them. Two or at most three haemorrhoids are treated at a time, the patient being in the knee-elbow position except when he or she is elderly, in which case the lateral recumbent position is preferable. Only two to four drops of the solution are introduced into each haemorrhoid, care being taken to avoid the often thickened and chronically inflamed extremity of the haemorrhoid, and to puncture laterally, near its base. On the rare occasions when necrosis supervened it is probable that the solution was deposited not within the haemorrhoid itself, but in the surrounding tissues. Such necrosis delays convalescence, but does not otherwise impair the efficiency of this treatment. It is easy to replace the haemorrhoids after they have been injected, the patients being allowed to go back to work forthwith.

8 Organotherapy of Peptic Ulcer

This is based, according to K. GLAESSNER (*Wien. klin. Woch.*, April 27th, 1934, p. 513), on the findings that peptic ulcer does not affect regions of mucosa in which parietal cells are present (the exceptions are in cases of aberrant inclusions, in such regions, of other gland types); that more severe subcutaneous ulcers are induced in animals by injection of gastric juice from patients with, than from those without, peptic ulcers; and that parenteral injections of neutral water-soluble pepsin from gastric mucosa accelerate the healing of such experimental subcutaneous ulcers. The organotherapeutic treatment which Glaessner recommends consists in injection, subcutaneous or preferably intramuscular, of extracts of gastric mucosa rendered sterile by filtration; small amounts of preservative and anaesthetic substances may be added. Two subsequent courses of injections at six months' intervals prevent recurrences. At the same time frequent mixed meals from which red meat and extractives are excluded, are given, and the treatment is ambulant. Each meal is preceded by exhibition of 20 grams of pure olive oil and followed by a protective dose of a bismuth salt. Atropine medication is usually, and the alkaline carbonates are invariably, forbidden. The principal contraindications are penetrating old-standing ulcers, marked stenoses, and acute haemorrhage. The cases treated on the e lines and adequately investigated by means which included x-ray and biochemical tests number about 1,000, of which some two-thirds were duodenal ulcers. Lasting cure was obtained in more than two-thirds. Recurrences were noted in 10 to 20 per cent.; unresponsive cases were often found to have morbid conditions of the bile passages or pancreas, or a malignant neoplasm—any of which might or might not coexist with peptic ulceration. Injections of which the pepsin had been destroyed by heating to over 60° C. were inactive. Loeper and his co-workers have had equally good clinical results from injection of 10 per cent. pepsin solution, the action of which they regard as one of desensitization: Glaessner visualizes, but does not decide amongst, three possible modes of action of his neutral pepsin—namely, (1) its production of protective antibodies, (2) production of an increased hormonal anti-pepsin titre in the blood, and (3) stimulation and replacement of gastro-genic hormones promoting repair.

9 Massive Atropine Dosage in Parkinsonism

G. MARINZANO and E. FAYON (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, April 2nd, 1934, p. 479) confirm the superiority of Romer's treatment by large doses of atropine in the Parkinsonian sequelae of encephalitis, and give the results in fifty-one cases. Complete cessation of tremor was noted in twenty-three instances, and diminution of rigidity in a larger proportion. A remarkable improvement occurred in these with involuntary move-

ments and torsion spasms, and oculo-gyric crises as a rule became less frequent and less prolonged. The usual dose was 10 to 16.5 mg. daily, occasionally as much as 25 mg.; the effects were better in recent cases, young subjects, and those who had not received hyoscine treatment. About one in three had dry mouth, improved by daily doses of 2 to 3 cg. of pilocarpine; one in ten had persistent trouble in accommodation; four had temporary psychic disturbances; those having anorexia reacted favourably to insulin therapy; and diarrhoea (secondary to diminished gastric motility and secretion) invariably ceased when pepsin and hydrochloric acid were given.

Dermatology

10 Recurrent Herpes Zoster

H. HRUSZEK (*Derm. Woch.*, April 28th, 1934, p. 515) describes two cases of recurrent herpes zoster. In the first the rashes occurred in the same thoracic zone at twelve months' interval, during which neuralgia had persisted. In the second a syphilitic male, aged 52, suffered from gluteal, and three weeks later from thoracic, zoster. In both patients cutaneous auto-inoculation tests and inoculation of the rabbit's cornea proved negative. Discussing differential diagnosis of herpes zoster from other herpetic forms, Hruszek concludes that localization and scar formation are significant, but that at present the inoculation tests are the most reliable.

11 Percaine in Diseases of the Skin

J. FÉNYES (*Wien. med. Woch.*, April 28th, 1934, p. 499) has investigated the action of percaine on certain diseases of the skin at the dermatological department of the Graf Apponyi-Alber-Poliklinik in Budapest, where, since 1930, he has used it in an alcoholic solution or in an ointment in some scores of cases. No definite results were achieved with a 1 per cent. alcoholic solution in pruritus, associated with internal conditions such as jaundice, diabetes, Graves's disease, or cancer, nor when there was an underlying 'nervous element' such as hysteria, neurasthenia, general paralysis, or tabes. Failure had also to be admitted in several cases of lichen. In forty-two cases the percaine was used as an ointment (percaine 1 part, liq. alum formicis 10, aq. hamamelidis 6, adipis lanae comp. ad 100). The best results were achieved in pruritus and eczema of the anus, particularly when they were associated with erosions and fissures. Painful and itching haemorrhoids, pruritus vulvae, eczema of the scrotum, burns of the first and second degrees, and varicose ulcers also responded satisfactorily. Variable results were observed in senile pruritus. Frostbites became less painful, but did not seem to benefit in any other way from this therapy. The author is, on the whole, favourably impressed with this treatment, whose effects he traces partly to the anaesthetic action of the percaine, partly to the other constituents of the ointment containing it. It is, in fact, to the cooling properties of this vehicle that he traces most of the good effects in those cases in which the skin was intact. Only when it is broken does the anaesthetic action of the percaine on the exposed nerve endings make itself felt.

12 Antileprol in Boeck's Sarcoid

S. LOMHOLT (*Hospitalstidende*, February 13th, 1934, p. 187) reports from the skin department of the Finsen Institute in Copenhagen his results in twelve cases of Boeck's sarcoid treated with antileprol, which is a mixture of ethyl esters of various unsaturated fatty acids derived partly from genuine chaulmoogra oil, partly from various hydrocarpus oils. It was first prepared in 1908 by Hoffmann and Taub (Bayer and Co.). Boeck's sarcoid has been hitherto considered as a very intractable condition; even in those cases in which certain remedies have achieved success it has not as a rule been permanent. Lomholt's tests with antileprol were prompted by the successes claimed for it in Cuta in the treatment of leprosy. As far as tests with lupus of the skin were

concerned, his results were discouraging, but they were surprisingly good in the cases of Boeck's sarcoid, the cutaneous infiltrations disappearing completely in eight cases after only three to ten weeks' treatment, and showing marked improvement in the remaining four cases. The associate condition of the mucous membranes responded very favourably to the treatment in three cases. On the other hand, there was no change in the quite superficial abnormalities of the skin, in its cyanosis, in the dilatation of the blood vessels, nor in the characteristic partial atrophy of the bones. Antileprol may be given by intramuscular injection, but Lomholt soon abandoned this in favour of the intravenous route. As a rule 1½ c.cm. was given every day, the dose being reduced to 1 or 0.5 c.cm. when a febrile reaction was provoked. In cases in which the drug was well tolerated the dosage was increased to 3 c.cm. The composition of antileprol being very mixed and lacking uniformity, and the aetiology of Boeck's sarcoid being still obscure (at present it is generally regarded as an infection by an unknown virus), this treatment is still on an empirical footing.

13 Leprosy Bacilli in the "Healthy" Skin of Lepers

A. A. STEIN and M. I. STEPERIN (*Norsk Mag. f. Lægevid.*, March, 1934, p. 278) report from the leprosarium of Krutijie Rutschi, Leningrad, observations made on the ninety-seven patients and forty-nine members of the staff. In none of the latter could leprosy bacilli be found in the nose, although the examinations were repeated in the case of the doctors and nurses. In a considerable proportion of the patients these bacilli were found in skin, although it looked healthy and had never been the seat of macroscopical leprosy changes. The technique employed was to cut the skin so superficially that no blood (only lymph) escaped, and to raise a blister by the application of carbon dioxide snow, and then to examine the lymph for these bacilli. The proportion of positive and negative findings varied with the forms of the disease examined, but even in those forms in which the bacillus of leprosy occurs in scant numbers and is difficult to find, it was occasionally demonstrated by the method described. It alone yielded positive results in three cases in which the patients were apparently cured, and in whose nasal mucosa the bacillus of leprosy could not be found, even after the administration of potassium iodide. The authors' success with the demonstration of the bacillus of leprosy in the apparently healthy skin does not detract from the great value they attach to the nasal mucosa as the surface most likely to yield the bacillus of leprosy on examination.

14 Bakers' Eczema

E. ZITZKE (*Deut. med. Woch.*, April 27th, 1934, p. 642) has carried out skin tests on 130 bakers suffering from eczema. Intracutaneous injections were given of extracts, in normal saline solution, of various flours and chemicals used in their preparation ("improvers"). The chemicals entering into the composition of "improvers" include ammonium persulphate and acid calcium phosphate. Sensitization to one or other of these substances was indicated by the appearance of vesicles at the site of injection in ten to fifteen minutes. Sensitization to the same substances was also investigated by the percutaneous test, which consisted in keeping the substance to be tested for twenty-four hours in contact with the skin under a hermetically sealed dressing. Though now and again sensitization to one or other of the substances tested was demonstrable, the worst offender proved to be ammonium persulphate, which, in the last series of twenty-two bakers examined, gave a positive reaction to the percutaneous test in as many as nineteen cases. Discussing the treatment of this condition, the author finds that change of occupation is the most effective remedy, but also a council of perfection. Considering how widespread and serious bakers' eczema has become since the introduction of "improvers" in the manufacture of flour, it would be well if prospective bakers were to be subjected to specific skin tests, so that those who reacted violently to one or other of the substances with which bakers come into contact could be persuaded to seek some other occupation.

Obstetrics and Gynaecology

15 Pituitary Extract and Rupture of the Uterus

F. v. MIKULICZ-RADECKI (*Deut. med. Woch.*, May 4th, 1934, p. 665) finds that rupture of the uterus is becoming alarmingly common on account of the popularity of two measures—Caesarean section and the administration of pituitary extract before the stage of dilatation is complete. As head of the University Gynaecological Hospital in Königsberg, Prussia, this author has recently had occasion to study two cases of rupture of the uterus following the intravenous injection of a pituitary extract by general practitioners, and he records a third case, observed by a colleague, in which the pituitary extract was given by intramuscular injection. To these three cases he adds eight from the literature. Common to ten of these eleven cases was the fact that the women were multiparae. The lessons he extracts from these cases are that "plugging in" pituitary extract at random during labour constitutes malpractice, that every successive dose should be given with reference to the patient's reaction to previous doses, and that the administration of this substance by intravenous injection should be banned, as it fails to provoke the desired rhythmic contractions. Instead, it gives rise to tetanic contractions which do not promote the dilatation of the passages through which the foetus has to pass.

16 Diffuse Squamous-Cell Carcinoma of the Corpus Uteri

F. v. MIKULICZ-RADECKI (*Zentralbl. f. Gynäk.*, April 14th, 1934, p. 850) recalls that "icing-sugar" carcinoma of the uterine interior—lined continuously by a whitish layer of squamous-celled carcinoma—was described by C. Ruge fifty years ago. About thirty cases have been recorded, and the writer adds two more, occurring in women aged 65 and 70 respectively. In the first patient pyometra had followed x-ray and radium treatment for advanced carcinoma of the cervix: penetration of the corporeal myometrium was well marked. The second had a cervical cancer, but no pyometra. The author agrees with R. Meyer that in these cases it is unlikely that the squamous-celled cancer should develop independently in corpus and cervix. Not all squamous-cell epithelium in the body of the uterus is malignant; it may be secondary to severe endometritis or pyometra. The distinction between malignant and non-malignant cases is difficult: in Hofmeier's case, first regarded as benign, an inoperable condition was found to have been reached four months later. Accordingly the detection, in curettings, of fragments of squamous epithelium which do not come from the cervix calls for resection of the uterus.

Pathology

17 Formation of Clubs in Actinomycosis

K. MEYER (*C.R. Soc. de Biol.*, 1934, cxv, 1684) disputes the truth of the widely accepted view that the clubs of actinomycetes are formed at the ends of the mycelial filaments either as the result of a degenerative or of a defensive process. He points out that club formation in the tissues has been observed with other organisms, such as the actinobacillus, the tubercle bacillus, and staphylococci, and brings experimental evidence to show that it occurs even when dead actinomycetes are introduced into the body. Cultures of human origin in glucose broth, which had been incubated for ten to fifteen days, were centrifuged; the deposit was washed with saline and a fine suspension obtained; the organisms were then destroyed by exposure to steam for thirty minutes. This suspension was inoculated twice intravenously at a week's interval into a rabbit. The animal was killed a fortnight after the second injection, and the lungs were fixed with

formol and stained with Gram. The sections showed masses of mycelial filaments, either naked or surrounded by radially disposed clubs, looking like typical actinomycotic granules. Incomplete granules were visible, in which the clubs were imperfectly developed, or not arranged radially, or distributed round one side only of the central mass. In these rudimentary granules the clubs were at some distance from the mycelium, and even in the typical granules the clubs could be seen to have no connexion with the mycelial filaments. The more marked the club formation was, the less preserved was the mycelium. The fact that the club formation occurred with dead actinomycetes, and that the clubs and mycelial elements appeared to be quite separate, leads the author to conclude that the clubs are formed by the host and not by the invading organism. It is interesting to note that they have been observed by Levaditi around inorganic substances, such as tellurium.

18 Healthy Carriers of the Meningococcus

G. RAKE (*Journ. Exper. Med.*, May, 1934, p. 553) reports an intensive study of the meningococcal carrier problem. For twenty months twenty-four persons on one floor of the Rockefeller Institute in New York were examined weekly, swabs being taken from the nasopharynx and plated directly on to a 4 per cent. rabbit blood, 0.03 per cent. glucose, nutrient agar medium. The proportion of meningococcal colonies was estimated, and the identification of the organisms carried out by morphological examination, fermentation, and serological methods. Ten carriers were found. Of these, five were chronic, four of them carrying the meningococcus for periods ranging from twenty-one to twenty-six months; two were intermittent, showing long intervals of freedom extending to four months and six months respectively; and three were transient, the meningococcus being found on one occasion only. The numbers of meningococci present varied considerably, but in some of the chronic carriers they constituted at times over 90 per cent. of the colonies on the plates. The effect of coryza and pharyngitis appeared to be negligible, unless of a type in which streptococci or other throat pathogens increased greatly in number, when the meningococci underwent a temporary or permanent diminution. A second community was examined, consisting of twenty-five girls varying from 6 months to 14 years of age, who were in a founding hospital suffering from gonococcal vaginitis; only two carriers were detected. This low incidence is more likely to have been due, the author thinks, to the strict isolation of the patients rather than to the comparatively short average period of observation—fourteen and a half weeks. A third community, consisting of 569 young men, of 18 to 25 years of age, collected in a concentration camp, was also examined, swabs being taken for only a few times from any given person. Twelve carriers were found, an incidence of only 2.1 per cent. Twenty-six carrier strains were examined serologically, and though only eight could be identified with one or other of Gordon's four types, absorption tests revealed their affinity to his Groups I or II. Altogether five of the twenty-six strains belonged to his Group I and twenty-one to his Group II. This work shows that the meningococcal carrier state may be far more persistent than has commonly been supposed.

19 Heterophil Antibodies in Glandular Fevers

L. MEIJLER and R. J. SIEMELINK (*Nederl. Tijdschr. v. Geneesk.*, May 5th, 1934, p. 1952) refer to the work of Paul and Bunnell, who were the first to show that heterophil antibodies in the form of agglutinins for the washed red corpuscles of sheep were present in high concentration in glandular fever. Meijler and Siemeling used the test in six cases of clinical glandular fever in patients aged from 2½ to 30, and found it positive in all, whereas in 400 cases of miscellaneous diseases the reaction was negative, except in a case of subacute myelogenous leukaemia and another of jaundice due to gall-stones. They conclude that the test is of great value in differentiating glandular fever from other diseases.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

20 Statistics of Haematemesis and Melaena

S. FROSTAD (*Norsk Mag. f. Laegevid.*, May, 1934, p. 578) has collected the cases of haematemesis and melaena (not including occult haemorrhages) observed in a public hospital in Oslo in the seventeen-year period 1916-32. There were 424 such cases, 250 of which were of haematemesis alone, 118 of melaena alone, and fifty-six of both haematemesis and melaena. The males were in the majority (59.4 per cent.). The youngest patient was 12, the oldest 81. As some of the patients represented readmissions the 424 cases corresponded only to 382 patients. Grouping of the patients according to their age showed that before 20 there were only eighteen cases, but between 20 and 30 there were as many as 109 cases. After 30 the incidence of haematemesis and melaena declined. There were as many as thirty-six deaths—that is, a mortality of 9.4 per cent. (not cases, but patients). This mortality was highest between the ages of 50 and 60, and among men. The cases were grouped according to the months of the year in which they occurred, so as to ascertain if a seasonal factor (vitamin C deficiency) existed. In the first half of the years there were altogether 197 cases, and in the second half 227—a finding which gave no support for the vitamin C deficiency hypothesis.

21 Investigation of Gastropotosis

E. BOIX REPOLLÉS (*Rev. Med. de Barcelona*, April, 1934, p. 297), analysing with detail twenty-two cases of gastropotosis investigated by all known methods, defines the condition as an enlargement of the stomach, of which no organic cause can be ascertained, and in which the increased size is a mere symptom, and by no means the most important. He adds that the general "make up" of the body—that is, height, weight, etc.—influences, but to a small extent, the shape and size of the stomach, and that atony and ptosis are far from being present at the same time. He found both lymphocytosis and reduced colour index and normal blood count, with normal or slightly low arterial tension, and a diminution of free HCl. The blood pH is inclined to be acid within normal limits; and while there is some connexion between the pH of the gastric juice and the percentage of free HCl, that between the gastric pH and the pH of the urine is by no means clear, even though it is manifest between the former and the pH of the blood. Vagotonia was present in all cases, and basal metabolism was lowered; while hypercalcaemia was detected by Waard's method. In his investigation of the gastric juice the author practised Linossier's technique; the blood sugar percentage was determined by the method of Folin and Wu, and the gastric and urinary pH by that of Hellige and Klark respectively. There was some menstrual disturbance in all the female cases. None of these had commenced to menstruate at an unusually early age, nor had any of them been pregnant, though several were quite anxious to become mothers. The author is far from discrediting the theory that the parathyroid bodies play a great part in the production of gastropotosis.

22 Coronary Syphilis

H. G. BRUENN (*Amer. Heart Journ.*, April, 1934, p. 421) has analysed 118 cases of cardiovascular syphilis with a view to determining the bearing of coronary orifice stenosis upon the pathological and clinical pictures of the disease. By actual measurement it was found that the normal healthy coronary orifice circumference was about 10 mm., the lower level of normality being 8 mm. In thirty-nine of the 118 cases either or both of the coronary orifices had a circumference of less than 7 mm., and all except five of these patients had aortic insufficiency. These cases were then compared with twenty-eight in the series

in which there was aortic insufficiency without coronary orifice stenosis. It was found that the right orifice was occluded eight times more frequently than the left, and that an abnormally high origin of these arteries appeared to be an important factor in the involvement of their orifices. On the average, the hearts with stenosed coronary orifices were found to be less hypertrophied than those with patent openings. Infarction was relatively rare in cases with syphilitic stenosis or occlusion of the coronary openings. A racial factor was detected, negroes being twice as prone to develop stenosis at the orifices as the white population. The duration of life from the onset of cardiac symptoms was shorter in patients with stenosed orifices than in the group with patent openings. No major differences were observed between the two groups as regards symptoms, findings on physical examination, or other diagnostic criteria. Extreme stenosis of both coronary openings due to syphilis predisposed to sudden death, but this was not the case when only one was narrowed intensely. Bruenn calls attention to one characteristic type of case. The patients are in the third or fourth decade of life, and there is no cardiac hypertrophy, the myocardium being free from gross fibrosis. Coronary arteriosclerosis is absent, although the orifices are extremely stenosed. Paroxysmal pain is the predominant symptom, and there is no oedema. The average duration of life after the onset of cardiac symptoms is 3.2 months, as compared with 9.9 months for the total series.

23 Polyneuritis in Mumps

T. C. MERRILL (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, April 23rd, 1934, p. 526), who records an illustrative case, states that the nervous complications of mumps may consist of polyneuritis, meningitis, or encephalitis, but that severe or fatal results are rare. Merrill's case was that of a woman, aged 65, in whom a mild attack of mumps affecting only the right parotid was followed by polyneuritis of the second, third, seventh, eighth, and ninth right cranial nerves. Involvement of the second nerve was shown by optic neuritis, of the third by lagophthalmia and lachrymation, of the seventh by facial paralysis of the eighth by deafness, and of the ninth by dysphagia, dysarthria, and motor disturbance of the tongue and pharynx. The polyneuritis lasted for two months and ended in complete recovery.

Surgery

24 Tuberculosis of the Shaft of Long Bones

G. VANGORDER (*Journ. Bone and Joint Surg.*, April, 1934, p. 269) points out the predilection of tuberculosis of the osseous system for the earlier years of life, although it may rarely occur in adults. The clinical features of the disease are local thickening of the affected bone, pain, muscular wasting, abscess formation, and sinus formation at a later stage. Other lesions of tuberculosis may be associated either in bone or other parts of the body. In tuberculosis of the shaft of a bone the local swelling may be yielding and indentable to pressure at first, but later becomes as hard as healthy bone. The enlarged shaft is not noticeably tender, and pain is variable according to the development of the disease. Abscess formation takes place as the local process of softening and caseation progresses inside the bone, and is one of the characteristic features of the disease. Sinus formation is seen in the late stages, when the bone abscess has extended into the soft parts and worked its way to the surface of the skin. Osseous tuberculosis may be divided into three varieties: the encysted tubercle, which is the most common and chronic; the atrophic tuberculous lesion, which is seen in the metaphysical ends of long bones, and is characterized by local atrophy of the lamellae; and the infiltrating tuberculous lesion, which represents the acute form of the

disease. A tuberculous focus may develop in any portion of the shaft of a bone, and its tendency is to form an abscess. This abscess may remain encysted, may spread along the marrow cavity, may extend from the medulla to the periphery involving the surrounding soft parts, or it may extend from an original metaphyseal focus into the epiphysis and later into a joint. Treatment should consist of the subperiosteal excision of the bone abscesses, and six cases are reported which were treated in this way. Of these, five complete cures resulted, and in one case no end-result was obtained.

25 Morbid Conditions Caused by Meckel's Diverticulum

O. UTTER (*Finska Läkaresällskapet Handlingar*, April, 1934, p. 349) has revised the 13,700 laparotomies performed during the past twenty years in a public hospital in Wiborg, Finland, and has found Meckel's diverticulum figuring in thirty-three of them. In twenty-six of these cases it showed some incidental pathological condition, or was actually responsible for the operation. As many as thirty of the patients were males. In seventeen cases Meckel's diverticulum caused intestinal obstruction, and in seven cases it was inflamed. In three cases it was found in an incarcerated hernia, and in six it was of secondary importance in relation to other conditions. It is not possible to draw a hard-and-fast line between the diverticulum which gives rise to intestinal obstruction and the inflamed diverticulum, for diverticulitis, by causing adhesions and bands, may be the primary factor in a subsequent attack of intestinal obstruction. According to observations made in Finland and Sweden, Meckel's diverticulum is responsible for about 2 per cent. of all cases of acute intestinal obstruction, and causes the death of the patient, as a sequel to the obstruction, in 32 per cent. of such cases. With regard to treatment, simple disinvagination of the invaginated diverticulum is not enough, for the invagination is apt to recur, and it did so in one of the author's cases with fatal results. Resection of the diverticulum, and in some cases of part of the gut as well, is indicated. Every diverticulum, diseased or healthy, should be removed, and whenever a normal appendix is found in an alleged case of appendicitis a Meckel's diverticulum should be sought.

Therapeutics

26 Administration of Thyroxine

W. O. THOMPSON *et al.* (*Endocrinology*, March-April, 1934, p. 228), who have been investigating the action of various compounds of thyroxine on the basal metabolism, report a comparison of the effects of administering thyroxine intravenously in alkaline solution with those of giving it in various forms by the mouth. In terms of the amount which had to be administered each day in order to keep the basal metabolism of patients with myxoedema (basal metabolism minus 37 per cent.) at the normal level, it appeared that the intravenous injection of thyroxine in alkaline solution (0.33 mg. daily) had about four times as much effect as when given by mouth in the form of its mono-sodium salt (1.33 mg. daily), and about 150 times as much effect as when given by mouth suspended in distilled water (50 mg. daily). Thyroxine administered intravenously in alkaline solution and desiccated thyroid given by mouth (1.38 grams daily, containing 0.21 mg. iodine) appeared to have the same effect on the basis of equivalent iodine contents. In patients with myxoedema a single intravenous injection of 10 mg. of thyroxine in alkaline solution caused the metabolism to increase 32 points (from minus 37 per cent. to minus 5 per cent. on the average), while the oral administration of equivalent doses of mono-sodium thyroxine, thyroxine in alkaline solution, and desiccated thyroid caused changes in the metabolism, respectively 22 per cent., 63 per cent., and 69 per cent. as great.

Thus, when the effects of single large doses are compared, 10 mg. of thyroxine given by mouth in an alkaline solution has the same effect as a dose of desiccated thyroid containing the same amount of iodine (6.5 mg.).

27 Malaria Therapy in Tabetic Optic Atrophy

Though the efficacy of malaria therapy in tabes has been disputed, and its use limited to visceral forms of the disease, certain German authorities have recommended its employment in tabetic optic atrophy, a strain of the plasmodium attenuated by quininization being used, as the fragility of the nerve necessitates avoidance of too high febrile crises and large doses of quinine. A. FRIBOURG-BLANC (*Rev. Méd. Franç.*, April, 1934, p. 379) records two cases in which this method was adopted. Though beneficial in both cases, the results were far less favourable in one than the other. In the case of semi-failure, the papillary atrophy with almost complete blindness was very advanced, and well established before treatment. The author concludes that the efficacy of malaria therapy depends on the stage of the disease, as the vaso-dilatating and eutrophic action of hyperthermia is ineffective in lesions of definitely established sclerosis. Hence, early treatment is necessary, and a strain of well-verified plasmodium vivax should be employed. This therapy is contraindicated in cachexia, pulmonary tuberculosis, and conditions with marked cardiac, hepatic, or renal lesions. Malaria therapy is exempt from all danger, and should therefore be applied in all cases of tabetic optic atrophy, especially in view of the gravity and serious prognosis of this disease.

28 Antistaphylococcal Vaccine in Treatment of Zoster

G. P. MARINOFF (*Thèse de Paris*, 1934, No. 70), who reports the histories of ten illustrative cases in patients aged from 16 to 79, in addition to giving a table of seventy-two cases in patients aged from 5 to 75, states that antistaphylococcal vaccination is one of the most efficacious methods of treatment in herpes zoster. It relieves the pain so effectively as to do away with the necessity for local analgesics. It shortens the duration of the eruption by half, and prevents secondary infection, so that local applications of any kind are not required. The treatment is successful at all ages. Though it does not have any effect on the neuralgia following zoster which has cleared up spontaneously, zoster which has been treated by the vaccine is never followed by neuralgia of this kind. In order to obtain the best results the injection of the vaccine should be given subcutaneously in the immediate neighbourhood of the eruption.

Neurology and Psychology

29 Extradural Cysts

According to C. A. ELSBERG, C. G. DYKE, and E. D. BREWER (*Bull. Neurol. Inst. of New York*, March, 1934, p. 395), there is a characteristic syndrome of compression of the spinal cord by an extradural cyst, usually of large size, and not dermoid or parasitic in nature. The patient is generally an adolescent, and four cases are recorded, in which the patients were aged 12, 15, 15, and 16 years, the last being a girl and the remainder boys. The history and symptoms suggest a progressive spastic paraplegia. Pain is usually absent or is not a prominent symptom. The objective disturbances of sensation are slight, and their upper level is in the mid-thoracic region, usually at the sixth or seventh thoracic dermatome. Manometric tests reveal a subarachnoid blockage, with the spinal fluid changes characteristic of cord compression. Measurements on antero-posterior x-ray films show that the interpedicular spaces of three or more vertebrae, somewhere between the fourth and tenth thoracic vertebrae, are enlarged. The pedicles of the affected vertebrae are narrowed and atrophic, especially those of the sixth,

seventh, and eighth. The authors claim that this combination of symptoms and signs justifies the diagnosis of a large extradural cyst of the spinal cord. The condition has to be distinguished from intramedullary disease, multiple sclerosis, and syringomyelia. In the four recorded cases the motor disturbances consisted of marked loss of power and increased tendon reflexes in the lower extremities, with bilateral ankle clonus and Babinski's sign. The limb on the same side as that on which the attachment of the cyst to the dura was found was in three cases the first to be affected, but both limbs soon become involved without muscular atrophy. In one patient in whom the symptoms had been present for three years, the erectores spinae were atrophied. The lower abdominal reflexes were lost in one patient, and all abdominal reflexes in the other three. In all the cyst was found to lie mainly under the arches of the sixth, seventh, and eighth thoracic vertebrae, which appear to be the usual site for these large extradural cysts. The authors suggest that the cyst formation is traceable to a congenital diverticulum of the dura mater, or to a herniation of the arachnoid through a congenital defect in the dura.

30 The Pre-motor Cortex Syndrome in Man

MARGARET A. KENNARD, H. R. VIETS, and J. F. FULTON (*Brain*, March, 1934, p. 69) record a case of forced grasping which, like other cases described in the clinical literature, exhibited spasticity, increase of the tendon reflexes of the digits, and gradual impairment of the skilled movements of the fingers. The patient was a man aged 34, and the first phenomena took the form of epileptiform seizures. The signs and symptoms named, together with vasomotor disturbances of the affected extremity (in this case the left arm), form a well-defined clinical entity which the authors term "the syndrome of the motor cortex." They state that all manifestations of the condition can be reproduced experimentally in the subhuman primates by lesions restricted to the pre-motor area. This syndrome can be differentiated clinically from the motor area syndrome on the basis of chronology of symptoms. In the case of pre-motor lesions, awkwardness, spasticity, and increase of tendon reflexes appear early before the onset of motor weakness; whereas in lesions of the motor area weakness begins early, the reflexes are at first depressed, and spasticity, if present, appears late. Experimental destruction of the pre-motor area in a monkey or chimpanzee was found to reproduce the pre-motor syndrome in its fully developed state, including marked vasomotor disturbance, forced grasping, spasticity, and failure of every type of skilled movement. The authors remark it as highly significant that during the period of recovery from such an experimental lesion the first symptoms to disappear (forced grasping and vasomotor disturbance) are those which appear latest in the clinical pre-motor syndrome, while the symptoms which persist longest after the experimental lesions (impairment of skilled movements and increase of reflexes) are those which appear first in the clinical anamnesis. The precocious disturbance of skilled movements must therefore be regarded as the most significant feature of the pre-motor syndrome. The forced grasping in the case described showed consistent variations with changes of position of the body in space, which, the authors point out, places the phenomenon in the category of the righting reflexes described by Magnus. They add that the changes in skin temperature and sweating on the side opposite the lesion indicate that representation of the autonomic nervous system exists in the cortex.

31 Transient Diplopia as an Early Symptom in Cerebellar Tumour

According to E. ROZNER (*Med. Klinik*, April 20th, 1934, p. 546), double vision is not rare in cerebellar tumour, but is usually a late symptom associated with pressure on the nuclei of the sixth, fourth, or third cranial nerve. A case is described in which transient attacks of double vision of two weeks' duration gave the first indication of a cerebellar tumour. The images appeared to be separated

by the same distance when the object was moved, and slight hyperesophoria was noted, so that a supranuclear fusion lesion was diagnosed. The other signs were slight papilloedema and left hypotonia; left dysidiadochokinesia and other cerebellar signs followed later, and operation showed glioma of the left cerebellar hemisphere. A similar early diplopia may occur in epidemic encephalitis, tabes, multiple sclerosis, syringomyelia, and Little's disease, and is due to lesions near the fourth ventricle. At a later stage impaired fusion may be masked by an ocular muscle palsy.

32 Importance of Early Malarial Treatment in G.P.I.

J. MADSEN (*Hospitalstidende*, April 24th, 1934, p. 481) deplors the fact that hitherto only about a quarter of the patients given malarial treatment recover from their general paralysis to such an extent that they can resume work; and he has conducted investigations which give statistical support to his theory that better results would be achieved if the interval between the first appearance of symptoms and the treatment were shortened. At the Danish asylum in which he works 293 patients were given malarial treatment in the period 1922-8. In the spring of 1930 follow-up investigations were made, and 231 patients were traced. They were classified, on the one hand, according as the interval between the first appearance of symptoms and the institution of treatment was three months or less, between three and six months, between six and twelve months, and over a year, and, on the other hand, according to the therapeutic results. As the various tables show, the proportion of cures, immediate and remote, varied indirectly with the length of the interval between the first appearance of symptoms and the institution of treatment. The same lesson was brought out by grouping the patients only in two classes—namely, those whose symptoms had lasted more or less than half a year before treatment was instituted. The ideal would be to give prophylactic malarial treatment before clinical symptoms had developed, and on the strength of other available evidence of impending dementia paralytica. Short of this ideal there is the alternative of speeding up the administrative machinery: at present in Denmark the transfer of a patient from an ordinary hospital to an asylum is liable to take months. There is also the difficulty of persuading a patient in the early, curable stage of his disease to enter an asylum. One remedy suggested by the author is to centralize malarial treatment in special hospitals, so that the malarial succession from one patient to another would not tend to delay the treatment.

Obstetrics and Gynaecology

33 Treatment of Hypogalactia

L. ROSENVASSER (*La Semana Médica*, April 12th, 1934, p. 1105) found that injections of the anterior pituitary extract gave very inconstant results in this condition, even though it always produced some local reaction in the breast. A 20 per cent. extract of the placenta of the cow or sheep, however, of which 1 or 2 c.cm. was daily injected for twenty days, was eminently satisfactory in forty out of fifty cases in which he tried it. His unsuccessful cases were generally elderly primiparae, or mothers otherwise too feeble to suckle. The injections were at times followed by rigors and local reactions in or around the breasts, such as pruritus, and an urticarial rash; but these were quite transient and disappeared in less than twenty-four hours. The author states that the variety of remedies tried for inducing the flow of milk in all ages is enormous. In the vegetable kingdom he instances angelica, cummin, fennel, anise, nettles, and gossypium; in the mineral, salts of lime and iron; the physical sciences have been called upon in respect of suction, massage, expression, extraction by pump—manual or electrical—actinotherapy, heliotherapy, galvanism, faradism, and diathermy.

34 Physical Culture during Pregnancy, Lying-in, and Lactation

DECUING and GUILHEM (*La Gynéc.*, March, 1934, p. 133), after describing the effects of pregnancy upon a woman's appearance, states that, except in the presence of certain obvious contraindications, including the times when periods would be due, active exercise during pregnancy, checked by the induction of fatigue, and adapted to the age, tastes, and constitution of the patient, should be the general rule. The objective is the prevention of adiposity, ptosis, yielding of the abdominal wall, constipation, and inefficient respiration. The movements required are therefore abdominal and thoracic exercises, preferably active, if necessary passive. Varices in the lower limbs may be avoided by regular movements, having them raised in bed, and wearing elastic stockings. During the lying-in period massage, early getting up, and especially movements described as "going for a walk in bed" are advocated. It is hoped that the French mother will continue deep breathing and abdominal movements, and engage in sports as do German and Swedish mothers with their entire families.

35 High Frequency in Vulvar Pruritus of Pregnancy

Vulvar pruritis, with or without vaginitis, is a frequent accompaniment of pregnancy, and is occasionally refractory to all usual therapeutic measures. In such cases J. HARTEMANN (*Bull. Soc. d'Obstét. et de Gynéc.*, *de Paris*, April, 1931, p. 317) has found that applications of high-frequency current produce a rapid cure, and records two illustrative cases. In one, applications were made to the different vulvar regions with Vignal's electrode, followed by an application (intravaginal) of about ten minutes' duration with Potret's grooved electrode. Owing to a slight recurrence ten days later this was repeated, with resulting cure. In the second case, after applying Vignal's electrode, electrodes of progressively increasing diameter were used, and finally Potret's. As next morning a less violent attack of pruritus occurred, an intravaginal application of ultra-violet light was made; this was followed by complete cure. This efficacious method is entirely without danger, and Hartemann considers that pregnancy is a supplementary indication to its use rather than a contraindication.

36 Delivery of Double-headed Monster

According to A. RYDÉN (*Zentralbl. f. Gynäk.*, April 28th, 1934, p. 972) the immature double-headed monster is usually, and the mature one occasionally, delivered spontaneously. In a case which he notes the two heads were expelled together, side to side, but looking to the mother's right and left respectively, the right side of one head being directed towards the pubis and the right side of the other towards the sacrum. The left apposed sides of the heads were flattened by moulding and occupied the transverse diameter of the pelvic outlet. The weight of the foetus was 5 kilos and the joint girth of the heads 50 cm. Nevertheless, labour, which was at term, lasted only three hours in the 23-year-old three-para, and was only complicated by episiotomy done before the presence of two heads had been found out.

37 Acute Pulmonary Oedema in Pregnancy

M. I. SZER (*Thèse de Paris*, 1934, No. 213), who records seven illustrative cases in women aged from 20 to 45, of whom three were primiparae and four multiparae, states that acute oedema of the lung in pregnancy is generally the complication of a recognized valvular disease. In some cases, however, it may be the first sign of a hitherto unsuspected cardiac disease such as mitral stenosis. It may also develop apart from any cardiac disease—for example, in the albuminuria of pregnancy with arterial hypertension. It is generally a late complication appearing in the fifth month of pregnancy or at term, or even after delivery. In exceptional cases it arises in the second month of pregnancy, when the prognosis is particularly grave. Treatment consists in the administration of cardiac tonics such as ouabaine and morphine

Pathology

38 Experimental Hyperglycaemia in Rabbits

M. E. DELAFIELD (*Brit. Journ. Exper. Path.*, April, 1934, p. 130) describes the effect of intravenous inoculation of rabbits with fractions derived from *Bact. aertrycke*—the organism which gives rise to a typhoid-like disease in rodents and to acute food poisoning in man. The active fractions were prepared by tryptic digestion of the bacterial bodies, followed by suitable alcohol precipitation. They contained polysaccharide components but no unaltered protein. Injection of 0.4 to 2.0 mg. per kg. body weight of rabbit was followed by illness, often of acute onset. Usually within fifteen minutes the animal was subdued and breathing rapidly. Coarse tremors and severe diarrhoea were common. The hind legs became weak, and some of the animals developed severe prostration. At the end of two hours the animals were usually very limp, the temperature had fallen, and the peripheral circulation was so depressed that blood could be obtained only by cardiac puncture. Death sometimes occurred in two to forty-eight hours; in animals that survived, improvement was noticeable after four hours, though the weight continued to fall for about four days. Examination of the blood showed in two hours a marked rise in the sugar, which sometimes reached a figure three or four times the initial one. The hyperglycaemia disappeared in twenty-four hours, and was usually followed by a slight hypoglycaemia. In animals that died the blood sugar fell, sometimes to the convulsive level. Post-mortem examination in fatal cases showed a marked haemorrhagic congestion of the thyroid with occasional haemorrhages in the intestines, adrenals, and kidneys. It is of particular interest to note that the toxicity of the various fractions tested ran closely parallel to their ability to induce antibacterial and antitoxic immunity in mice.

39 The Blood in Measles

G. STANCANELLI (*La Pediatria*, May 1st, 1934, p. 457) examined the blood of nine infants with measles, aged from 5 to 12 months, and came to the following conclusions. During the incubation and prodromal periods there was a diminution of haemoglobin and of the red blood corpuscles, while there was a gradual increase in the white cells during the eruptive stage. In the occurrence of complications leucocytosis was frequently observed; myelocytes and metamyelocytes were often seen in the prodromal period, and subsequently until recovery took place. There was a shift to the left in the Arneth scheme in the prodromal and eruptive periods and during the presence of complications.

40 Tubercle Bacilli in the Circulating Blood

W. KOLLE and E. KÜSTER (*Deut. med. Woch.*, March 2nd, 1934, p. 309) report, from the Chemotherapeutic Research Institute Georg-Speyer-Haus in Frankfurt a. M., investigations which altogether fail to confirm the claims made by E. Loewenstein, who has found tubercle bacilli circulating in the blood of some 50 per cent. of the subjects of tuberculosis, and in a considerable proportion of cases of rheumatic polyarthritis, schizophrenia, and multiple sclerosis. Following Loewenstein's technique, the authors have made 1,033 examinations of 953 patients suffering from tuberculosis or from one of the other diseases already referred to. Positive results were obtained in only seven cases. In one of these seven cases the bacilli were found by animal experiments to be virulent. In five of the seven positive cases the disease from which the patients were suffering was tuberculosis, definite or suspect. Among the 111 rheumatic cases, which included some of erythema nodosum, there was only one positive blood finding. The remaining positive finding belonged to the group of 128 cases of schizophrenia and allied conditions. All the fifteen cases of multiple sclerosis and all the sixty-eight cases of various other diseases yielded blood in which no tubercle bacilli could be found.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

41

Latent Pellagra

E. RUB (*Hospitalstidende*, May 1st, 1934, p. 513), attached to a hydropathic establishment in Denmark, believes that latent pellagra may not be rare, and that it may be responsible for several of the cases hitherto labelled as nervous anorexia or dyspepsia, colitis or neurasthenia, in persons of the asthenic type, nervous and irritable, under weight in spite of a good appetite, and suffering from chronic digestive disturbances and slight anaemia refractory to iron. He has observed five such cases, details of one of which he records at length. The patient was a married woman, aged 50, who had suffered for fifteen years from constipation, and whose vague pains and great lassitude could not be traced to any demonstrable organic lesion. She was put on an almost exclusively vegetarian diet, with a little meat only twice a week and no milk. The constipation ceased, but she rapidly lost weight, and her previous symptoms became much worse. Insomnia, apathy, depression, loss of hair, cessation of the growth of the nails, diarrhoea, and various other troubles overtook her, and, latent pellagra being suspected, although there was no rash or pigmentation of the skin, she was put on an anti-pellagra diet, which included a daily ration of meat, a couple of eggs, "decamin," and yeast. She made a dramatic recovery, and when she reported again for observation between four and five months after discharge her improvement was such that she was hardly recognizable. After she had discontinued the yeast for three weeks loss of weight and pain recurred, whereupon she resumed the yeast and lived for a couple of months on a preparation rich in vitamin B. Her improvement was now resumed. Discussing the pathogenesis of this class of case, the author suggests that the change from an ordinary mixed diet to one which is almost exclusively vegetarian may upset the balance of an already unstable metabolism and give rise to the clinical picture just described. The cure of the constipation may also have reduced the absorption of vitamin B by the intestines. Cases such as this should be a salutary warning to dietetic enthusiasts who, in their treatment of colitis and ulcers of the digestive tract, are inclined to prescribe a dietary deficient in the anti-pellagic factor.

42

Mortality of Acute Appendicitis

From a study of 500 cases of acute appendicitis, J. J. WESTERMANN (*New York State Journ. Med.*, May 1st, 1934, p. 388) concludes that mortality can be definitely lowered by ensuring great care and gentleness at the operation. The smallest degree of exposure compatible at removal and the provision of adequate drainage make for the smoothest convalescence. If considerable difficulty attends appendicectomy, drainage alone may prove very useful. Westermann distinguishes three types of acute appendicitis. The first group (numbering eighty-three in his series) contains cases in which the disease is presumably haematogenous, being coincident with, or immediately subsequent to, respiratory or other infections—twenty-five of the eighty-three having had tonsillitis, twelve otitis media, and ten pneumonia. The morbid process is limited to the outer coats of the appendix, and is usually streptococcal. The mortality rate was 7.8 per cent., the patients' average age being 13½ years. Trauma and excessive operative intervention aggravate the condition and interfere with the peritoneal resistance. An intramuscular incision is preferable with drainage if free fluid is found. The appendix should not be removed if difficulty is entailed. Ileostomy and other secondary measures are very poorly tolerated and light up the infection. The early and copious administration of fluids is essential, including large saline and glucose injections, and repeated blood trans-

fusion. The second group (numbering 372 in the author's series) comprises cases resulting from injury of the appendix mucosa, with ensuing infection by faecal organisms. The average age of the patients was 30.6. These cases are not fulminating, and general peritonitis is not an early complication, a localized abscess being a more common sequel. The mortality rate, which was only 4.1 per cent. in the series, is raised by undue operative interference; eleven patients with right rectus incisions and five subjected to ileostomy died. The most effective procedure in the presence of abscess formation or localizing peritoneal involvement is the induction of drainage at the site with a minimum of surgical trauma. The patient is warned to seek surgical assistance early in the event of the symptoms returning. The third group of patients numbered forty-five, with an average age of 56. The onset is described as slow, with general digestive symptoms and physical signs in the lower part of the abdomen from the start. The appendix has been the seat of previous inflammation; in twenty-two of the forty-five patients there was abscess formation within four days of the onset. The mortality rate tends to be high (11.1 per cent. in the author's series), but simple drainage of the abscess, preferably under local anaesthesia and with a minimum of operative exposure, lowers it. Westermann discounts the value of ileostomy, except when there is mechanical obstruction; seven out of nine patients subjected to it died. Blood transfusion, infusions of saline solution and glucose, and administration of fluids otherwise are the only permissible measures in the presence of general peritonitis and dynamic ileus. Lavage of the peritoneal cavity is not commended. In sixteen cases the appendix was not primarily removed, and eleven of these patients recovered.

43

Submaxillary Mumps

S. L. JOHNSON (*Arch. of Pediat.*, April, 1932, p. 240), during May and June, 1932, saw eight cases of submaxillary mumps, of which he records five in patients aged from 11 months to 38 years. The incubation period ranged from eighteen to twenty days. The onset was sudden. All had been exposed to epidemic parotitis, and none had had a previous attack of mumps. There was no regularity in the involvement of the submaxillary gland, either or both being affected. One or both parotids were affected in half the cases. The sublingual gland was not involved in any case. The cases were fairly mild, and no complications developed.

Surgery

44

Fracture of the Neck of the Femur

S. JOHANSSON (*Svenska Läkaresällsh. Forhand.*, April 30th, 1934, p. 49) has found 390 fractures of the neck of the femur among 3,940 fractures and dislocations treated in a Swedish hospital in the ten-year period 1922-31. In 75 per cent. the age of the patients was over 60 and in 50 per cent. it was over 70. In 17 per cent. the patient's age was over 80. There were 289 women to 101 men. The fractures were classified according as they were median or lateral, the former including subcapital and transcervical fractures, and representing 60 per cent. of the total. On account of the high average age, the mortality was as high as 20 per cent. The treatment of this fracture was unsatisfactory until Whitman introduced the system of immobilization in plaster-of-Paris for three to six months after displacement had been corrected by abduction, extension, and inward rotation. Until recently, operative measures, from excision of the head of the femur to suturing, with or without free exposure of the fracture, have been less effective than conservative treatment. The

Smith-Petersen device for immobilizing the fractured bone by a metal rod has given surgery a new opening, and the author describes his own modification, which differs from the original Smith-Petersen operation, in that the site of the fracture is not exposed. This means that the operation is simplified to such a degree that it can be recommended as a routine procedure, even for elderly patients. Before he undertakes this operation Johansson secures exact readjustment of the fragments, employing Whitman's system in doing so. He has already performed his operation in forty-seven cases, forty-three of which represented median fractures. Bony union was achieved in thirty-one of the forty-three median cases, with restoration of normal functions in thirty cases and with good function in one. Seven cases were still under treatment and five patients had died. Restoration of normal functions, with bony union, was achieved in all the four cases of lateral fracture. Hence the author's conviction that his extra-articular osteosynthesis should for the future take the place of both conservative treatment and of the operations which entail exposure of the fracture.

45 Angioma of the Kidney

G. GAYET, A. GABRIELLE, and J. MARTIN (*Journ. d'Urol.*, April, 1934, p. 297) describe angioma of the kidney as a comparatively rare condition but one which is becoming recognized more frequently as the result of microscopical examination following nephrectomy. The condition may occur at any age, but is most common between 18 and 25 years. The most characteristic symptom is haematuria, which is usually preceded or accompanied by a form of renal colic. The haematuria is similar to that of a renal neoplasm, and is variable in profusion and also in frequency. The urine is usually clear, but microscopical examination will reveal many red corpuscles. Several years may elapse between the first and second haemorrhage, and the attacks may last either for a few days or for some weeks. The bleeding is sometimes so abundant as to render an immediate nephrectomy a matter of urgency owing to anaemia. Angioma of the kidney seldom grows to a large size, but is irregular in shape and has the appearance of a conglomeration of small red pearls. The most frequent site of the tumour is in the medullary zone immediately under the mucosa of the calyces. Diagnosis is usually easy, but the lesion may sometimes be mistaken for a nephritis with haematuria or for tuberculosis. Angioma is the most common form of benign tumour of the kidney. At the present time nephrectomy appears to be the operation of choice, but it is suggested that a less mutilating procedure may some day take the place of the radical operation. If the tumour is of small dimension and the remainder of the kidney unaffected, it is possible that the tumour may be removed by means of the electric cautery after nephrotomy. In the event of post-operative haemorrhage a secondary nephrectomy could afterwards be performed if necessary.

-46 Early Diagnosis of Coxa Vara of Adolescents

According to K. LINDEMANN (*Zentralbl. f. Chir.*, April 14th, 1934, p. 887) coxa vara in adolescents is primarily an affection of the epiphyseal junction, and the patients are not uncommonly above average weight, showing signs suggesting some degree of hypogenital dystrophy. Early diagnosis, though difficult, is important if a consecutive deforming arthritis is to be avoided. Lindemann describes four cases (three in girls) in which the diagnosis could be made radiographically at a stage in which the clinical signs, after two to six months, consisted in inconstant pain and limp; absent or very slight shortening; and no limitation of movement, or only slight restriction of internal rotation, abduction, or flexion. It is essential, he finds, that the plate should be taken with the rays directed to the hip from below, and the hip flexed to 70 degrees and abducted. The early radiological signs are poorness in line of the whole coxal end of the femur, but chiefly its epiphyseal portion; apparent smallness (due to backward displacement) of the epiphysis in pictures

made in the usual position; and retroposition of the epiphysis as seen in the flexion-abduction picture. Even at this stage treatment extending over some twelve months is necessary.

Therapeutics

47 Oral Administration of Typhoid Vaccine

A. MORGADAS, writing in the *Rev. Med. de Barcelona*, (April, 1934, p. 291), states that in the village of Cardedeu in Catalonia in October, 1931, there were five cases of typhoid fever with one death. After a short interval seven fresh cases resulted in three deaths—that is, a mortality of 33 per cent. in twelve cases, all of a serious type, several with haemorrhage and endocarditis. Prophylactic administration of a vaccine supplied by the Municipal Laboratory of Barcelona was commenced in May, 1932, and during that year there were thirty cases, of which five were fatal. In these figures are included those who presented early symptoms of the disease before the completion of the course of vaccine and one case which had received none. Those vaccinated who contracted the disease ran an extraordinarily mild course, while all unvaccinated sufferers were gravely ill. So slight were the symptoms of the vaccinated that diagnosis was effected only by laboratory tests. Their temperature never exceeded 38.5° C., their stools were normal, and delirium was entirely absent. No other cases supervened. Administration of the vaccine, which was by the oral route and according to the technique of Domingo and Vidal, was at once followed by reduction of the mortality rate by 50 per cent., and by the complete disappearance of the disease in this little community within twelve months. Parenteral vaccination might have had a more energetic action on the morbidity, but this advantage is balanced by the ease with which the vaccine was administered orally, and by the fact that its administration was never followed by symptoms of intolerance. In all, 1,500 persons were vaccinated, with the results as above indicated.

48 Trypsamide Treatment of Pemphigus

A. R. ESLER (*East African Med. Journ.*, April, 1934, p. 16) reports a case of the rapid cure of pemphigus by trypsamide. The patient had large bullae on the body and extremities, which broke down into large raw ulcers with an offensive smell. He was tremulous when standing or walking; ankle clonus was present on both sides, the right knee-jerk was elicited with difficulty, and the left knee-jerk was exaggerated. Previous treatment with "914" and stovarsal had failed. The first trypsamide injection was given intravenously, the dose being 3 grams; no new bullae formed after it. Nine injections were given, four of 3-gram doses and the others of 2 grams. Owing to the great difficulty of finding a suitable vein only three intravenous injections were made, the others being intramuscular. All the raw surfaces had healed in four months after the first dose. Esler found that intravenous medication caused more rapid and marked improvement in the symptoms than did the administration of trypsamide by the intramuscular route.

49 Immunity by Diphtheria Toxoid

J. GREENGARD (*Amer. Journ. Dis. Child.*, April, 1934, p. 799) reports his observations on 214 susceptible infants of ages ranging from birth to 2 years, of whom 93.4 per cent. gave a negative Schick reaction after two injections of 1 c.cm. of commercial diphtheria toxoid (Ramon's anatoxine). Of sixty-three immunized infants retested at intervals after the negative Schick reaction eleven (17.2 per cent.) showed a positive reaction again. Of fourteen infants who failed to show a negative Schick reaction after injection of toxoid thirteen were immunized during the first six months of life. Of eleven immunized

infants whose reactions became positive again ten were immunized while under 6 months of age. In a small group of infants in whom the duration of immunity could be tested, the immunity seemed to be more lasting in those who presented a negative Schick reaction most rapidly.

Disease in Childhood

50 Minimum Diet for Infants and Children

J. L. MORSE (*New England Journ. Med.*, May 17th, 1934, p. 1057) maintains that the optimum diet for an infant or child contains the minimum amounts of food elements sufficient to promote health and growth, either excess or deficiency being undesirable. He indicates the caloric needs of boys and girls at different ages, and points out that the storage in the body of protein for growth will be defective if the dietary does not contain sufficient, for some of the protein will be consumed in supplying energy. The optimal amount of carbohydrates for the infant is from 10 to 14 grams per kilo body weight, and from 8 to 10 grams for older children. This corresponds to 40 to 60 per cent. of the total caloric intake. An excess of carbohydrates in the diet is probably the most common mistake, the usual symptoms being indigestion and loss of appetite, with the appearance of glycosuria if the excess is great. Morse thinks that an infant on modern whole-milk mixtures is receiving from 15 to 30 per cent. only of its total calories as fat, which is too little. More than 35 per cent. is probably not fully utilizable, and probably interferes with the utilization of calcium. The main symptoms of fat insufficiency are referable to inadequacy of vitamins A and D. The author's optimum diet is stated as one in which protein makes up from 10 to 15 per cent. of the total caloric intake, carbohydrate from 40 to 60 per cent., and fat from 30 to 35 per cent. The cheapest diet which will meet the nutritive needs is one in which 10 per cent. of the total caloric intake is provided by protein, 60 per cent. by carbohydrate, and 30 per cent. by fat. If a child gets a reasonable amount of milk, an occasional egg, some meat, and whole grains, it is very unlikely to lack vitamins. If the milk is not raw, an infant needs an antiscorbutic, while children should have vegetables as an additional safeguard. Infants should also be given vitamin D in some form during the winter. A child needs one gram of calcium and one and a half grams of phosphorus a day. A retention of half a milligram of iron a day is required during the first six months, and the store of this in the liver of the average infant is probably adequate to make up for any deficiency. During the rest of childhood two milligrams are essential, and are preferably obtainable from eggs, prunes, and green vegetables, although the relative importance of the last-named has been much exaggerated.

51 Heart-block in Rheumatic Fever

According to M. POMERANCE and S. FRUCHT (*Amer. Journ. Dis. Child.*, May, 1934, p. 1087), heart-block in rheumatism is so characteristic that a presumptive diagnosis of rheumatic fever may be made several days before the onset of the clinical manifestations. Three cases are recorded to illustrate the fleeting character of the abnormal rhythm; the accelerated ventricular rate in complete heart-block, making the clinical diagnosis impossible; the curious auriculo-ventricular dissociation in which the ventricular rate is higher than the auricular; and the necessity for keeping exact records in all cases. Heart-block appears and disappears at first with a disconcerting suddenness, which is comparable, however, with the fleeting joint pains in children, the ephemeral nature of the rheumatic nodule, the transitory pericardial friction rub, and the instant cutaneous manifestations. When the rheumatic attack has been exceptionally severe scar tissue replaces the myocardium, and more or less permanent functional changes result, with a lasting modification of the electrocardiogram. In some instances the tracing revealed such

an acceleration of the heart beat—for example, to an auricular rate of 120 and a ventricular of 80—that diagnosis became impossible by ordinary clinical methods. The authors conceive it likely that cases of complete heart-block in rheumatic fever go unrecognized because the ventricular rate is over 70, and that therefore an electrocardiogram is essential for accurate diagnosis. The curve sometimes shows also a ventricular rate faster than the auricular one; an illustration is given of a case in which the former was 120 and the latter 108. In the authors' series of thirty-one rheumatic cases there was prolongation of the P-R interval (incomplete block) in twenty-eight, the other three showing complete dissociation, complete heart-block, and left bundle block respectively. It is contended that, while compression of the fine coronary arterial branch lying adjacent to the oedema round the Aschoff body may be in part responsible for the cardiac functional irregularities, there must also be present some toxic factor acting on the ventricular musculature which accounts for the singular acceleration of the ventricular rate in complete heart-block.

52 Solar Irradiation and Hypervitaminosis D

E. C. DODDS, J. D. ROBERTSON, and H. J. ROCHE (*Arch. Dis. in Child.*, April, 1934, p. 91) have exposed a series of twenty-eight children to solar irradiation during the summer months. Clinical examinations and biochemical investigations were made periodically during the treatment. A further series of twenty children had similar tests at the end of the summer. All except three were between the ages of 6 and 15, and were suffering from various orthopaedic conditions. The degree of pigmentation attained its maximum between the end of June and the middle of July. The general condition improved steadily, the most marked amelioration being that noted soon after admission. There was no loss of appetite or other adverse sequels. An increase in the blood calcium and phosphorus values was demonstrable during the insolation, but the highest serum calcium levels did not always follow the sunniest periods. No cases were found in which any hypervitaminosis D could be suspected. The increase in the serum calcium and phosphorus fell within the physiological limits, and it was therefore evident that the irradiation was not acting to such an extent on the ergosterol in the skin as to free an excess of vitamin D. The patients showed no clinical symptoms of such an excess—for example, drowsiness, diarrhoeas, or mental depression. It was noted that on a normal diet doses of vitamin D such as are produced by irradiation caused a greater increase in the blood phosphorus than in the serum calcium.

53 Epilepsy in Children

K. RUPILIUS (*Med. Klinik*, May 4th, 1934, p. 604) alludes to the difficulty in distinguishing genuine from "residual" epilepsy, due to healed morbid cerebral processes (among which birth trauma has a part). He reports 113 in-patient cases of epilepsy in children; in twenty-nine of these an organic cerebral lesion could not be excluded with certainty. Lues was present in one case only. Parental epilepsy was present in three cases; parental psychopathy, psychosis, neuropathy, syphilis, or alcoholism in twenty-three; a history of difficult labour was obtained in 21 per cent. In one-third of the cases the first fit had occurred before the age of twelve months. Two-fifths of the patients showed some degree of imbecility or idiocy. Ten patients had well-marked attacks of petit mal; three had Jacksonian attacks. There were two cases of "reflex epilepsy" in children in whom orthopaedic manipulations had been done, and neither appeared to have had previous fits. In-patient stay in many cases diminished the frequency of the attacks; a hysterical component was recognized in nineteen cases. No therapeutic gain followed natural or induced pyrexia. Encephalography (air being injected as a rule after lumbar puncture) was done in twenty-eight cases, had some diagnostic use, and in one case in four was followed by improvement of symptoms. Improvement occurred in three of the six children who were subjected to x-radiation of the skull.

Obstetrics and Gynaecology

54 Types of "Pregnancy Kidney"

SERGE SELITZKY of Moscow (*Gynéc. et Obstét.*, April, 1934, p. 325) discusses at length and with reference to many authorities the differential diagnosis of the forms of pregnancy kidney and true nephritis. He classifies renal lesions into (1) those connected with pregnancy, of degenerative histological type; (2) those primarily renal, of inflammatory nature. He insists that the origin is toxic, from some part of the embryo. Incidence of renal lesions in pregnancy, according to figures collected at two institutions, is 3.6 to 10 per cent., whereas that of simple nephrosis or pregnancy kidney is about 2 per cent.; nephritis 2.1 to 4.9 per cent.; mixed forms 4.8 to 10 per cent.; chronic nephritis 7.2 per cent. Primiparae suffer most frequently from pregnancy kidney (that is, simple nephrosis). Older primiparae reach 53.9 per cent. of all cases, second pregnancies 15.7 per cent., and third 8.6 per cent. Age incidence is about 60 per cent. between 21 and 30. Pregnancy kidney always develops in the second half of pregnancy. Though the fulminating form may begin without preliminary, albuminuria is the first sign of simple and serious cases alike. The proportion of albumin is of neither diagnostic nor prognostic significance. Toxic cases are recognizable by a gradually mounting oedema, fatigue, hemicrania, and, most reliably, a loss of muscle tone. The chronic form of nephritis shows little oedema, less rise of blood pressure, and more compensatory effects—for example, cardiac hypertrophy. Hypertonus is a constant and early sign of kidney affection, running parallel with its development and with metabolic changes. Prophylaxis is of major importance. Rest in bed is specially advised, with elimination of salt, fat, and carbohydrates from the diet, and restriction of fluids. Diuretics have been discarded, also baths and hot packs and injections of normal horse serum, etc. The author believes that any treatment may help or fail, and relies upon the development of symptoms as the guide to intervention and to the choice of method. End-results, which may be long in developing, depend upon the type and degree of the lesion. Complete and rapid recovery usually follows parturition. Most statistics give 2 per cent. of reappearance. Selitzky's figures show after nephropathy 10.7 per cent., after nephrosis 20 per cent., and after nephritis 84.6 per cent. The type may be different; acute forms seldom reappear, nor does eclampsia supervene. Further pregnancy, therefore, need not be forbidden, provided a reasonable interval be assured and meticulous precautions be taken from the commencement of a succeeding pregnancy. As to chronic nephritis, therapeutic abortion was called for in 36.7 per cent. of the author's cases. The outlook for both mother and child is, generally speaking, unfavourable.

55 Parietal Bone Depression in the Newborn

Owing to modern pre-natal care, cranial depressions in the newborn are now usually seen only after urgent obstetrical intervention, such as forceps and version extractions. M. MERCENIER (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, April, 1934, p. 330) reports a case of this nature where the newly born infant showed a large depression on the left parietal bone which was evidently insufficiently deep to cause a cerebro-meningeal lesion. Parietal depressions are very characteristic of a flattened pelvis—the head, slightly deformed, is engaged while transverse, and with slightly strong traction, especially of an after-coming head, the parietal bone is forced against the promontory with a resulting saucer-shaped lesion. Commandeur divides these depressions into three groups: simple indurition without apparent fracture, depression with fissured fracture, and depression with evident fracture. According to Bue, three sequelae may follow this lesion: meningeal haemorrhage, which may cause death or secondary symptoms (coma and convulsions); perfect tolerance, after a latent period of several months, secondary conditions, such as cerebral hemiplegia, psychic deficiency, generalized epileptiform attacks at puberty, etc.

Four methods of treatment may be employed. In slight cases massage of the head by occipito-frontal pressure or by pressure on the edges of the depression frequently suffices for cure. Another method is to introduce an auger or corkscrew as far as the internal table of the bone and by traction reduce the depression. A third method consists in an intracranial reduction of the depression either through the suture or the bone. The fourth method, which should be reserved for cases in which a marked intracranial haemorrhagic area is suspected, is trephining. In the present case the intracranial sutural operation was employed with excellent results.

Pathology

56 Non-Perforative Biliary Peritonitis

According to A. ROSARIUS (*Zentralbl. f. Chir.*, May 12th, 1934, p. 1091) non-perforative biliary peritonitis was first described by v. Haberer and Clairmont fifteen years ago: its existence has been doubted, for microscopical examination in some cases has revealed small necroses of the walls of the bile passages and/or very small perforations. The case is recorded of a man aged 66 who had signs of acute peritonitis with icteroid conjunctivae and some urobilinogen but no bile pigments in the urine; at operation the colon contained much free bile-stained fluid, and there was a necrotic zone in the fundus of the gall-bladder but no apparent perforation. No other operative measure than drainage was undertaken and the patient recovered. The peritoneal fluid was sterile and did not contain pancreatic ferments; calculi were not present.

57 The Blood-Urine Urea Ratio

Referring to his previous work on the subject, J. COTTER (*Presse Méd.*, May 12th, 1934, p. 762) reiterates his opinion that the blood-urine urea ratio furnishes a simple clinical means of evaluating the functional activity of the kidneys and, according to the degree of this activity in known conditions of the urea and water excretion, of their secretory value. For the test, the total twenty-four-hour urine, collected in the morning, is employed, and the blood, to avoid the transitory influence of food on the blood urea, is also taken in the morning while fasting. The resulting amount of blood urea in centigrams is divided by that of the urinary urea expressed in grams; the quotient multiplied by 100 gives the stated ratio. This oscillates between 1 and 2 in subjects having a normal renal secretory power, provided that the ureic and aqueous excretions are respectively equal to 15 grams and 1,500 c.cm. in the twenty-four hours; in these conditions the ratio is the higher as the renal secretory power is diminished. A clinical study of this ratio shows the important influence of the aqueous diuresis on renal functioning. The influence of this diuresis on renal functioning, and therefore on the urea secretion, is well illustrated by the syndrome of nitrogenous oliguria of non-renal causation. Cure of this condition is most important; this can be attained mainly by a cure of the diuresis and by a judicious liquid dietary. Thus the humoral adulteration, as evidenced by a raised blood urea, is remedied, and the kidneys guarded from the ultimate damage caused by habitually secreting too concentrated a urine. Notes on three cases are given to illustrate various points in this paper.

58 Schick Test after Tonsillectomy

W. H. PARK, C. KERESZTURI, and D. HAUPTMAN (*Amer. Journ. Dis. Child.*, March, 1934, p. 565) review the literature and report their observations on forty-six children who had been Schick-positive before tonsillectomy and were retested six months after the operation, when 18 per cent. gave negative reactions. On the other hand, of forty-seven Schick-positive controls in whom tonsillectomy had not been performed, 21 per cent. became negative after about six months. All the subjects came from congested urban districts. The carrier rate was not higher in the controls than in those tonsillectomized.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

59 Haemorrhage from Gastric and Duodenal Ulcer

E. HJORT (*Norsk Mag. f. Lægevid.*, May, 1934, p. 542) has scrutinized the records of 4,460 post-mortem examinations carried out in hospital in Bergen between 1909 and 1933. In 108 cases ulcers of the stomach and duodenum were found. The stomach was ulcerated in eighty-four cases, the duodenum in twenty-two, and both in two. The ulceration was associated with haemorrhage in twenty-two cases and with perforation in thirty. In connexion with the teaching that the frequency of haemorrhages increases with age, and that they are much more common after than before 40; it should be noted that in only five of the twenty-two cases of haemorrhage had the patients been under 40. The author set himself the task of answering the question: "How many of these twenty-two patients could have been successfully operated on?" To judge by the local conditions, fourteen of them were operable, five not operable, and three borderline cases. To judge by the general condition of these patients, in only about half of them would there seem to have been a reasonable prospect of an operation being successful. Among the remainder there were such complications as diseases of the vascular system which might well have impaired the chances of a successful operation. After emphasizing the limitations of his method of retrospective calculation, the author concludes that, though in certain cases it is possible to operate on a bleeding ulcer with success, the surgeon must be prepared for unpleasant surprises of a purely local character. He should also, in the light of this study, let his operative indications be influenced by the patient's general condition.

60 Gas Analysis in the Diagnosis of Pleuro-Pulmonary Perforations

C. A. BIRCH (*Lancet*, May 12th, 1934, p. 1002) reports that in ten cases analysis of the pleural gases was of value in demonstrating the presence and state of a pleuro-pulmonary perforation. Details are given of three of these. To obtain a sample of the gas for analysis a special sampling tube was made, having a capacity of 25 to 30 c.c.m., enabling the gas to be removed at about atmospheric pressure by the displacement of mercury, and obviating the necessity of a special tube for washing out the connexions. When air is introduced into the pleural cavity, CO₂ diffuses into it from the capillary blood more rapidly than oxygen passes from the pleura into the blood, thus causing a temporary increase in the volume of the pneumothorax, equilibrium being restored in a few hours. The actual composition of the pleural gas is changed by variations in the degree of the collapse of the lung, histological changes in the pleura, and the presence of pleural effusion. In 150 cases it was found that, whereas the atmospheric air contains about 21 per cent. of oxygen, and practically no CO₂, the air of a dry pneumothorax cavity contained between 1 and 5 per cent. oxygen and between 6 and 8 per cent. CO₂. The presence of inflammatory exudate lowers the oxygen content—even to below 1 per cent.—while the CO₂ is high, usually exceeding 10 per cent. In the author's series of cases without fistula the oxygen content of sixty dry cases ranged from 0.9 to 4.56 per cent., and the CO₂ content from 5.85 to 10 per cent. In ninety cases with definite fluid present the oxygen content ranged from 0.4 to 4.31 per cent., and the CO₂ from 9.84 to 14.7 per cent. In one of the author's cases in which there was a spontaneous pneumothorax the oxygen percentage for a time was just over 2 and the CO₂ percentage between 11.3 and 13.2. After a sudden attack of dyspnoea and pain in the chest amphoric breathing and bubbling sounds were heard at the left base. Gas analysis showed that the oxygen

percentage had risen to 10.21, while the CO₂ was 9.85, indicating that air had entered the pleural space from the lung. At necropsy a pyopneumothorax with a bronchial fistula was found. In another case of spontaneous pneumothorax successive gas analyses revealed oxygen percentages of 3.8, 2.1, and 1.2, with corresponding CO₂ percentages of 8.2, 8.7, and 11.3. When fluid appeared the gas analysis showed an oxygen percentage of 0.9 and a CO₂ percentage of 12.6. The patient later developed pyrexia, dyspnoea, and cyanosis. A gas analysis showed an oxygen percentage of 8.5 and a CO₂ percentage of 11.7, indicating that a pleuro-pulmonary fistula had opened. The coughing up of gomenol in oil previously introduced into the pleural space confirmed this diagnosis.

61 Sudden Death while Swimming

O. GOEBEL (*Deut. med. Woch.*, June 29th, 1934, p. 982) relates a personal experience which throws some light on the origin of sudden death while swimming. As a lad of 8 or 9, he went for a swim one warm summer day in a swimming-bath soon after the midday meal. The water was not cold, and the drums of his ears were intact. Having entered the water from steps, he had swum about eight metres along the side of the bath when he became powerless and could no longer swim. He promptly went under, without making any resistance or even calling for help. He thought the end had come, but was not alarmed. Presently a pole was extended to him, and he seized it and was pulled up by a rescuer. He had no memory of what happened immediately afterwards. There were no sequels to this incident, which never recurred, although he continued to bathe. There could be no question of cold as an aetiological factor, and as consciousness was retained all the time, there could have been no complete anaemia of the brain with fainting. The sensation of the skin was undisturbed, as he felt the pole when it was extended to him. There was also no paralysis, as he was able to seize the pole and walk out of the bath. As far as he knows, he carried out no instinctive, violent, irregular movements, such as are provoked by fear in drowning persons. What happened was that the will to continue swimming suddenly ceased—that is, there was a sudden break in the nervous connexions concerned with the movements of arms and legs. It is conceivable that this may have been due to anaemia of the brain provoked by the abnormal position of a full stomach.

Surgery

62 Results of Thoracoplasty for Pulmonary Tuberculosis

R. C. OHMAN (*Finnska Läkarsällskapets Handlingar*, April, 1934, p. 291) shows, by a study of seventy thoracoplasties, that the prognosis is approximately three times better for patients thus treated than for those in the same category given conservative treatment. His seventy patients were operated on in the period 1924-25, and follow-up investigations made at the end of 1933 showed that forty-five were still alive, and as many as thirty-seven of them were fit for work, although they belonged as a rule to the labouring class. The indications for thoracoplastic operations were: advanced pulmonary disease, failure to induce a therapeutic pneumothorax (fifty-two cases), extensive adhesions limiting the volume of a pneumothorax (six cases), and empyema (twelve cases). Eight deaths occurred within the first two months after the operation and twenty within the first year after it. There were only five more deaths beyond this time limit. The patient, therefore, who can survive one or other of these operations by more than a year has an excellent chance not only

to live, but also to work. Another benefit conferred by these operations on the patients' surroundings was the disappearance of tubercle bacilli from the sputum in about 90 per cent. of all the cases. With regard to the choice of patient and time of operation, success largely depends on the other lung being healthy, and on the operation being performed at a time when the disease is least active. About 90 per cent. of the patients were afebrile when the operation was undertaken. In fourteen cases only a partial thoracoplasty was performed, the indication for it being solitary cavities in the upper part of the lung, in the rest of which there was little disease. The operations were usually performed under local anaesthesia and in two stages, the average total length of the resected ribs being 138 cm. for complete thoracoplasties. The statistical evidence in favour of this treatment may be impressive, but what carries more conviction is the clinical study of the individual case whose prognosis without operative interference is as bad as can be.

63 Operation for Spinal-Cord Tumour in the Neck

W. TÖNNIS (*Zentralbl. f. Chir.*, April 21st, 1934, p. 930) describes a case of long-standing spastic diplegia with decubitus in a man aged 46; the location of a lipiodol block intraspinally, and the presence of subcutaneous ganglioneuromata, facilitated the diagnosis of extramedullary neurofibroma of the fifth or sixth left cervical nerve root. At operation the tumour, which weighed 8 grams, was found to be chiefly ventral: the difficulty which its removal (without injury to the spinal cord) would have presented was overcome by use of the technique described by Cushing and Olivecrona for resection of deep capsulated cerebral tumours. The capsule was incised, and the tumour shelled out by diathermy, a weak current being used; the remaining tumour parts were severed intervertebrally from the motor and sensory roots of C.6. Nine months later the patient could walk and do light work, but a paresis of the triceps and extensors of the fingers persisted.

64 Primary Carcinoma of the Liver

A. L. ABEL (*Brit. Journ. Surg.*, April, 1934, p. 684), describing primary carcinoma of the liver as a rare disease, states that it occurs chiefly in males between the ages of 40 and 60. The two main types of tumours are hepatoma, or carcinoma of the liver cells, and cholangioma, or carcinoma of the intrahepatic bile ducts. Cirrhosis of the liver is frequently associated with primary carcinoma, to which it is probably antecedent. Diagnosis of the carcinoma is difficult, as there is no definite symptomatology, although icterus, ascites, oedema, splenic enlargement, and pyrexia may be present. Fixation of the liver with upward enlargement is sometimes present, and may be confirmed by x rays. Owing to the late development of symptoms, the rapid progress of the disease, and its quick dissemination, operative treatment is rarely possible, but it is suggested that with earlier and more accurate diagnosis an improvement in results might be obtained. Death is usually due to a rapidly progressive malignant cachexia, but may also occur in some cases from severe intraperitoneal haemorrhage due to malignant erosion of a large vessel. Intrahepatic metastasis is common, and on this account preliminary radiological examination should be carried out.

65 Foreign Bodies in the Stomach

MOREAU and NOGUERA (*Semana Médica*, April 26th, 1934, p. 1318), collating their experience with that of surgeons all the world over, unhesitatingly condemn precipitate operation in the above condition, and stress the importance of frequent "screening," which should never be omitted in cases about to be operated upon after the anaesthetic has been administered, as it has been proved that a foreign body, long stationary in the stomach, has frequently passed through the pylorus while the patient is "going under." One of the three cases they report was a child of 20 months, who at noon on November 1st swallowed a slightly bent tie-pin, 5½ cm. long, with a small glass ball at one end. On screening at 3 p.m. the pin was seen to

be in the stomach, but at 3.30 p.m. gastrotomy disclosed an empty stomach. On November 3rd the pin was seen in the right iliac fossa, and on the 4th at the hepatic flexure of the colon. On the 5th the patient was lipolytic, with rapid pulse and cold sweats, but in the early hours of November 6th the pin was passed without any trouble. These authors state that the surgeon's best policy is one of watchful expectancy, always remembering the size of the various portions of the duodenum, and if in doubt, waiting rather than operating. Purges and massage should be avoided. Feeds of wholemeal bread, boiled lentils, peas, and beans (dried) with mashed potatoes can be given. Once the duodenum is passed all fears may be put aside; but it should not be forgotten that this organ in a young child is fixed, and will measure 15 centimetres.

Therapeutics

66 Liver Treatment of Granulocytopenia

B. VON BONSDORFF (*Finska Läkarsällskapets Handlingar*, April, 1934, p. 317) recalls the high mortality associated with granulocytopenia and its failure to react uniformly to any of the many forms of treatment recently prescribed for it. In two seemingly desperate cases he gave a liver extract by intramuscular injection with such success that he is inclined to hope it may prove a specific. The first patient was a servant-girl, aged 18, admitted to hospital in a very feeble condition, with redness of the pharynx and inflammation of one tonsil, which began to ulcerate two days later. The blood picture was that of agranulocytosis, a malignant granulocytopenia. She had taken no drugs and undergone no radiotherapy which might have injured the bone marrow. Between November 25th and December 27th, 1933, she was given every day by intramuscular injection three ampoules containing 2 c.cm. each of campolon, 2 c.cm. of which is said to be equivalent to 500 grams of fresh liver. From December 28th, 1933, to January 4th, 1934, she was given the contents of only two ampoules a day. As she also received other treatment, including blood transfusion, the scientific value of this therapeutic experiment was limited. It was much more clearly demonstrable in the second case, that of a woman of 47, whose granulocytopenia was probably provoked by the neosalvarsan and bismuth she had been given. Her case was so desperate that a spontaneous recovery was most unlikely. Her response to the liver treatment was so prompt and effective that her recovery must assuredly be traced to it, more especially as the case had not been obscured by other therapeutic ventures.

67 Treatment of Varicose Veins

W. COOPER (*Ann. of Surg.*, May, 1934, p. 799) states that, whereas the majority of patients with varicose veins may be treated successfully by the injection method alone, there is a large group of patients who need preliminary ligation before a cure can be effected. It has been found that recurrence follows the obliteration of a varicose internal saphenous vein unless high ligation of the vein is practised. The first step in treatment should be the classification of the patient by means of the Trendelenburg test, so that the sources or points of reverse flow from the deep veins into the superficial veins can be accurately localized. Trendelenburg-positive cases are those in which the reflux of blood through the saphena magna in the thigh is marked and the valves are incompetent. In these ligation at the highest palpable point in the thigh or at the fossa ovalis should be carried out. Negative cases are those in which the reflux takes place from the deep veins through incompetent veins in the leg. Unless the veins are very large preliminary ligation is not necessary in these patients. When large and extensive varices are present, multiple ligations are performed at all the demonstrable points of back-flow, followed by sclerosing injections. It was found that sodium morrhuate, 5 per cent. strength, did not cause toxic symptoms or infectious phlebitis if used correctly, nor did an ulcer or slough occur if acidi-

dentally injected into the perivenous or subcutaneous tissues. In a series of 293 cases of extensive and recurrent varicose veins treated by preliminary ambulatory ligation and subsequent injections there was no instance of recurrence, and immediate symptomatic relief followed ligation. It was found that after ligation the veins were partially collapsed, and so required smaller quantities of sclerosing solution than when distended; also, the number of injections was diminished. The sclerosed vein disappeared more quickly than when treated by injection only.

68 Calcium in Epididymitis

E. RUPEL (*Urol. and Cut. Rev.*, May, 1934, p. 331) records his observations on eighty cases of epididymitis (forty-eight were specific and thirty-two non-specific), in which calcium therapy was used as an adjuvant in addition to heat, rest, and support. The gluconate salt was chosen because it is not irritating and has a low toxicity. It is given intravenously in 10 or 20 per cent. solution in doses of 10 c.cm. As a supplement it can also be given by mouth in 60-grain doses three or four times a day, either four hours after or one hour before meals. The injections are given daily for five or six days, sometimes longer. In most cases where calcium was used the disability was considerably lessened as regards time and severity.

Laryngology and Otology

69 Cholesteatoma of the Temporal Bone

I. DAVID (*Rev. de Laryngol., d'Otol. et de Rhinol.*, April, 1934, p. 511) gives full details of a case of primary cholesteatoma of the left temporal bone, with congenital malformation of the auricle and absence of the external auditory canal. The patient, aged 29, had suffered from deafness in this ear since birth. The auricle presented a very marked congenital deformity, the concha being funnel-shaped. The navicular fossa was absent. At the site of the external auditory meatus a small, almost impervious, fissure was found, and behind the deformed auricle a small tumour. By an operation, which is fully described, marked improvement in the hearing was obtained. A child of this patient, aged 3 months, presented a similar condition on the right side. Various theories as to the pathogeny of these growths are cited. Many authors consider that they are always secondary to unrecognized otic suppurations. David divides them into two main groups—those with and those without suppuration of the tympanic cavity—and believes that both forms may be attributed to an active mitosis of a group of embryonic cells not utilized in the formation of the ear at the embryological epoch. Cholesteatomata without suppuration (the primary forms) are much the rarer; those with this condition are much commoner, as the suppuration acts as an irritant to the enclosed embryonic cells, thus activating them and giving rise to the cholesteatoma.

70 Radiation Treatment of Oesophageal Carcinoma

F. J. CLEMINSON and J. P. MONKHOUSE (*Journ. Laryngol. and Otol.*, May, 1934, p. 313) report the results of radon treatment of eighty-nine cases of carcinoma of the oesophagus (excluding post-cricoid growths) in the Middlesex Hospital during the years 1925–32. They suggest that this treatment may be actually harmful, for these patients might actually live longer if their only treatment were preliminary removal of all teeth followed by gastrostomy. As a rule they do not seek advice until peripheral extension of the malignant growth and early metastasis have made it impossible for the radiation to reach the outlying parts of the carcinoma with effective strength. It is even possible that there may be some danger of stimulation of the growth at the periphery, and the termination be thus hastened rather than delayed. The mode of treatment was to perform first an oesophagoscopy for diagnosis, with removal of a fragment of the growth for section. The patient was then examined by x rays to determine the length of the stricture, the Trendelenburg position being

essential for this procedure, for otherwise the lower end of the stricture is not defined. From this information the dose of radon to be used and the length of the applicator were deduced. At a second oesophagoscopy the radon was placed in position and left for seven days. In several cases the ulceration disappeared after this treatment, but columns of cancer cells were found in the subjacent lymphatics between the muscle bundles, if not also in the actual stricture substance. The average survival period for the whole series was 5.6 months; for growths in the upper part 6.7 months, the middle part 5.4 months, and the lower part 6.9 months. For the ten women it was 8.5 months and for the seventy-nine males 5.2 months. The average length of the history of dysphagia was: for women 5.4 months and for men 3.8 months, women having thus a longer history and a longer survival period. A short history does not therefore indicate that the case can be considered early. It would seem that a preliminary gastrostomy might be beneficial, especially if preceded by removal of all remaining teeth. Increasing the dose of radon was associated with an even shorter period of survival, and the optimum dose appeared to be a moderate one of about 5 mc. to the inch, screened by 0.5 mm. of platinum. The authors add that deep x-ray therapy may be a more promising line of treatment.

71 Removal of Dentures from Oesophagus

In the experience of A. SOULAS (*Bull. et Mém. Soc. Méd. de Paris*, May 11th, 1934, p. 315) the "swallowed" denture more frequently becomes lodged in the thoracic or abdominal portion of the oesophagus than in the air passages. In the thoracic oesophagus retention usually occurs at the constriction corresponding to the superior thoracic aperture, the aorto-bronchial constriction, or the juxtaphrenic region; as a rule the mucosa is uninjured, and it is right to await for twenty-four to forty-eight hours the passage of the denture through the stomach into the intestine. If this does not occur, oesophagoscopy will usually lead to easy extraction, but occasionally the denture will be found to pass into the stomach or become impacted in the subphrenic oesophagus. In this situation impaction, primary or secondary, is of serious import; inflammation and stenosis are apt to occur, and it is best to remove the denture from below after gastrostomy, the wound not being immediately sutured.

72 The Toe Reflex: A Diagnostic Aid in Ear Affections

A. MALHERBE and R. VILENSKI (*Bull. de l'Acad. de Méd.*, May 22nd, 1934, p. 682) describe a reflex of value in the diagnosis of ear conditions in young children. When pressure is made at the level of the postero-lateral fontanelle in the newborn, extension of the great toe occurs, with simultaneous fan-shaped separation of the other toes. In older children the point of pressure is at the junction of the line drawn from the mastoid point to the vertex and a horizontal line passing through the highest part of the cavity of the ear. In the nursing it is found a little further down and posteriorly. If pressure is made on the right side the reflex will be elicited in the right foot if the ear is healthy, and in the left foot if the ear is diseased. The reflex is found in all children with auricular affections under 2, usually in children under 6, and less commonly in those over 6. The exact point of pressure must be found, otherwise the results may be vitiated. An assistant should extend both legs and exert light pressure under the knees to prevent spontaneous movement of the toes. The reflex seems to be due to irritation produced by intratympanic pressure, and it passes down the crossed pyramidal tract to the toes. It disappears when there is free discharge of pus through a perforated tympanic membrane, but if it persists it indicates involvement of bone. It also appears typically under an anaesthetic. The authors do not believe that there is any relationship between the intensity of the reaction and the gravity of the disease. Two variations of the reflex occur—namely, there may be extension of the great toe with flexion of the other toes, and slight extension of the great toe with marked separation of the others.

Obstetrics and Gynaecology

Pathology

73

Pelvic Extravasations

J. GOODALL (*Amer. Journ. Obstet. and Gynecol.*, May, 1934, p. 646) postulates that uterine loss depends upon: (a) one or more consecutive or alternate causes; (b) the "habit" of menstruation—that is, the constant state of ebb and flow in the reproductive function; and (c) the changes in the general circulation operating through the blood itself upon the intima of the capillaries. Oedema may be due to extravasation from blood vessels (purpura), retention of plasma (urticaria), or retarded lymphatic absorption (white leg). Causes are grouped as mechanical, destructive, toxic, blood diseases, and familial blood dyscrasias. Primary and secondary causes may be distinguishable—for example, in the presence of a fibroid haemorrhage may be due to its mechanical influence, a blood dyscrasia, hormonal disturbance, or any combination of these. With regard to abortion, this may be initiated by a blood dyscrasia, either infective or metabolic (focal sepsis, chronic or acute), and is then notably severe. Often endocrine dysfunction is behind the blood condition, and calls for treatment. A case illustrating the peculiar tendency of the uterus to haemorrhage is quoted. Blood transfusion was being performed preparatory to laparotomy, when urticaria—that is, extravasation of plasma into the skin—developed, but from the uterus there was extravasation of blood. Hence, also, the frequency of menorrhagia and the supervention of haemorrhage in chronic simple subinvolution. Endocrine imbalance is evidenced at the menopause by irregular menorrhagia. The causes of hormonal dysfunction are: advancing age, with reduction of endocrine reserve and increased susceptibility to vitiated metabolism, toxæmias, etc. The toxic extravasations may be traced to food, avitaminosis, microbic invasion, or disease of one gland affecting its function, and so the whole body economy. Low-grade protracted infections may be cumulative, and to epistaxis, petechiae, etc., may be added metrorrhagia. The same is true of the toxæmias of pregnancy. Goodall stresses the importance of endocrine balance and interaction, especially in pelvic vascular extravasations. Here the sequence of ovarian follicular hormone with that of the luteinizing agent is frequently disturbed. Research must track the cause of such disturbances and strengthen therapeutic attack. Hysterectomy irradiation is a confession of failure.

74 Hormonic Reactivation of the Senile Ovary

A. WESTMAN (*Zentralbl. f. Gynäk.*, May 12th, 1934, p. 1090) quotes as evidence of experimental reactivation in animals of the senile ovary: (1) the finding of Steinach, Kun, and Hohlweg that serial injections of folliculin induced oestrus, and that if they were sufficiently often repeated spontaneous oestrus and then conception might follow; and (2) Zondek and Aschheim's restoration of oestrus, with ovarian enlargement and production of ripe follicles and corpora lutea containing haemorrhages, by implantation of anterior lobe of pituitary gland, or by injection of prolactin present in the urine of pregnant persons. That the primarily active hormone is of pituitary origin therefore seems probable. Westman describes two cases in which a human experiment was employed. Blood from a patient in late pregnancy was chosen as likely to afford the best source for intravenous injection of the anterior pituitary hormone in large amounts. The first patient, a virgin aged 51, had metrorrhagia from carcinoma of the uterine body three years after the menopause: a week before removal of the uterus a quarter of a litre of blood from a patient eight months pregnant was infused intravenously. One of the ovaries, which measured 4 x 3 x 1.5 cm., contained a cyst, of which the lining was chiefly composed of lutein cells, partly haemorrhagic. In the second case, which was clinically similar, only six months had elapsed since the cessation of the menses in the 48-year-old patient: the ovarian findings were similar, and in addition the endometrium showed proliferation and tortuosity, resembling that of the proliferative intermenstrual phase.

75

Cholesterin in Acute Peritonitis

M. TABANELLI (*Arch. Ital. di Chir.*, March, 1934, p. 332), as the result of the examination of the cholesterin in the blood of thirty-three cases of acute peritonitis, came to the following conclusion. In favourable cases a progressive fall in the cholesterin values was followed by a return to normal, and in rare cases to an abnormally high level, simultaneously with general recovery. In fatal cases, on the other hand, there was a progressive fall in the cholesterinaemia. Investigation of the cholesterin of the organs most concerned with metabolism—namely, the liver, spleen, and suprarenals—in the course of acute experimental infections of the peritoneum showed that in cases which tended to recover there was a diminution of the cholesterin values in the liver and suprarenals, and a slight increase in the spleen followed by a return to normal in convalescence, while in fatal cases there was a progressive fall in cholesterin in the liver and suprarenals, and an increase in the spleen. The changes in the cholesterin appear to be due to various causes, the most important of which seems to be the state of temporary functional inhibition of the more important organs concerned with metabolism. The increase of cholesterin in the spleen seems to be due to the excessive destruction of the red cells caused by the acute infection and the liberation of the cholesterin contained in them.

76 Natural Immunity to Tetanus in Ruminants

G. RAMON and E. LEMÉTAYER (*C. R. Soc. de Biol.*, 1934, cxvi, 275) have been studying the natural immunity to tetanus possessed by certain ruminants. In a previous paper they recorded that of eighty-two cattle examined in France, every one showed the presence of antitoxin in the blood in greater or less quantity. Antitoxin was also found in the blood of some sheep and goats, but not in that of horses or pigs. In the present paper they record the results of examining ruminants in Morocco, Tunis, Senegal, Sudan, and Syria. Of seventy-five cattle examined, fifty-eight showed the presence of antitoxin. Antitoxin was found in twenty-four out of thirty-four other ruminants, including zebu, buffaloes, chamois, and dromedaries. The last two species of animals, however, had less antitoxin than the other ruminants studied, in this respect approaching sheep and goats. There seems to be a more or less general relationship between the antitoxin content of the serum of the ruminants and the bacterial flora of the soil on which they live. The more tetanigenic the soil is, as gauged by the incidence of tetanus in animals, the higher is the antitoxin content of the blood. The frequent presence of antitoxin in ruminants and its absence in man, horses, pigs, and dogs, lead the authors to suggest that the large stomach of ruminants is concerned in the development of natural immunity to tetanus.

77

Chemistry of Retroplacental Blood

L. PUCCIONI and I. PINELLA (*Ann. di Ostet. e Ginecol.*, April 30th, 1934, p. 457), who had previously shown that the calcium and potassium content of the retroplacental blood was higher than that of the peripheral blood, more recently investigated the differences in the glucose and bilirubin content in the two varieties of blood with the following results. The glucose content of the peripheral blood in labour was always higher than normal, while in the retroplacental blood the glycaemia was always below that of the peripheral blood, and in many cases even below the normal amount, this diminution being explained by utilization of the glucose by the foetus. The bilirubin in the peripheral blood, which was investigated by van den Bergh's indirect method, was often above the normal amount. In the retroplacental blood the bilirubin content was always increased, sometimes to a considerable degree. It is suggested that the increase of bilirubin in the retroplacental blood is due to local transformation of the haemoglobin of the red corpuscles by the reticulo-histiocytic system.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

78 Allonal as a Cause of Agranulocytic Angina

MADISON and SQUIER (*Journ. Amer. Med. Assoc.*, March 10th, 1934, p. 755) state that the increase in agranulocytic angina has paralleled the increase in the use of drugs containing pyrimidon (amidopyrine), and especially those containing pyrimidon with a barbiturate—for example, allonal. They publish fourteen cases of agranulocytic angina in which the onset of the disease was directly preceded by the use of pyrimidon or allonal. Six of these patients continued with the drug during their illness, and they all died, in spite of nucleotide treatment. Of the eight patients who stopped the drug, two died. When two of the convalescent patients were given 5 grains of pyrimidon as a test, the granulocytes practically disappeared from their blood. Eighteen rabbits were given large doses of allonal, and one died with agranulocytosis. The authors believe that pyrimidon is capable of producing agranulocytosis in certain individuals who have developed a sensitivity to the drug.

79 The Hour of Death

H. J. JUSATZ and E. ECKARDT (*Münch. med. Woch.*, May 11th, 1934, p. 709), of the Hygiene Institute of the University of Marburg, have undertaken a chronological study of 3,294 notifications of deaths which have occurred within the past six years. Stillbirths and deaths due to accidents and suicide were not included in this study. The notifications having included statements as to the hour at which death occurred, the number of deaths for each of the twenty-four hours was charted. The resultant curve showed the highest peak between 4 and 5 a.m. Both midday and midnight showed comparatively low levels. The authors record on the same chart the results of three other investigations, one of which dates back to 1846. The main features of all four curves showed a striking similarity, the early hours of the morning being invariably the most fatal. In their discussion of the possible explanation of this phenomenon, the authors draw attention to a study published in 1922 by A. Schlenk of Innsbruck. He showed that the hourly variations of electrical conductivity followed a curve whose course coincided with remarkable accuracy with that of the death rate recorded hour by hour in Marburg.

80 Congenital Syphilis

J. G. NAVARRO (*Semana Médica*, April 9th, 1934, p. 1157) points out the differences between congenital syphilis as it is now seen and that described in the textbooks. In the children's department of the Ramon Mejia Hospital (Buenos Aires) three sections are assigned to children in the post-lactation period of infancy and two to nurslings under the age of 2 years. In the second half of the year 1932, 2,109 patients were examined, of whom 3.36 per cent. were syphilitic. In the first half of 1933, 2,449 were examined, including 707 nurslings under 2 years and 1,742 of more than that age; of these 3.02 per cent. were infected. The figures in Berlin were in nurslings from 2.81 to 3.34 per cent.; in Munich, 2.7 per cent. in all children; in Prague, 2.33 per cent.; in North America, 3.3 per cent. of all children examined in various clinics. French figures are much higher. Amongst nursing patients Lesné at the "Trousseau" found 10 per cent.; Hutinal 40 per cent.; Marfan 30 per cent.; and Lemaire and David 19 per cent. The fact that definite clinical value was attached to signs of a merely presumptive character will account for these high French figures. On reviewing the files of 100 of his own presumably syphilitic patients, Navarro found only five who were definitely positive, and of these only one showed signs of active disease. He states that the only reliable signs of the

disease are perineal condylomata, interstitial keratitis, Parrot's pseudo-paralysis, syphilitic osteitis, luetic aortitis, and mucous plaques. Positive parental proof constitutes the admitted infection of one or of both parents, general paralysis of the insane, and tabes if these are confirmed by serological tests. Probable parental evidence is afforded by the knowledge that a parent is undergoing treatment for lues, by definite syphilitic aortitis, chronic headache, pains in the bones, alopecia, and hemiplegia; and if the mother has had premature births, stillbirths, multiple abortions, and twin births! In the child, the probable manifestations will be Olympe forehead, saddle nose, splenic enlargement, enlarged and especially hard liver, convulsions, encephalopathy, bronchial asthma, and testicular atrophy. During lactation the patient may show signs of rickets, hydrocephalus, double irreducible hydrocele, sanguineous coryza, and various osteopathies. After two years, alopecia of hairy parts (especially the eyebrows), headache, pains in the bones, and dental anomalies, though the writer very rarely meets with Hutchinson's teeth. Serological tests, though immensely valuable when dealing with adults, are of little use in the hereditary or congenital syphilis of the child. Kahn's test is preferable to the Wassermann reaction, being easier to take and to read.

81 Subsequent Fate of Scrofulous Children

V. HALBERG (*Ugeskrift for Læger*, May 17th, 1934, p. 515) has conducted follow-up investigations which suggest that tuberculous glands in childhood are seldom precursors of serious tuberculous disease later in life. Between 1910 and 1925, 553 patients suffering from enlarged lymphatic glands attended the dermatological department of the Finsen Institute in Copenhagen. The author's follow-up investigations concern 125 patients treated in the period 1919-21 and traced in the winter of 1932-3. It was found that only four had died in the interval, pulmonary tuberculosis being the cause of death in only one of these cases. Among the 121 survivors were 117 whose health was excellent. Of the four whose health was poor, three suffered from tuberculosis. Comparing the fate of all his patients with that of the general population at the same age, the author finds that the tuberculosis mortality among the former was only about half that among the latter. In eighty-four cases the follow-up investigations included x-ray examinations, which in fourteen cases showed signs of pulmonary tuberculosis. The author considers the high recovery rate among these ex-scrofulous persons as a tribute to the treatment they received as children with universal light baths, introduced by Reyn of the Finsen Institute in 1913. For, while the recovery rate, as far as the enlarged glands were concerned, among the author's 125 patients was 97.6 per cent., it was only 39 per cent. for a similar group of patients given only x-ray treatment and reported on by Reyn in 1924.

82 Primary Tuberculous Infection in the Adult

P. NOICA (*Thèse de Paris*, 1934, No. 162) records four cases of primary tuberculous infection in young adults aged from 18 to 26, three of whom were women and one a man. The clinical picture was that of Landouzy's typho-bacillosis associated with erythema nodosum. All the patients came from healthy families, and no case of tuberculosis had occurred in their immediate neighbourhood. In addition to pulmonary localization other forms of primary tuberculosis in the adult are: a pleuritic form, which is fairly frequent; a form characterized by phlyctenular conjunctivitis; and other forms in which the symptoms are less definite and the condition is likely to be mistaken for influenza or bronchitis. Lastly, as in the child, primary tuberculosis in the adult may be absolutely without any symptoms, and can only be detected by tuberculin tests and radiological examination.

Surgery

83 Early Diagnosis of Cancer of the Breast

A. LÄWEN (*Deut. med. Woch.*, May 11th, 1934, p. 707), who is in charge of the University Surgical Hospital in Königsberg, gives an account of his system for discovering cases of cancer of the breast before signs of it had been detected by the patients themselves. As the result of an educational campaign 1,227 women were induced to present themselves for examination by Professor Låwen's staff of four women doctors, who, when they found any morbid conditions, referred them to him. The rate of examination was about fifty women per hour for every doctor. In this way one carcinoma was diagnosed. There were also ten women, previously operated on for cancer of the breast, eight of whom showed no sign of recurrence. In as many as 103 cases chronic mastitis was diagnosed; they included two cases in which suspiciously hard nodules led to an exploratory excision. Among these 103 cases were also two characterized by haemorrhage from the nipples. Para-mammary lipoma was diagnosed in three cases and fibroma of the skin in sixteen. The most striking feature of this "comb-out" was the high proportion (8.4 per cent.) of cases of chronic mastitis. Its incidence was greatest between the ages of 30 and 50; only ten were unmarried, and as many as eighty (77.7 per cent.) had had children. The author maintains that the early diagnosis of cancer can only be achieved by the systematic examination of the whole population between the ages of 30 and 70; and he refers, by way of contrast, to statistics he has recently compiled in East Prussia, where, between April 1st and October 30th, 1932, only 104 out of 367 cases of cancer were found to be operable.

84 Arteriography as a Guide to Arteriotomy

L. BAZY, H. REBOUL, and M. RACINE (*Bull. et Mém. Soc. Nat. de Chir.*, May 5th, 1934, p. 625) write with enthusiasm of the help given by arteriography in deciding on and planning operations for arteritis of the lower limbs. It is certain, they say, that arterial puncture and injection by the Santos technique is without danger, and that the use of organic iodine compounds, injected at suitable pressures, is not liable to aggravate an arteritis, although occasionally small discrete patches of cutaneous necrosis follow the injection of any contrasting solution. Lipiodol, sodium iodide, and thorotrast are not free from danger, and should be replaced by one of the organic iodine compounds. Injection of these is painful, so that, unfortunately, it is necessary to give a general anaesthetic. The pictures give valuable information concerning the endarterial and parietal lesions and their relation to the collateral circulation, as well as the anatomy and sufficiency of the latter. In a case described, arteriography in a syphilitic male aged 47, with threatened gangrene of the great toe, showed partial blockage from the popliteal to the upper part of the posterior tibial artery, ending immediately beneath the origin of the inferior external articular artery. Section of the popliteal artery below that origin was followed by resumed pulsation (partly a sympathectomy effect), and, after removal of the superjacent 7 cm. of the arterial trunk, cure followed. Arteriography proved equally useful in indicating a successful arteriotomy in a case of senile gangrene.

85 Cervical Sympathectomy for Disseminated Sclerosis

WETHERELL (*Journ. Amer. Med. Assoc.*, May 26th, 1934, p. 1754) publishes a fifth case to be added to Royle's four cases of sudden improvement in disseminated sclerosis following the removal of the superior dorsal and inferior cervical ganglions. The object of the operation is to improve the circulation in the brain and spinal cord. The speech of Wetherell's patient improved immediately after the operation, and within a few days his intention tremor had so diminished that he was able to feed himself again. The author claims an improvement of 40 per cent. in his condition, and states that the possibility of a marked natural remission in five cases immediately after operation is extremely remote.

240 B

Therapeutics

86 Bilateral Pneumothorax

G. NADEAU (*New England Journ. Med.*, May 10th, 1934, p. 1012) records twenty-six cases of bilateral pneumothorax. In twenty-four the two lungs were submitted to collapse at the same time, while in two the opposite lung was only collapsed after the first had re-expanded. In thirteen the disease was moderately advanced, and in the others far advanced. The first seven cases were almost terminal, pneumothorax being tried only as a last resource. Four had complications such as tuberculous laryngitis and enteritis. After about a year the treatment had to be discontinued in five instances because the progress of the disease could not be checked. These five patients died, but the remaining two survived and are doing well. Thirteen patients are improving under treatment; three have had one intrapleural pneumolysis, two had two pneumolysis operations, and one had three. Phrenicectomy was performed on four patients. Seven patients have been discharged and are doing well. In Nadeau's sanatorium the proportion of the bilateral to the unilateral pneumothorax is about 10 per cent.

87 Ox-Bile Therapy in Icterus

Haemorrhage in icterus is a well-known complication which occurs most frequently in grave cases or in those of long duration. H. TENNESEN (*Lyon Chir.*, May-June, 1934, p. 290) cites statistics compiled by Petré showing that haemorrhage caused death in 10 to 15 per cent. of the fatal cases and in 1 to 2 per cent. of all operated biliary cases; in eighty deaths among 549 of his own biliary cases four (short notices of which are given) were due to haemorrhage. He points out that in cases of chronic biliary fistulae a haemorrhagic tendency can also be noted, which is manifested by similar haemorrhages. Both these conditions have two points in common: the haemorrhagic tendency, and a lack of biliary supply to the intestine. Seifert thinks that this tendency in icteric patients is due to a faulty resorption of intestinal fats, or to lack of bile or of vitamins, and disorders of changes of the calcareous matters. In light of this theory Tennesen believed that the oral administration of bile should improve this condition, and he has since employed this treatment in such cases. Should the blood coagulation time prove abnormally long, he gives ox-bile by the mouth (the dosage is not clearly defined) and finds this materially shortens the period. Three illustrative cases are reported. These show that this treatment reduces the blood coagulation time to normal, and therefore also the tendency to haemorrhage; later bleeding, due to the operation, may, however, occur, as is evidenced by one of the recorded cases.

88 Therapeutics of Filix Mas and Ol. Ricini

W. KUCK (*Med. Welt*, May 12th, 1934, p. 661) notes that while all are agreed as to the efficacy of extract of male fern and its dosage, some still consider its combination with castor oil as dangerous, while others hold that the risk of poisoning is reduced if castor oil is given at the same time or a little later. The investigations of Fahin have revealed the publication of forty-six cases of poisoning by extract of male fern during the past forty years. In as many as thirty-seven of these cases no castor oil was given. In three of the nine cases in which it was given the dosage of the vermifuge had been far too great. In another case it was probable that the poisoning was due to idiosyncrasy to male fern, and there remained, therefore, only five cases in which the combination of castor oil with a normal dose of male fern coincided with poisoning by it. The author has himself combined extract of male fern with castor oil in 123 cases without any mishap other than the occasional return of the drug by vomiting. He gives the extract (8 grams for a man, 6 grams for a woman, and 4 grams or less for a child) with a mixture of castor oil and malt extract, and as the treatment is apt to be heroic he does not recommend it for elderly folk, nor for

the subjects of acute diseases, uncompensated heart disease, aneurysm of the aorta, and abdominal disorders, nor during pregnancy and the puerperium, nor for persons subject to haemorrhage from the gastro-intestinal tract. The old-fashioned preliminary treatment of the patient is not only weakening, but also favours absorption of, and poisoning by, the extract. Even able-bodied persons should be kept in bed so as to lessen the chances of vomiting.

Ophthalmology

89 Dystrophy of Corneal Endothelium (Cornea Guttata)

E. L. GOAR (*Amer. Journ. Ophthalmol.*, March, 1934, p. 215) records that this condition, which is always bilateral though more advanced in one eye, is responsible for many unexplained cases of loss of vision over 40. The slit-lamp at first shows central, well-defined, discrete, rounded, dark areas in the zone of specular reflection. Later these are also found peripherally. The endothelial cells are absent in such areas, while fine dust-like pigment is deposited between them. The areas mark a thickening of Descemet's membrane, which becomes abnormally visible. As the slit-lamp beam is swept across the endothelium, "glinting" is observed. In the last stages there may be epithelial dystrophy. Whether this is due to the action of the aqueous is not generally agreed. Endothelial dystrophy must be differentiated from iridocyclitis, perforating wounds, low-grade uveitis, old interstitial keratitis, and the result of iridencleisis operations.

90 Sympathetic Ophthalmia

A. JESS (*Münch. med. Woch.*, May 25th, 1934, p. 786) states that the smallest perforating wound may be followed by sympathetic ophthalmia. The onset is from fourteen days to several years after the injury. Sympathetic irritation may not progress to ophthalmia, the premonitory signs of which are the early signs of iridocyclitis. The histology of the exciting and sympathizing eyes closely resembles that of tuberculosis, though the bacillus has not been demonstrated. Purulent endophthalmitis by its severity nearly always safeguards the other eye by overwhelming the unknown agent of sympathetic ophthalmia. The treatment is difficult and disappointing. Careful and immediate attention is of supreme importance, and the injured eye, even in the absence of inflammation, should always be enucleated directly it becomes blind or on the appearance of a progressive iridocyclitis with a prospect of blindness. Daily observation of both eyes by the slit-lamp is necessary after a perforating wound.

91 Headaches and Ocular Diseases

B. L. GORDON (*Arch. of Ophthalmol.*, May, 1934, p. 769), basing his findings on 1,339 cases, believes that ocular pain is extracranial, and is reflexly seated in the muscles of the head. Heredity plays an important part, the Semitic, Celtic, and Italian races being more prone to headaches. Impaired health, nervous exhaustion, and neurasthenia are predisposing factors. He recognizes three classes of ocular headache: organic; due to retinal irritation; and to eye strain. The organic type is exemplified in glaucoma, iritis, retrobulbar neuritis, and choroiditis. Retinal irritation follows exposure to the sun's rays, lightning, electric flashes, x rays, and coloured silks, and is associated with local ocular signs of congestion and inflammation. He found 60 per cent. of his cases had headache due to eye strain. The topographical site of the pain is suggestive of the type of ocular trouble, and he gives charts showing the different areas affected in various ocular defects. Astigmatism accounts for most cases of headache. It is the low degree of ametropia and muscle imbalance, unsuspected because the vision is normal, that causes most severe headaches. With a low error the patient struggles to overcome it, while with a larger one the attempt is abandoned. A weak correcting glass should be worn, even though it blurs the distance vision.

Headache is rare in monocular people because the complexity of fusion, with its associated muscular adjustments, is eliminated. Disappearance of a headache when one eye is covered always suggests heterophonia, and it is a safe practice to consider all headaches as ocular until proved otherwise. Headache due to organic disease is persistent with exacerbations, while that due to eye strain is relieved or abolished by resting the eyes. Of other types of headache the nephritic is throbbing, migratory, and often associated with vertigo and tinnitus; the uterine is occipital, radiating, and sharp; the anaemic is pressing in character; the hysterical is as if a nail is being driven into the vertex; the neurasthenic is like a tight band, worse in the morning, and the migrainous has a persistent similarity and periodicity. Careless refraction increases headache, and ill-fitting glasses will make matters worse, however careful the refraction. Finally, headaches which are due to ametropia are not always cured directly glasses are put on the nose.

Obstetrics and Gynaecology

92 Pregnancy and Labour in Morphine Addicts

According to E. MENNINGER-LERCHEHNTAL (*Zentralbl. f. Gynäk.*, May 5th, 1934, p. 1044), while relevant statistics have not been published, it is probable that female morphine addicts have comparatively a very low fecundity rate: they come usually from classes in which children are not keenly desired and contraceptive measures present little difficulty. Amenorrhoea is one of the most constant symptoms of the malady. Balász has recently described the case of a midwife, three years addicted and one year amenorrhoeal, who went to term after taking 60 c.cm. of a 3 per cent. solution daily, intravenously; and childbirth has been described after four years' cessation of the menses. Sometimes a healthy child is born to parents who are both addicted, but normal pregnancy is rare in the wife of a male morphinist. Premature labour is frequent in the female addict. The child may be born healthy, but is exposed to some danger from withdrawal of a drug to which he has become habituated. Treatment of the mother by reduction of the drug is inadvisable after the third month and impossible during labour: between these times it is usually inexpedient, and withdrawal of morphine has frequently been followed by uterine colic, foetal hyperactivity, and danger of premature labour and/or foetal death.

93 Reinfusion of Blood in Ruptured Ectopic Gestation

According to O. HAJEK (*Med. Klinik*, May 11th, 1934, p. 639) extrauterine pregnancy has, since the war, become more frequent in Germany, Hungary, and Switzerland; in Russia the increase has been reported as eightfold. Aetiologically, antecedent pelvic inflammation is of great importance: in a series of 500 cases seen at Prague during the past eight years only forty-eight had not had previous pregnancies or abortions, and in only thirty-four of these were signs of inflammation absent. Thirty patients had small or large cysts of one or both ovaries. In this series diagnostic puncture of the pouch of Douglas was usually done in recent cases, and as a further diagnostic aid the Aschheim-Zondek reaction or the analogous accelerated test in the rabbit was invariably accurate. Hajek discusses the utility of reinjection into the patient of the blood which is found in the peritoneal cavity at operation. This was recommended by Thies in 1914, but has been judged to be not free from inconvenience and danger. Reinfusion of the blood was done in fifty-four of the 129 ruptured cases of the present ectopic series—100 to 350 c.cm., mixed with saline and/or citrate solution, was usually given. Response was, as a rule, better than that noticed after saline infusions. Eight cases proved lethal, and the present practice is to restrict reinfusion of blood to severe cases with grave anaemia; in such cases it may be a life-saving measure, but its routine adoption is judged to be unjustifiable.

Pathology

94 Endemic Pneumococci of Type I

G. JORRICH (*Klin. Woch.*, May 5th, 1934, p. 661) gives an account of the endemic existence of pneumococci of Type I in a rural area in Germany. In this area there was a home for about thirty children of all ages in the charge of nurses and domestics. The presence of the endemic was detected in the middle of December, 1933, when a 2-year-old boy was transferred from this home to hospital, suffering from double pneumonia and a purulent pleural effusion. He died on December 24th, after having developed purulent meningitis. In the cerebro-spinal fluid, in both lungs, and in the pleural fluid pneumococci of Type I were found. A few days later three more children were admitted to hospital from the same home. The clinical and x-ray evidence was indicative of croupous pneumonia. The temperature fell by crisis in all three cases, in which Type I was invariably found. A bacteriological examination was now made of the other inmates of the home, and among the twenty-three cases in which pneumococci were found were fifteen whose pneumococci belonged to Type I. A score of the persons examined were more or less ill, suffering from pharyngitis, tracheitis, bronchitis, etc. While some had been febrile for several days, others had escaped more lightly, and there was no relationship between the age of the patients and the severity of their symptoms. Indeed, in the case of a 7-months-old artificially fed infant the only manifestation of the infection was a slight coryza and cough. Among seven persons found to be clinically well were four harbouring the pneumococcus. The infectiousness of this type of pneumococcus was almost as great as that of influenza, but the disease took the form of croupous pneumonia only in a few cases. Discussing the outstanding features of what he calls an endemic, the author points out that elsewhere and ordinarily, among healthy persons, pneumococci of Type I are demonstrable only in 1 to 3 per cent. This proportion may be increased four times in the presence of cases of pneumonia. But in the present instance more than 60 per cent. of the persons examined harboured this special type of pneumococcus.

95 Diagnosis of Glanders

GÓMEZ-DURÁN (*Arch. Med., Cir. y Esp.*, April 28th, 1934, p. 458), writing from the Military Hospital, Tetuan, believes that in the absence of a pustular eruption and profuse nasal secretion, and owing to the failure of the mallein test in the human subject, glanders is frequently overlooked. Indeed, he says that the glanders of the textbook variety is but rarely seen, and that the acute variety is often confounded with typhoid, rheumatism, septicaemia, pyaemia, miliary tuberculosis, or sporotrichosis. The detection of the *B. mallei* in pus is rare, though its growth on potato is distinctive; but there is one great positive test, devised by R. Strauss, which is quite easy to carry out. This observer injects suspected pus into the peritoneal cavity of the guinea-pig, and if the animal be examined on the third day a profuse vaginal discharge containing numerous *B. mallei* will be detected if the case be one of glanders.

96 Cultivation of the Leprosy Bacillus

C. W. DUVAL and R. A. HOLT (*Proc. Soc. Exp. Biol. and Med.*, April, 1934, p. 828) describe a new method for the cultivation of leprosy bacilli. It rests on the earlier observations of Duval that these organisms continue to multiply outside the body so long as autolysing pieces of leprosy tissue are available. The organisms are unable to utilize whole protein, and consequently they die out in subculture when the original autolysate is no longer present in adequate amount. To remedy this defect the authors have prepared a medium containing protein split products. Its detailed preparation cannot be described here, but it consists essentially of an agar base, to which

are added aqueous solutions of tryptophan, cystin, tyrosine, and leucine, followed by placenta autolysate, banana infusion, and glycerin. The technique of cultivation consists first of all in the excision under aseptic conditions of a subcutaneous leprosy nodule. The nodule is then cut into small pieces and digested for thirty-six to forty-eight hours at 37° C. with a 1 per cent. solution of trypsin which has been sterilized by filtration. The effect of this treatment is to reduce the pieces of tissue to the consistency of soft butter. In this state they can be transferred to slope tubes of the special medium, and spread over its surface with an ordinary loop. The tubes are fitted with paraffined cotton plugs, which are temporarily removed every three or five days to permit of the access of air. Growth becomes evident in four to six weeks, and continues in subculture so long as the trypsinized leprosy material is transferred. The crucial point comes when this is exhausted, and the organisms have to obtain their nutriment from the medium. The incorporation in the medium of protein split products is intended by the authors to facilitate this transition.

97 Transmission of Kala-Azar

C. E. FORKNER and LILY S. ZIA (*Journ. Exper. Med.*, April 1st, 1934, p. 491) examined material obtained by gently passing culture swabs into the nasal passages of fifteen patients suffering from proved kala-azar, and then smearing slides. In nine cases typical Leishman-Donovan bodies were found in the smears in small numbers. Smears from the tonsillar surface and from the saliva in one of these cases also revealed the presence of these bodies. The tonsils of this patient, who died as the result of kala-azar and secondary infection, were found at the necropsy to be massively infected with Leishman-Donovan bodies. The organisms in the nasal discharge of two patients were shown by inoculation into susceptible animals to be viable and capable of producing infection. The authors state that sufficient time has not yet elapsed to determine the viability of the organisms recovered from the remaining cases. They conclude, however, that there has thus been demonstrated for the first time the existence of a rich source of infective material, occurring in a large proportion of patients, and available for the transmission of the disease. They add that the only point which now needs to be demonstrated in order to confirm the finding that one of the natural modes—possibly the most important—for the transmission of kala-azar from person to person is to transmit it experimentally by this route. The experiment has been approached in two ways: by transferring infected material from the nasal cavities of patients to the nasal and mouth cavities of hamsters, and to the nasal cavities of two human volunteers. It is stated to be too early as yet to report the results, but it is remarked that such a conception of transmission suffices to explain many of the epidemiological problems, and is open to no serious objection from the epidemiological or protozoological points of view.

98 Therapeutic Pneumothorax in Pneumonia

L. M. LIEBERMAN and S. S. LEOPOLD (*Amer. Journ. Med. Sci.*, March, 1934, p. 315) have collected from the world literature, dating from 1921, fifty cases of the use of therapeutic pneumothorax in human lobar pneumonia. Only three of these patients died. An average of two injections of 400 c.cm., with an interval of eighteen hours between them, produced a spontaneous crisis followed by convalescence in most of the cases. The authors corroborated these results experimentally by producing lobar pneumonia in thirty-six dogs by bronchoscopic introduction of virulent pneumococci into the lower lobes of the narcotized animals. Eighteen dogs were given two pneumothorax injections, producing a fall in temperature, a drop in leucocytosis, a negative blood culture, and a rapid return of strength in fifteen of the animals. The remaining three died. Of the untreated eighteen control cases thirteen died. X rays were used in every case. The article concludes with a warning that pneumonia is not a suitable disease in which to acquire experience in pneumothorax technique.

104 Uraemia following Abdominal Operation

R. LEBOVICI and F. POILLEUX (*Rev. de Chir.*, April, 1934, p. 328) point out the frequency with which uraemia occurs as a post-operative complication. The onset may be either acute or subacute, with repeated and profuse vomiting, dryness of the tongue, abdominal distension, and deterioration of the general condition. The symptoms simulate incomplete obstruction or peritonitis, and it is possible that a further intervention may be considered, unless the blood urea is examined, when an exact diagnosis can be made. Treatment by means of saline solution should be immediately carried out, and the success depends on early diagnosis. Although uraemia may occur after such operations as hysterectomy or ovariectomy, it is most common after gastric operations. The authors report two cases of uraemia following gastro-enterostomy. In one of these saline treatment was instituted immediately the condition was recognized, and the patient made a rapid and complete recovery. In the other case, through an error, treatment was delayed and the patient died. Three reasons are given for post operative vomiting: a mechanical obstacle due to some faulty technique, an inflammatory condition, or a high blood urea. Vomiting from the last of these causes does not occur until after the eighth day, and is abundant, containing water and free bile. There is also evidence of dyspnoea without obvious cause, whilst the prostration and delirium of the patient are signs of severe toxæmia. These symptoms should lead to a diagnosis of uraemia. Hypertonic saline solution should be injected slowly and frequently—2.6 grams may be given each day, although as much as 10 grams may be given without ill effect.

Therapeutics

105 Multiple Tappings in Cirrhotic Ascites

A. RAVINA and S. BRUNET (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, May 28th, 1934, p. 751) report a case of ascites in which apparent cure was established by multipleappings. During the course of two years the patient, who had been a heavy drinker, was tapped eighty-four times, a total of 950 litres of ascitic fluid being withdrawn; no other form of treatment was employed. Such cases are not exceptional; Chabrol and Cottet have reported cure in two cases of cirrhosis after twenty-eight and sixty-eightappings respectively. Cure in the present case has been maintained for four years; the patient is in excellent health, and is capable of performing heavy work. A marked hepatomegaly, coincident with a return to alcoholic habits, is, however, present. This case confirms the classic theory that resorption of the ascites is especially possible in cases of hypertrophic cirrhosis: such cures necessitate integrity of the renal functions.

106 Methylene-blue-Glucose Solution in Gas Poisoning

F. DEUTSCH and E. WEISS (*Wien. klin. Woch.*, May 18th, 1934, p. 618) believe that in a glucose solution of methylene-blue they have discovered a valuable therapeutic measure in the treatment of poisoning by gas. In 100 c.c.m. of solution there is 0.25 to 1 gram of methylene-blue and 10 grams of glucose, the pH of this solution being 7. Twenty c.c.m. of 1/4 to 1 per cent. methylene-blue-glucose solution is injected intravenously. Twelve cases of severe gas asphyxia treated in this way are described, many of which were in deep coma with serious damage to the central nervous system and circulation. All recovered in a few minutes to a few hours without the help of any other therapeutic measures. They describe the rationale of the treatment as follows. It has been shown experimentally that the living cell possesses an iron-containing complex ferment which enables it to make use of the oxygen in the circulating blood. The iron acts as a catalyst. If this ferment is damaged by

poisonous gases, accessory catalysts come into being to prevent the danger of asphyxia. Methylene-blue has the same action as the accessory catalysts, and can act as a substitute for them, resisting the poisonous gases even when the normal accessory catalysts have been put out of action. It turns haemoglobin into methaemoglobin, protecting the organism against the rapid absorption of the gas. But in addition to its protective action there is that of increasing oxidization by converting the Fe₂ of the haemoglobin and the cells into Fe₃. The presence of glucose has been shown experimentally to increase the oxidizing power of methylene-blue by rapidly reconverting the methaemoglobin into haemoglobin.

107 Treatment of Gonorrhoea in Women

K. JOHNNEN (*Münch. med. Woch.*, May 18th, 1934, p. 746) gives an account of the experiences of the University Hospital for Women in Freiburg, where treatment of gonorrhoea with vaccines is not favoured because of its liability to stir latent foci of disease into activity. The therapeutic induction of fever suffers from the same objection, and on one occasion gonorrhoea was cured at the cost of a latent tuberculous focus rendered active. In the period 1927-33, 243 cases of gonorrhoea were treated. They included 134 cases of unilateral or bilateral disease of the uterine appendages. In order to compare the respective merits of conservative treatment (strict rest in bed, hot and cold applications, etc.) with active treatment (local applications with silver preparations, etc.) 109 patients were kept under close supervision, bacteriological examinations being made once or twice a day of the in-patients and at intervals of two to four days in the case of the out-patients. The criterion of a cure was failure to demonstrate gonococci on three consecutive occasions after menstruation. Thirty of the patients were given conservative treatment and seventy-nine active local treatment. The proportion of cures was approximately the same (sixteen for conservative treatment and forty for active treatment). The average stay in hospital for the patients given conservative treatment was five and a half weeks; for the others it was six and a half weeks. The 134 cases complicated by involvement of the uterine appendages were also classified according as the treatment was conservative or active, and again little difference could be found in the results. The author would therefore have been tempted to abandon active measures but for his recent experiences with an acridin preparation, "flavadin," which contains an organic compound of arsenic. From 1 to 4 c.c.m. of a 2 per cent. solution are slowly injected into the urethra and cervix, a course of treatment consisting of eight injections, at intervals whose length the author does not mention. A cure was effected in eighteen out of twenty-one chronic cases, the average duration of in-patient treatment being only two and a half weeks. Among the three failures were two which could be accounted for as representing reinfections.

Anaesthetics

108 Local Anaesthesia in Major Abdominal Surgery

H. FINSTERER (*Med. Klinik*, May 4th and 11th, 1934, pp. 597 and 631) publishes statistics showing a diminished post-operative morbidity and mortality from the use of general instead of local anaesthesia in major (and especially major abdominal) operations. He finds the use of a local anaesthetic enables the most serious operations to be done in aged and cachectic subjects. Among examples of successful operation under local anaesthesia, in patients in whom surgical treatment had been deemed inexpedient, Finsterer mentions the following cases: (1) a hemiplegic male aged 78, who had subtotal gastrectomy for ulcer; (2) a female, aged 75, with high pyrexia and obstruction of the common bile-duct, who had appendicectomy, cholecystectomy, and choledochoduodenostomy; (3) radical resection in four stages of a fixed, externally visible carcinoma of the sigmoid colon; (4) suture of a perforated

duodenal ulcer and gastro-enterostomy in a woman aged 71; and (5) total obstruction by volvulus of six days' duration, followed by removal of the gangrenous sigmoid. Forty-nine cases of appendicectomy with local anaesthesia in children (twenty-four under the age of 11) are mentioned. In some 4,500 laparotomies with local anaesthesia (one-sixth of the patients being aged 60 to 86) Finsterer had a mortality rate from pneumonia of 0.24 per cent.: the 610 done in general anaesthesia had a death rate of 1.3 per cent. For cancer of the stomach local anaesthesia is used almost exclusively, resection being done in 66 per cent.: in simple resections the mortality was 8.4 per cent. in 271 cases. Where operation was complicated by resection of pancreas, liver, or colon the operative mortality was 41 per cent. (153 cases), but 30 per cent. of survivors (5 to 18 years) were attained. Partial gastrectomy for ulcer, in Finsterer's hands, had 14.7 per cent. mortality after general and 3.5 per cent. after local anaesthesia: the latter gave diminished incidence of shock and peritonitis. Operating in local anaesthesia for haematemesis, Finsterer had one death in thirty-nine early cases, fourteen in forty-six late cases (all resections). His mortality rate in eighty-nine gall-stone operations with complete obstruction of the common duct was only 7.8 per cent.; in 116 cases of acute intestinal obstruction (excluding strangulation of herniae), 16.3 per cent.; in forty-one of these cases requiring removal of gangrenous gut, 22 per cent.—all these series were done in local anaesthesia.

109 Anaesthetic Properties of Cyclopropane

J. A. STILES *et al.* (*Anaesthesia and Analgesia*, March-April, 1934, p. 56) presents a preliminary clinical report on cyclopropane (trimethylene), an isomer of propylene, with a density of 1.46 compared with air. It is compressible in steel cylinders without polymerization or other known chemical change. Stiles has found the gas satisfactory as an anaesthetic agent, particularly since adequate muscular relaxation is obtained with concentrations of less than 20 per cent. in oxygen. It appears to have no more effect on the vital functions than have other anaesthetics, and as regards post-operative complications it compares favourably with ether. The gas has no undesirable physical properties, and, although explosive, is less so than ethylene. The signs of the depth of anaesthesia resemble those in the case of ether, with the exception that there is a roving eyeball usually into the second stage, and occasionally even into the third. Cyclopropane is very powerful and rapid in action; it has been used successfully for infants and in neurological surgery. A slight respiratory depression induced favours its use in chest surgery. Very little of the drug is retained in the body after its administration is stopped. The author adds that care must be taken to avoid high concentrations which are irritating, 10 per cent. being sufficient for light and 14 to 16 per cent. for deep anaesthesia.

110 Nitrous Oxide Anaesthesia in Orthopaedics

SCHREUDER (*Le Scalpel*, June 9th, 1934, p. 821) favours nitrous oxide and oxygen as the anaesthetic of choice, especially in orthopaedics, where the same patient has to be anaesthetized frequently. As this mixture does not produce the necessary relaxation, subcutaneous injections of morphine with atropine or scopolamine, given forty-five minutes before the anaesthesia, are necessary. Schreuder usually injects a maximum of 15 mg. of morphine (approx. 1/4 grain) with 3/8 mg. of atropine (approx. 1/150 grain); this dose is given in two injections only to strong subjects; weaker patients receive less morphine, and children under 5 years of age usually none. When commencing the anaesthesia, nitrous oxide alone should be administered, at the rate of three to four litres per minute, with the mask held slightly above the face to avoid causing a sensation of suffocation; it is placed on the face when the patient loses consciousness. Oxygen is slowly added immediately the subject becomes cyanotic. The nitrous oxide is progressively diminished, one and a half litres per minute being finally sufficient; the oxygen must be correspondingly decreased. If still greater

muscular relaxation is required, ether (15 to 20 c.cm. usually suffices) may be added to the nitrous-oxide-oxygen mixture.

111 Avertin in Oto-rhino-laryngology

Though essentially a basal anaesthetic, A. MALHERBE, G. THÉVENARD, and R. VILENSKI (*Presse Méd.*, April 7th, 1934, p. 560) assert that avertin, given rectally, is ideal for many operations on the head and neck. A few whiffs of ethyl chloride may be necessary to complete the anaesthesia. The authors employ a solution of avertin in amylene hydrate. The patient's tension, pulse, weight, sex, general condition, and oculo-cardiac reflex should, it is stated, be taken into consideration. The evening before operation an evacuating enema is given, and half an hour before the anaesthetic an injection of morphine or pantopon; this supplements the effect of the avertin, and does not cause post-operative vomiting. The patient is kept in strict quietness, preferably in semi-darkness. The avertin enema is heated to 38° or 40° C. Anaesthesia commences in five to ten minutes in young subjects, in fifteen to twenty in the aged, and is complete in fifteen to thirty minutes after administering the avertin injection; it lasts for nearly two hours. Giordan's scheme of dosage is used. The authors emphasize the following points as essential for a successful anaesthesia: the preliminary evacuating enema; the pre-operative morphine injection; correct dosage and temperature of the avertin injection; its administration in strict quiet; waiting a necessary thirty minutes before commencing the operation.

Obstetrics and Gynaecology

112 Methylene-blue in Puerperal Septicaemia

C. G. N. NOË (*Nederl. Tijdschr. v. Geneesk.*, June 9th, 1934, p. 2599), who records three illustrative cases, recommends that every case of puerperal infection should be given an intravenous injection of 300 mg. of methylene-blue, whether the disease is localized or not. The injection should be given as soon after the onset as possible, but may be of service even at an advanced stage. In each of Noë's cases the temperature fell to normal within twenty-four hours after the injection, and rapid recovery took place. The method also deserves trial in non-puerperal infections.

113 Treatment of Uterine Myoma

C. BUCURA (*Wien. med. Woch.*, May 5th, 1934, p. 513, May 12th, p. 544, and June 2nd, p. 634) finds that in about 60 per cent. of all cases of myoma of the uterus no treatment is necessary. But even in such benign cases with no manifestation other than a rather excessive menstruation the patient should be examined every six months and told to report herself promptly if any new symptoms appear. When menorrhagia is the only sign treatment may be limited to the exhibition of ergot, quinine, and calcium lactate during menstruation, which, if it is profuse and protracted, may also be an indication for the injection of a pituitary preparation. Subserous myomata do not react satisfactorily to medicinal treatment, which is indicated only for the submucous and intramural myomata, whose growth is apt to be checked by it. Professor Bucura has little good to say of curetting as a remedy for myomata, and as a diagnostic aid in cases suspected of malignant disease it is unreliable, for islands of malignant disease may be situated in recesses of the cavity of the uterus and elude the curette. In the hands of an expert it can do little harm, and the removal of the hypertrophic lining of the uterus often reduces the haemorrhage. But a too vigorous curetting is liable to promote rather than to arrest haemorrhage, and to favour secondary infections. As for x-ray treatment, it should not as a rule be recommended for women under 46, as it acts indirectly on a myoma through the ovaries, whose functional elimination induces a premature menopause, with all its concomitant discomforts. This objection does not

apply to operative treatment, provided the surgeon is dexterous enough not to injure the ovaries. Women under 46 are better served as a rule by operative than by x-ray treatment, and among the 541 operations for myoma performed by himself, the author has had to record only nine deaths—an operation mortality of 1.68 per cent. In 292 of these cases total hysterectomy was performed by the vaginal route and in 159 by the abdominal route. Supravaginal amputation was performed in fifty-nine cases, and in thirty-one cases the tumour was removed while the uterus was left in place, the abdominal route being chosen in twenty-six of these cases and the vaginal route in five. None of these thirty-one cases terminated fatally.

114 Vaginal Ligation of the Uterine Artery

M. HENKEL (*Zentralbl. f. Gynäk.*, May 19th, 1934, p. 1153) remarks that in functional gynaecological bleedings curettage is as a rule without therapeutic utility; in the absence of subinvolution following abortion or birth, its uses are to exclude carcinoma and to furnish material for microscopical examination of the endometrium. Among functional bleedings he includes those of the menopause and those due to myoma uteri: in both cases, he thinks, the inclination to employ castrating irradiation as a therapeutic short-cut should be resisted. Castration is in either case an acute shock to the organs of internal secretion, whose functions are already deranged. This derangement is shown by the fact that menopausal haemorrhage occurs, or, in the case of myoma, by the postponement, for several years, of the menopausal epoch. Henkel's extensive experience of conservative myoma operations (myomectomy) has convinced him that they are followed by a normal and rightly timed climacteric. As a measure in conservative surgery of the uterus Henkel now recommends bilateral ligation of the uterine artery. This he first did, having found it necessary for anatomical reasons, in a patient aged 34, in whom abdominal myomectomy was performed for a submucous myoma. The immediate post-operative course was uneventful, and subsequent menstruations were normal. In eight other instances he has ligated both uterine arteries from the vagina in cases of severe haemorrhage about the menopause in patients with or without myoma, or those with prolapse or retroflexion. The procedure has the advantages of safety and simplicity; it is, as a rule, done immediately or shortly after the curettage, of which the purpose is to exclude carcinoma of the body. In Henkel's clinic it has to a great extent replaced irradiation treatment. Ligation of the uterine arteries from the vagina was recommended and practised some forty years ago by Gottschalk and by O. Küstner.

Pathology

115 Splenomegaly in Infantile Tuberculosis

M. M. CHASIN (*Thèse de Paris*, 1934, No. 67), who records ten illustrative cases in children aged from 2 months to 2 years, states that enlargement of the spleen is a very frequent symptom of tuberculosis in infants. A comparative study of two groups of children, one of whom had negative and the other positive cuti-reactions, showed that the incidence of splenomegaly in the former did not exceed 6.1 per cent., whereas in the latter it was as high as 31.3 per cent. This justifies the conclusion that the presence of splenic enlargement in a child should at once suggest tuberculosis and the performance of a cuti-reaction. The prognostic value of splenomegaly in a tuberculous child is considerable, for while the mortality of tuberculous infants with splenomegaly is 36.7 per cent., it does not exceed 6.8 per cent. in tuberculous infants with normal spleens. Histological examination of the spleen in infants who have died of tuberculosis shows that lesions of this organ are very frequent. Discordance between the macroscopical appearance, which may be

normal, and the degree of changes noted on microscopical examination, the polymorphism of the histological lesions, and the scarcity of bacilli are constant features.

116 Attempted Immunization with Tuberculo-Protein

K. C. SMITHBURN, F. R. SABIN, and J. T. GEIGER (*Journ. Exper. Med.*, May, 1934, p. 562) have studied the effect of injections of tuberculo-protein on the skin sensitivity and the resistance to infection of laboratory animals. Tuberculo-protein (MA100), obtained from the Mulford Laboratories, was inoculated subcutaneously in increasing dosage into eight rabbits and nine guinea-pigs during a period of thirteen weeks. Six injections were given every week, the dose in rabbits being increased from 0.00000001 mg. to 1 mg., and in guinea-pigs from 0.00000000015 mg. to 0.15 mg. At the end of this treatment all animals reacted to the intracutaneous inoculation of the tuberculo-protein, showing that this substance was capable of giving rise to skin hypersensitiveness. The rabbits were then inoculated intravenously, along with thirty control rabbits, with 0.1 mg. of virulent bovine tubercle bacilli, while the guinea-pigs were inoculated subcutaneously, along with ten control animals, with 0.01 mg. of virulent human bacilli. The tuberculo-protein was continued in the treated series for about three weeks after infection. Each animal was allowed to die naturally. The average survival time of the eight treated rabbits was 154 days, and of the thirty control rabbits 201 days—a difference which by reason of the smallness of the numbers in the treated series is probably insignificant. The nine treated guinea-pigs survived on an average 172 days, while the control guinea-pigs survived on an average 154 days—again a difference which is probably insignificant. These results indicate that it is possible to induce skin hypersensitiveness in animals without appreciably increasing their resistance to active infection, and suggest to the authors that allergy and immunity do not necessarily develop simultaneously.

117 Proteolytic Activity of Gastric Juice—Normal and in Pernicious Anaemia

W. J. GRIFFITHS (*Biochem. Journ.*, 1934, xxviii, No. 2, p. 671) has been studying the digestive activity of gastric juice at a pH of 6, using as substrate the beef muscle globulin employed by Castle in his classical experiments on the extrinsic factor of normal haematopoiesis. Griffiths set out to find if there was in normal gastric juice a proteolytic enzyme with an optimum pH between 3.5 and 5.5, the limits of the activity of commercial pepsin and trypsin respectively, and whether this enzyme was absent in cases of pernicious anaemia. His results are suggestive, but not absolutely conclusive: at a pH of 6 eight out of thirteen normal gastric juices produced active proteolysis, two were completely inactive, and three were weakly active. In nine cases of pernicious anaemia the gastric juices showed only one active, four completely inactive, and four weakly active. The suggested conclusion is that Castle's intrinsic factor is a proteolytic enzyme, active at a pH of about 6, which produces the normal haematopoietic factor from beef muscle globulins.

118 Physiology of the Amnion and Vernix Caseosa

H. KIEFFER (*Bull. de l'Acad. de Méd.*, May 1st, 1934, p. 576), as the result of previous investigations, states that from the third month onwards the amniotic epithelium secretes a fatty substance chiefly composed of cholesterol bodies: the vernix caseosa he believes to be not of foetal but almost entirely of amniotic origin, and to possess anti-haemolytic and anti-bacterial properties, as well as to assist in nutrition and growth of the embryonic cells. As further evidence of the physiological importance of the amnion, Keiffer now reports having found nerves in the amnion of the mature ovum of the guinea-pig. A modified Bielchowski method of staining showed numerous non-medullated subepithelial fibres, with branches penetrating the cells, but not provided with special end-organs.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

119 Indications for Operation in Chronic Gastric and Duodenal Ulcer

A. NIELSEN (*Hospitalstidende*, May 8th, 1934, p. 542) discusses the comparative merits of conservative and operative treatment of chronic gastric and duodenal ulcer, and finds from a statistical study of his own cases and those of others that when symptoms have existed for more than five years before the institution of conservative treatment, it can be expected to confer permanent freedom from symptoms only in from 7 to 15 per cent. Another 15 to 25 per cent. may benefit from conservative treatment to a degree which enables them to keep fairly well, provided they take dietetic precautions and avoid severe exertion when subject to pain. It is doubtful if these mediocre results can be appreciably bettered by ringing the changes on dietetic-medicinal measures; and the direction in which real advances still seem feasible is in the more discriminate selection, with the help of the x rays, of cases for operation. At the author's hospital in Denmark an arrangement has been made between the medical and surgical departments, according to which patients whose ulcer symptoms have lasted more than five years are drafted to the surgical department on admission. If an operation is recommended, the patient has the advantage of being all the time under the care of one and the same doctor—a factor of considerable psychological importance. While most surgeons still consider an acute dangerous haemorrhage as an indication for operation—that is, resection—the author dissents, pointing out that it is very difficult, if not impossible, to gauge the severity of a haemorrhage or to know whence it comes. Besides, conservative treatment, supported if need be by blood transfusion, tides the patient over the crisis in the vast majority of cases, whereas resection is particularly dangerous for these very exhausted patients. As for the possibility of chronic ulceration leading to perforation, and therefore being an indication for an operation, it should be noted that it is the early rather than the chronic case which is complicated by free perforation. Indeed, the danger to life, as distinct from troublesome but not fatal symptoms, is far less in chronic ulceration than was thought to be the case some time ago.

120 Treatment of Addison's Disease

H. LISSER, F. B. TAYLOR, and N. B. LEET (*Endocrinology*, May-June, 1934, p. 333) summarize the results obtained by treating over 100 cases of Addison's disease with suprarenal cortical extracts. In some instances apparently imminent death was averted and the duration of life considerably prolonged, but only in a few cases was the blood pressure raised and pigmentation reduced. In the absence of any reliable clue to the variations in suprarenal insufficiency the dosage has necessarily been empiric. The doses usually necessary for beneficial results have been from 50 to 100 c.cm. in times of crisis and 2.5 c.cm. daily as a maintenance dose for very long periods. In view of the very heavy expense thus entailed the authors think it not wise to resort to this therapy in ordinary clinical practice, but point out that it is possible that the utilization of high salt diets may reduce the amount necessary. Experimental studies and clinical observations suggest that the hypotension, hypoglycaemia, and pigmentation in this disease are ascribable to the suprarenal medulla primarily, and are therefore only occasionally and probably indirectly influenced by cortical extracts. The asthenia, the gastro-intestinal symptoms, and the manifestations of shock and crisis are, however, most likely due to cortical deficiency, and therefore most consistently alleviated by such extracts. This does not explain the failure of medullary extracts to rectify the chronic hypotension or diminish the characteristic pigmentation.

M. M. CANTOR and J. W. SCOTT (*ibid.*, p. 341) report a case of Addison's disease in which experimental relapses and remissions were brought about by substituting saline injections for extracts prepared from the whole suprarenal gland. They remark that, as in the case of insulin, it is clear that the quantity administered must be generously increased during any infections and in relapses due to withdrawal. There is an increased tendency in these patients to abscess development and to succumb to mild intercurrent infections. In the authors' case treatment was continued for more than twenty-six months, experimental relapses and remissions being induced on eleven occasions without any lasting ill effects. Sexual vigour was restored, indicating the relationship between the suprarenal cortex and the gonads. Leucodermic patches also developed, supporting the view that decrease in pigmentation during remissions is attributable to dissolution of pigment in the skin rather than to decrease in the deposition of pigment.

121 Allergic Reactions of Veins

J. LOUVEL (*Presse Méd.*, May 26th, 1934, p. 860) points out that in the treatment of venous affections one must bear in mind not only the therapeutic agent, but also the venous tissue, and obviate those things which might stimulate it to an antagonistic reaction. Familial predispositions must be remembered—for example, sclerosing injections of the same nature and strength may produce different results in different persons. Small doses of sclerosing substances should be given at first in order to find out if the person is unduly susceptible. In provocative sensitization a mild injection followed by no reaction at all, and repeated a few days later, may produce a reaction which is comparable to anaphylactic shock. Such cases of allergy are found not only in hypersensitivity but also in immunity reactions. It is necessary to increase rapidly the succeeding doses, otherwise the veins accustom themselves to them, and resist them even when they are concentrated. It is difficult to explain those cases in which, after the injection of one sclerosing agent has turned the vein into a fibrous cord, a new agent produces inflammation in a venous segment one would have believed to be altogether immune and incapable of a reawakening of its primary susceptibility. The fact that one and the same sclerosing agent may in one case produce sensitization and in another immunity must be interpreted as due to these being two extremes of a defence process. One venous segment seeks to protect itself by intensifying the inflammatory reactions, another shelters itself under cover of immunity and the refractory state. The reactions of veins to sclerogenic substances may be classified as: reactions of primary hypersensitivity, secondary reactions by sensitization, and refractory states by immunization.

Surgery

122 Spina Bifida and Cranium Bifidum

S. W. GROSS and E. SACHS (*Arch. of Surg.*, May, 1934, p. 874) report ninety-six cases of spina bifida in infants or young children, and five cases of cranium bifidum. Two cases are also included of spina bifida occulta in young adults. Operation was carried out in cases where the epithelial covering of the spina bifida was intact, when hydrocephalus was not extreme, and when there was some function in at least one lower extremity. Absence of bladder control or the presence of deformities such as club-foot were not considered to be contraindications for operation. In the series reported forty-six patients were not operated on, and of these thirty-six died while in hospital, twenty-three being afflicted with hydrocephalus and paralysis of the lower limbs. Of the ten who survived, six had extensive defects and four

had leaking and infected sacs. Fifty-seven patients were operated on, and, of these, forty-three cases of spina bifida and four of cranium bifidum were under a year old. Operation was not undertaken until the baby was in the best condition possible. Each infant was kept in a crib with a tent round it, heated by electric light bulbs and maintained at a temperature of about 98° F. The child wore no clothing, and was placed on its abdomen on a pillow. There was no dressing over the spina bifida. These precautions were taken to prevent injury to the lesion and soiling of the operative field with urine or faeces. The infant received 200 to 250 c.cm. of saline solution subcutaneously before operation. The sac was dissected out and the neck opened, all nerve elements being freed and replaced in the spinal canal, and enough of the sac retained to close the defect without tension. End-results were obtained in twenty-six cases; eleven of these had had simple meningocele, and ten were reported to be well in every respect, whilst one had slight awkwardness of the fingers. Of the remaining fifteen cases, twelve had had myelomeningocele, and two died shortly after leaving hospital. Details are given of ten of these cases, and show varying results, with improvement in many instances. Three of the patients with cranium bifidum are living and in good health.

123 Diathermy in Prostatic Hypertrophy

C. PERMIN (*Hospitalstidende*, May 8th, 1934, p. 521), with a personal experience of eleven cases of hypertrophy of the prostate treated by diathermy, and after a study of the literature of the subject, discusses the comparative merits of this and operative treatment. Although hundreds of cases have been published in connexion with both treatments, it is impossible to form a reliable opinion of their respective merits simply by statistical methods, for much depends on the selection of cases for one or other treatment, and on the technique employed. Considering that surgeons are inclined to keep the best cases for themselves, and to leave the less satisfactory cases alone, to be treated by such methods as diathermy, no fair comparison can at present be made; but it seems to be generally agreed that diathermy increases the chances of recovery for the inoperable case. Disagreement begins over the operable case. The author suggests that, having scored so many successes among the inoperable cases, diathermy is entitled to at any rate a share of the operable cases; but he admits that, in spite of the progress made by diathermy, the final verdict on its merits has not yet been given. H. VIETHEN (*Zentralbl. f. Chir.*, June 2nd, 1934, p. 1273) describes thirty cases in which prostatic patients who rejected operations or were unsuitable for it, by reason of morbid conditions of the heart, lungs, or kidneys, were treated by diathermy. The instrument used was that described by v. Lichtenberg-Heywalt in 1932, and is provided with a current with damped oscillations. Anaesthesia was induced by intrasacral injection of 30 c.cm. of 2 per cent. novocain. A groove 2½ mm. deep was burnt in one lobe at each sitting. One death followed from bronchopneumonia; the remainder showed well-marked improvement, none having large amounts of residual urine and six none at all. The electrotome employed can be used for histological distinction between malignant and benign prostatic enlargements; the excised fragments are caught in a cylindrical gauze filter, which is placed within a metal section of the tube through which the bladder is washed out.

124 Operative Treatment of Aneurysm

R. SANTOS (*Bull. et Mém. Soc. Nat. de Chir.*, May 12th, 1934, p. 660) points out that the dangers of aneurysm depend on the possibility of rupture and on the circulatory complications associated with it. Treatment must aim at the obliteration of the sac. Complete removal achieves this, but is a dangerous procedure on account of the risk of injury to the surrounding nerves and the collateral vessels. The most satisfactory operation is Matas's endoaneurysmorrhaphy. By this means all the vascular communications with the aneurysm are closed from the

interior of the sac, and the chances of the development of the collateral circulation are good. It has been found that arteriography helps the diagnosis and makes the operation of Matas considerably more simple. The first essential of the operation is to produce a temporary haemostasis. If it is possible to use a clamp the procedure is simple, but if the aneurysm is situated at the base of a limb it is a delicate or even dangerous operation. Two cases are reported of aneurysms which occurred in the popliteal artery. Radiographs are given which show the condition of the blood vessels before and after operation, and it is seen that a month after treatment an extensive collateral circulation had developed. In cases of aneurysm of the pelvic arteries the condition is more difficult to treat, but in three instances reported the exact position of the aneurysm was located. The first case was cured by the Matas operation after a recurrence which had followed ligature a year previously. In the second case the temporary haemostasis was not satisfactory for the Matas operation to be carried out, and the artery was ligatured, but the patient died after four days from gangrene and heart failure. In a case of aneurysm of the right iliac artery the sac was as large as a pear, but, following a Matas operation, the patient made a good recovery, as shown in a subsequent radiograph. Emphasis is laid on the value of radiography in diagnosis, in showing the position, extent, and type of aneurysm prior to any operative treatment.

125 Misuse of Crutches in Knee Cartilage Injuries

W. EHALT (*Münch. med. Woch.*, May 11th, 1934, p. 709) gives details of two cases illuminating his thesis—namely, that it is a serious mistake to temporize with crutches and immobilization when the articular cartilages of the knee have been injured. The temptation to do so is enhanced by the suspicion at the back of the practitioner's mind that his diagnosis of injury to an articular cartilage is mistaken, and that, if it is correct, the relief of pressure afforded by crutches will hasten repair and recovery. As for the possibility of a mistaken diagnosis, an injury to an articular cartilage can with certainty be demonstrated by clinical examination; and as for the possibility of the spontaneous union of a ruptured articular cartilage, it simply does not exist, be the relief from pressure afforded by crutches, plaster-of-Paris, etc., ever so adequate. Both the author's cases ultimately came to operation, but in the interval valuable time had been wasted. In the first case the crutches gave moral as well as material support to a work-shy individual ready to snatch at any evidence calculated to facilitate his claims on the community's purse. In the second case, the patient was most anxious to return to work as quickly as possible, and his failure to do so was not his fault, but that of his procrastinating medical attendant.

Therapeutics

126 Yeast in Pernicious Anaemia

H. K. RUSSELL (*Ann. Int. Med.*, May, 1934, p. 1398) reports four typical cases of pernicious anaemia in which a slight but definite reticulocyte response followed the administration of brewer's yeast. He concludes that the gastric secretions of these four patients contained some intrinsic factor, but in insufficient amount to prevent symptoms of the disease. It would also appear that small amounts of extrinsic and intrinsic factors were present and administered in the brewer's yeast, or were present in the patients (possibly stored in the body as the result of previous treatment) in amounts insufficient to prevent symptoms, and were activated by the large amounts of yeast which these patients received. Alternatively, it might be argued that Castle's explanation is not correct and that small amounts of extrinsic factor (brewer's yeast) are by themselves capable of stimulating haematopoiesis. Russell considers it likely that many

cases of true pernicious anaemia contain lesser amounts of the intrinsic factor than are necessary to prevent the development of the disease, but are not entirely devoid of it. The symptoms would then be the result of a quantitative rather than of an absolute lack of the factor. Spontaneous remissions, which are characteristic of the disease, would seem to indicate that this must be true. Such a partial deficiency might have been present in the four recorded cases, and their response have been the result of such a mechanism as Castle postulated.

127 Intravenous Sodium Benzoate in Peptic Ulcer

F. FERNÁNDEZ MARTÍNEZ (*Semana Médica*, April 26th, 1934, p. 1329) writes that he tried this method—introduced a year ago by Bazzano of Rome—on nine cases in which the presence of ulcer had been determined by full clinical, radiological, and laboratory examination. All patients were poverty-stricken peasants relieved by the State, whose symptoms were in the fullest phase of development. They were confined to bed, their mouths carefully cleansed, and the bowels well opened. For a few days they were on milk diet, to which was gradually added boiled rice and eggs, broth, boiled whiting, roast potato, minced beef, bananas, grapes, and a slice of bread. Weight, chemical condition of the gastric juice, and radiographic appearance of the stomach were ascertained every ten days, as was the microscopical condition of the stools. Each had a series of from twenty-five to thirty intravenous injections of 2 c.c.m. of 25 per cent. sodium benzoate. Some had two or three such series. The only complications encountered were sclerosis of the vein at the site of injection, and "flushings" which required the addition of an alkali to the benzoate. The immediate results were invariably good; the occult blood disappeared from the stools, weight increased, general health improved markedly, and the radiographic signs of ulcer very often vanished. The acid of the gastric juice was but little affected, and at times increased, even though the patient felt much better. None the less, it was found quite impracticable to revert to ordinary diet, as the signs invariably returned. Hence the writer regards the treatment as suitable only for the earliest stages of the disease, as it does not cure the ulcer, which will yield only to a very lengthy dietetic regime in addition to bismuth, alkalis, and belladonna.

Radiology

128 Radiography in Amoebic Dysentery

K. IKEDA (*Radiology*, May, 1934, p. 610), who records a series of cases, finds that radiography of the colon is a satisfactory method of determining the site, extent, and degree of involvement in amoebic dysentery, and of observing the progress of the disease under specific treatment. A small area of fresh inflammation or the reactivation of old lesions can be thus demonstrated, even when clinical improvement, and the laboratory is negative or inconclusive. Radiological examination of the colon in this disease may therefore be a valuable guide to treatment. In the early stages there are no definite changes, but as the disease progresses, projections develop later along the colon representing small superficial ulcers which become obliterated by inflammatory oedema. Fine feathery or thorny filling defects in the ulcerated wall generally indicate a later stage of lesion in which the submucous and muscular layers are involved in an extensive inflammatory granulation. A somewhat characteristic deformity of the descending and ascending colon can be observed radiographically during the subacute or early chronic stage of the disease, when there may be an apparent shortening or retraction of the wall, with induration and filling defects of varying degrees. These changes are seen to be rapidly eradicated by emetine treatment. An advanced amoebic

lesion, when diffuse and extensive, is not likely to be confused with cancer. When localized and obstructive, however, it may be so mistaken, for there is no radiological means of differentiation. Ikeda adds that the radiographical appearance of the colon in amoebic dysentery may be suggestive or presumptive, but it is not to be taken as definitely diagnostic without supporting clinical and laboratory evidence. On the whole, however, the picture does not represent that of non-specific ulcerative or tuberculous colitis, nor does it usually simulate cancer. As a rule, varying amounts of barium residue were observed in the caecum after the evacuation of the enema during the stage of active dysentery, indicating the absence of spasm in the affected portion. A wide patency of the ileo-caecal ring was also frequently observed, allowing a constant flow of the clysmas into the terminal part of the ileum which was apparently invaded by the infection.

129 Spindle Radiograms in Dorsal Pott's Disease

In 1912 C. ROEDERER (*Bull. et Mém. Soc. Méd. de Paris*, March 24th, 1934, p. 205), with Weil, noted in radiograms of dorsal Pott's disease an ovoid or triangular shadow resembling that of an abscess round the lesion and more or less round the vertebral column. This, however, gave no clinical symptoms, while a lumbar abscess, often palpable, showed no radiological signs. The shadow is not always oval or triangular, but is frequently spindle-shaped, and lies on the vertebral shadow. It is seen only in antero-posterior radiograms, and consists of a dark centre with lighter periphery. It is an early symptom which appears coincidentally with the sensation of constriction, and is possibly due to tuberculous of long evolution. The sign is pathognomonic of Pott's disease; in forty cases examined by the author with Graffin, it was absent in only two, and in only one or two dorsal cases studied by Delchef and Bailleux. Roederer has never found this spindle shadow in epiphysites and other spinal affections. It persists during the evolution of the disease; when it ceases to increase in size and becomes retracted and denser, and if at the same time the calcification of the vertebrae increases, the malady has fully evolved and operation may be safely performed.

130 Preoperative Diagnosis of Diverticulum of the Gall-bladder

J. H. VASTINE (*Amer. Journ. Roentgenol. and Rad. Ther.*, May, 1934, p. 603) reports two cases in which the diagnosis of diverticulum of the gall-bladder was made by cholecystography before any operation. In one instance the cholecystograms corresponded as regards both the size and position of the diverticulum with those of the case of Bárony and von Friedrich, but in Vastine's case no operation was performed. In the present author's second case a calculus was present in the diverticulum which, since it was completely outside the shadow of the gall-bladder, might easily have been mistaken for a renal calculus. No similar case could be found in the literature in which a preoperative diagnosis had been made. Vastine thinks that a diverticulum so diagnosed in an otherwise normal gall-bladder is probably of little clinical significance, although Abbott has recorded a case in which he found an inflamed diverticulum projecting from an uninfamed gall-bladder. He points out that differentiation of such an abnormality has to be made from congenital malformations such as double gall-bladder, hour-glass gall-bladder, redundant gall-bladder due to the presence of a peritoneal fold (the cystoduodenal or cystocolic ligament), and pericholecystic adhesions causing deformity of an otherwise normal gall-bladder shadow. The differentiation should be made easier by films taken at various angles, in some of which the redundant or double gall-bladder shadows can be shown in a position in which there is no overlapping. Vastine adds that the findings in his cases suggest that radiograms taken after a meal rich in fat indicate less decrease in the size of the diverticulum, due to the absence of muscle fibres in its wall.

Obstetrics and Gynaecology

131 Pregnancy and Heart Disease

R. SCHOEN (*Münch. med. Woch.*, May 18th, 1934, p. 739) discusses the fate of sixty-five pregnant women who suffered from heart disease and who were sent to a maternity hospital in Leipzig with a view to the induction of abortion being considered. In as many as fifty-eight of these cases the mitral valve was involved. In thirty-one cases the pregnancy had not lasted three months. The ages of the women ranged from 20 to 35 years, and twenty-six of them were primiparae. Abortion was induced in twenty-one out of the forty-eight cases in the first half of pregnancy. In the remaining forty-four cases it was decided not to interfere with the pregnancy, and among these were thirty-five women who were successfully confined. Discussing the indications for the interruption of pregnancy on account of heart disease, the author holds that when it is compensated and there are no signs of dilatation of the heart or of obstructed circulation, the pregnancy should be allowed to continue. Even when compensation is faulty, the patient may in rare cases be allowed to go to term if she is anxious to have a living child and if her social status is such that she can be well cared for in the interval. There is, in the author's opinion, no such thing as a social indication by itself for the induction of abortion; it is only when social conditions have a material effect on the patient's health that they can be taken into account. With regard to the special position of mitral stenosis in connexion with pregnancy and labour, no untoward events need be anticipated during the pregnancy itself provided complete compensation has been assured. But labour is apt to be dangerous, for when it is completed and the circulation in the uterus is much reduced, the quantity of the blood in circulation is in excess of the capacity of the vessels through which it circulates. The result is liable to be oedema of the lungs, evidenced by cyanosis, dyspnoea, sputum, and rales. This condition may be relieved by venesection. As a general rule, the interruption of pregnancy on account of heart disease with faulty compensation should be limited to the first half of pregnancy.

132 Avitaminoses in Pregnancy

VIGNES and OLIVIER (*Gynéc. et Obstét.*, May, 1934, p. 443) state that vitamin insufficiency is common in the pregnant and nursing mothers and the child: even normal infants have no more than a bare adequacy. The proportions present in milk are so small that other foodstuffs should be added early. Avitaminosis A predisposes to puerperal infectivity; extreme cases (for example, in post-war Vienna) show hemeralopia, and in the foetus poor nutrition. When present in the nursing mother, its signs in the infant are anorexia, slow growth, and catarrhal conditions of intestines, and especially of eyes and nose. Thus, cream, yolk of egg, cod-liver oil, and carotene-containing foods must be fed to the nursing and expectant mother. Avitaminosis B emphasizes the normal metabolic strains in pregnancy. Therefore, such symptoms as vague or marked neuralgias, lumbago, scattered cutaneous and muscular pains, sense of weight in the limbs, gastrointestinal disturbances, and pruritus (which may be paradiabetic) are relieved by the administration of brewer's yeast. Beri-beri, which may develop or be increased in pregnancy, and polyneuritis following hyperemesis are of the same origin. Sucklings and older infants with constipation, muscular rigidity, or anorexia need yeast preparations. Avitaminosis C seems comparatively well tolerated in pregnancy, but is well known to result in infantile scurvy and anaemia, particularly in twins. Prescurbutic conditions are pallor, lack of muscle tone and appetite, persistent rise of temperature, and haemorrhage. Fruit juices are curative. Avitaminosis D in the mother causes osteomalacia, and probably influences the development of rickets in the infant. Nursing mothers require large quantities of vitamin D to keep up the amount in the milk. Irradiated yeast can be given. The avita-

minoses also affect reproduction. Lack of vitamin A hardens the endometrium and prevents rupture of the Graafian follicles. Lack of vitamin B results in atresic follicles. Reproduction in rats on a diet lacking nothing but vitamin E closes with death and reabsorption of the embryo, but on return to full diet becomes normal again. Vitamin E is not stored in the body. It is concerned with the metabolism of Fe, as vitamin D is with that of Ca and P. Sources are fresh lettuce, muscle, yolk of egg, peas, and cereal grains.

Pathology

133 The Thyroid in Experimental Ovariectomy

V. DOGLIOTTI (*Ann. di Ostet. e Ginecol.*, May 31st, 1934, p. 547) made a histological examination of the parathyroids and thyroids of adult rabbits which had undergone ovariectomy, and came to the following conclusions. While the parathyroids did not reveal any obvious changes due to the operation the thyroid presented evidence of histological hyperplasia which showed a progressive increase according to the duration of the experiment. In view, however, of the present state of our knowledge and the difference of opinion on this subject, Dogliotti is unable to state with certainty whether the hyperplasia is accompanied by a corresponding degree of hyperfunction.

134 A Case of Amyloidosis

I. F. GERBER (*Arch. of Pathology*, May, 1934, p. 620) describes an interesting case of generalized amyloidosis, in a white man of 44, with no suppurating focus to cause amyloid disease. It is suggested that this case is a link, pathologically, with amyloid disease and with so-called "nephrosis." Clinically, the case showed a large liver, albuminuria, and hypercholesterolaemia. Two and a half years from the first diagnosis the patient died in uraemia with pulmonary oedema. Post-mortem showed characteristic amyloid changes in all organs, including bones and vertebrae, in which they are rarely found. In a gland removed at biopsy no doubly refracting crystals had been found, so that the renal lesion was in this sense probably different from "lipoid nephrosis"; also the main brunt of the disease falling on the blood vessels and not on the tubules was the cause of the terminal uraemia and vascular failure. The theoretical importance of the case is threefold: first, it is one of a spontaneous general metabolic failure giving rise to amyloid degeneration in all blood vessels and organs; secondly, the whole syndrome of "lipoid nephrosis" was present without the oedema; thirdly, this strange variety of vascular degeneration produced the same terminal results as the more usual forms of arteriosclerosis and hypertension—namely, uraemia and acute pulmonary oedema.

135 Hormones in the Suboccipital Cerebro-spinal Fluid

H. HOFF, K. KÖCK-MOLNAR, and H. URBAN (*Wien. klin. Woch.*, May 11th, 1934, p. 584) recall that folliculin and prolactin, as well as pituitrin, are absent from fluid obtained by lumbar puncture, but that pituitrin has been identified in liquor from suboccipital puncture. In numerous patients the writers found folliculin in the suboccipital fluid; in those cases in which it was possible to test fluid taken directly from the lateral ventricle, folliculin was found to be absent, and in nearly all cases its concentration was less in the blood than in the suboccipital liquor. There was evidence of a cyclical menstrual hormonal variation in this fluid. The patients included males and females, and not only those with cerebral tumour or inflammation, but also those with cancer elsewhere; folliculin appears, therefore, to be associated with cellular proliferation. Prolactin was detected in the suboccipital fluid in two cases only—both had a basophil adenoma of the pituitary, and this seems to confirm the view that prolactin is a product of the basophil cells.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

136 Nematodes in the Brain in Pellagra

G. TÖRRICH (*Deut. med. Woch.*, June 1st, 1934, p. 814) records the case of a married woman, born in 1891, who presented a characteristic clinical picture of pellagra before she died. When her brain was fixed in formalin, serial sections were cut and stained according to Nissl's method. An almost exclusively lymphocytic meningitis, mainly basal, associated with a granular ependymitis, was found. At three different points in the serial sections of the brain nematodes of a type hitherto not associated with human beings were seen. One of them was a sexually mature curved male found in the liquor of the third ventricle. The other two were immature worms. The association of a hitherto unknown parasite in the brain with such a rare disease as pellagra raises the question whether the one may not be the cause of the other. If this is so, it is easy to explain the oversight of the parasite in post-mortem examinations in cases of pellagra, for with few exceptions no systematic examination of the base of the brain has been made in such cases. The elusive life-history of nematodes also helps to explain negative findings when the conductor of a post-mortem is not helminthologically minded. As the larvae of nematodes may be found in the sputum of the host, the author suggests that the sputum of patients suffering from pellagra should be examined with this possibility in view. To the same end the cerebro-spinal fluid should be examined for nematodes when it shows signs of a lymphocytosis.

137 Aberrant Intrathoracic Goitre

According to M. MÁRYÁS (*Zentralbl. f. Chir.*, May 26th, 1934, p. 1219) an intrathoracic goitre can cause serious symptoms of pressure on the lungs, mediastinum, or great vessels, and, having developed progressively, it may reach regions remote from its substernal origin, lose connexions with the thyroid, and simulate tumour of the lung. The case is recorded of a woman, aged 47, who had oedema of the right arm and right side of the neck, swollen right thoracic veins, dullness over the upper lobe of the right lung, and radiological signs of underlying tumour thought probably to be a hydatid cyst. At operation an encapsulated tumour (histologically a benign thyroid adenoma) surrounded entirely by lung tissue was removed; death followed three days later from pulmonary embolus.

138 An Outbreak of Food Poisoning

R. HUSS and B. LINDSTRÖM (*Hygiea*, May 15th, 1934, p. 305) give an account of an outbreak in Sweden of food poisoning in some fifty persons who had partaken of a boiled ham served in a large railway office, which, since it was first opened in 1912, has been the scene of eight such outbreaks including the last, which occurred on November 10th, 1933. On every occasion the poisoning was traced to some meat or other, and only a fraction of the persons fed from the same kitchen fell ill. The frequency with which such outbreaks had overtaken this institution led to an expert investigation seventeen days after the outbreak on November 10th. There was then no ham to examine. Bacteriological examinations of the stools of the kitchen staff and of the ex-patients proved negative, but the blood of four members of the kitchen staff and of five ex-patients agglutinated dysentery bacilli of the Kruse-Sonne type. Failure to demonstrate it in the stools may have been due to the length of the interval between the outbreak and their examination. It transpired that on the day before the outbreak a member of the kitchen staff had handled the ham, then just boiled, though suffering from an acute gastro-intestinal infection. The chances of her having infected it on November 9th, and thus caused the outbreak on the

10th, are the greater because her blood was found on November 28th to agglutinate Kruse-Sonne dysentery bacilli. The previous outbreaks may possibly have been connected with the faulty sanitary arrangements found by the authors, who noticed that the kitchen and adjoining quarters were below ground level and only four metres from a septic tank. But they are inclined to trace the last outbreak to the person who had handled the ham the day before it was eaten, and they conclude with the recommendation that "persons who deal with foodstuffs, particularly those who serve in dining-rooms, should at once discontinue work when they fall ill. This is most important when the illness involves the gastro-intestinal tract."

Surgery

139 Tonsillectomy in Cases of Pulmonary Tuberculosis

J. D. ARAÓZ (*Semana Médica*, May 17th, 1934, p. 1515) records his experience with 149 cases of both sexes, with ages ranging from 14 to 41, on which he operated during the past three years. All of these had definite pulmonary or pulmonary and laryngeal tuberculosis, and the result of operation was so satisfactory that he declares that it has no contraindications except tuberculous affections of the mouth or pharynx, which, of course, include tuberculous disease of the tonsils. Tonsillectomy not only improves the general condition, but is a substantial help to the special—that is, climatic, dietetic, and medicinal—treatment adapted to the stage or type of the disease. Prior to operation, the coagulation time of all patients had been carefully estimated, and some had to be specially treated before this reached the normal standard. Only 3 per cent. of those operated upon manifested any unusual loss of blood, and four out of the 149 complained of pharyngeal tension when cicatrization was complete. The writer adds that his favourable experience has been shared by Dr. H. Newhart, who has published in the review, *Minnesota Medical*, a series of 112 cases, of which eighty-one were in adults and forty-one in children.

140 Metastases from Thyroid Tumours

R. DINSMORE and N. HICKEN (*Amer. Journ. Surg.*, May, 1934, p. 202) report 124 cases of metastases from malignant thyroid tumours. The total number of cases of thyroid malignancy was 264. In the series cervical gland and pulmonary metastases were the most frequent, with ninety-four cases occurring in the cervical nodes, thirty-six in the lungs, and only eighteen in the bones. It is suggested that the small capillaries in the lungs arrest the progress of the neoplastic emboli in the blood, and the malignant cells become established by means of rapid cellular proliferation and invasion of the parenchymatous tissue. Metastatic cancer may also reach the lungs by direct extension from the mediastinum, or by lymphatic permeation from the cervical nodes. Skeletal metastases occur more frequently where red bone marrow is found, such as in the skull, vertebrae, pelvic bones, ribs, and the proximal end of the humerus and femur. At first the tumour develops inside the medullary canal and causes a pressure erosion of the bone, osteoporosis or rarefaction taking place until the entire bony cortex may be destroyed and pathological fractures occur. Sometimes a metastatic skeletal tumour is the first sign of a thyrogenic neoplasm. If the metastatic lesion involves the vertebrae, the tumour produces a compression myelitis, and paralysis develops. The prognosis in malignant disease of the thyroid gland is unfavourable. Of the thirty-six patients with pulmonary metastases, two died in hospital, twenty-three lived for an average of twenty months, seven could not be traced, and four are still living after varying times up to five years. The prognosis is slightly better in cases of osteogenic metastasis, and of the eighteen cases reported, two are still living after

three and five years, and the remaining sixteen patients lived an average of two and a half years after the thyroidectomy. Treatment should consist of thyroidectomy, lobectomy, decompression, or tracheotomy, supplemented by x-ray therapy.

141 Ultimate Results of Phrenicectomy

R. JEANNERET, M. RIET, and F. FAMÉ (*Presse Méd.*, May 9th, 1934, p. 748) state that in recent years many authors have noted a return of the diaphragmatic functions after phrenicectomy, and that this is frequently accompanied by a recrudescence of the pulmonary lesions. Two cases are recorded to illustrate this fact. Reviewing the anatomy of the phrenic nerve, the authors describe it as arising from the cervical roots by three branches from the third, fourth (the principal), and fifth roots. The branch from the fifth root frequently arises from a common trunk with the subclavian nerve, forming an accessory phrenic; this branch and that from the third root rejoin the main trunk of the phrenic lower down. Other accessory phrenics are formed by anastomoses with all the cervical and even the first dorsal roots, these ultimately rejoining the main phrenic trunk. Branches may also be received from the hypoglossal and supra-scapular nerves. More important are the anastomoses with the cervical sympathetic (superior, middle, and inferior ganglia), the opposite phrenic, and with the inferior diaphragmatic plexus. These anatomical points confirm the authors' opinion that the phrenic with its accessories forms the sole pathway of motor and trophic impulses to the diaphragm, and consequently a return of its functions implies a reconstitution of the circuit uniting the cervical plexus to the diaphragm. This may be due, as Cardis and Giraud consider, to an insufficient exeresis of the nerve; experiments of Sergent and Launey confirm this view. If this theory of regeneration be admitted, two interventions are indicated—an examination of the main trunk at the site of the old cicatrix, and if this be negative, the performance of Goetze's operation on the hypothesis that the regeneration occurs in the accessories and not in the main nerve. The authors believe that a secondary phrenicectomy will prove efficacious.

Therapeutics

142 Statistics of Measles Prophylaxis

G. S. BUCHANAN (*Bull. Off. Internat. d'Hyg. Publique*, May, 1934, p. 888) states that convalescent serum has been employed at the Hospital for Sick Children at Great Ormond Street since 1925, but that it is only recently that it has been used on a large scale in other London hospitals. In 1931-2, during an epidemic of measles in London, an investigation was made under the auspices of the London County Council as to the value of adult and convalescent serum for the protection of contacts. Of 2,020 children 680 were given convalescent serum and 1,333 adult serum, while 207 did not receive any preventive injection. Of the last group, only 25.1 per cent. did not develop measles, whereas 90 per cent. of those who had convalescent serum and 76.7 per cent. of those given adult serum escaped an attack. Of the inoculated children only 3 per cent. had an unmodified attack as compared with 70.5 per cent. of those who had not been inoculated. The doses of convalescent serum were 10 c.cm. for children under three years, when complete protection was required, and for older children 1 c.cm. for each year multiplied by four. In such cases the serum was given during the first five days after exposure. When the serum was given after the fifth day, or when the dose, though given within the first five days, was reduced by half, more than half the contacts had a mild or abortive attack. During the last four years an extensive use has been made at Birmingham of adult serum, which is made available by the Health Department for any practitioner who needs it. A similar use of convalescent or adult serum is made in the hospitals at Liverpool, Manchester, and Brighton.

143

Fixation Abscess in Asthma

P. A. SIMON (*Thèse de Paris*, 1934, No. 355) reports fourteen cases of asthma in patients aged from 24 to 32, in which rapid relief was obtained by treatment with a fixation abscess. The success of the method appeared to be due to: (a) the powerful effect exerted by the derivative and decongestive action on the more or less latent bronchial inflammation; (b) a considerable discharge of microbic toxin; (c) a temporary production of fever accompanied by an intense increase in leucopoiesis, which permanently modified the resistance to the toxic-infection and restored the disequilibrium of the neuro-vegetative system; and (d) a psychotherapeutic action on persons of a neuropathic constitution. The contraindications for fixation abscess are anasarca, pulmonary tuberculosis, and diabetes on the one hand; and on the other hand, mild attacks which are not worth treating by a method which, though free from risk, is decidedly painful and immobilizes the patient for a considerable time.

144 Novocain-Suprarenin Injections in Neuralgia

W. T. SCHMIDT (*Med. Welt*, June 2nd, 1934, p. 770) has treated over 160 cases of chronic neuralgia with perineuritic injections of novocain-suprarenin, and has found them, on the whole, more effective than injections of alcohol or normal saline solution. Indeed, the results were often so lasting that it would seem that the injections had not been merely symptomatic in their effect, but had achieved a more or less radical cure by virtue of the anaesthesia and rest of the nerve involved. With regard to sciatica and its notorious tendency to relapse, success largely depends on the accuracy with which the nerve is located before the injection is given. A useful indication is the sense of tingling lower down his leg of which the patient complains when the point of the needle or the injected fluid first comes into contact with the nerve. Should sciatica have to be treated under ambulatory conditions, the dosage of the novocain-suprarenin should be comparatively small in order that the patient's departure may not be hampered by the local anaesthesia. As the illustrative cases show, it was sometimes necessary to administer a general anaesthetic as a preliminary to the injection. It may be repeated every day or at intervals of two or three days, the dosage being in one of the author's cases 3 c.cm. of a 1 per cent. solution and in another case 5 c.cm. of a 2 per cent. solution. In cases of severe and protracted sciatica the injections have to be repeated many times, and even after the pain has practically ceased the treatment should be continued for two or three weeks more. It is of some psychological importance to over-estimate rather than to under-estimate the time this treatment will require when it is first mentioned to the patient.

Neurology and Psychology

145

Sodium Evipan in Psychiatry

W. KUNTZE (*Münch. med. Woch.*, June 22nd, 1934, p. 937) began in April, 1933, to administer sodium evipan by intravenous and intramuscular injection to violent patients, and his first satisfactory experience with an unruly epileptic has since been repeatedly confirmed. He has, in fact, never had to record either a failure or a fatality with this treatment; nor has he ever observed the brief stage of excitement reported by others as an immediate sequel to this treatment. He prescribes it when excited and restless patients have to be moved from one place to another, and as a preliminary to exploratory punctures and artificial feeding. In the twenty-one cases in which he gave the drug to patients about to be transferred to an institution, he usually administered 10 c.cm., partly by intravenous, partly by intramuscular, injection. An interval of ten to fifteen minutes between the intravenous and the intramuscular injection prevented the too abrupt action of the drug. When the patients awoke in the institution to

which they had been removed they did so rather suddenly, but they did not complain of headache or any other discomfort. Patients thus treated were suffering from epilepsy, schizophrenia, general paralysis of the insane, and acute alcoholic poisoning. Even when general paralysis was associated with heart disease the drug did no harm, but it was found to be less suitable for prolonged treatment than for an emergency. In the most difficult cases, and when sufficient assistance is not available, it may be necessary to avoid the intravenous route and give the drug exclusively by intramuscular injection. In one such case 10 c.cm. was given in a single dose by intramuscular injection, and the sedative effect was not obtained till fifteen to twenty minutes later. Even when some of the total dosage of 10 c.cm. is given by intravenous injection the patient is, as a rule, quieted for only two to three hours. Powerful men often sleep only for an hour to an hour and a half. It is exceptional for the effect of the drug to last four to six hours.

146 A Physiological Conception of Neurosis

In an attempt to reach a physiological interpretation of obsessional neurosis and paranoia, I. P. PAVLOV (*Journ. Ment. Sci.*, April, 1934, p. 187) cites some results obtained in a recent study of conditioned reflexes in dogs. It was found possible to produce a pathological disturbance of the activity of the nerve cells, an alteration of the normal balance between two sides of their activity (the excitatory and inhibitive processes), with an abnormal predominance of the excitatory process, which was reducible by treatment with bromides. By further experiments a new phenomenon was discerned, defined as "pathological inertness." Evidence was obtained for assuming that under the influence of various morbid factors of a functional character in the cerebral cortex distinctly isolated pathological points or areas might originate, and it is thought conceivable that this might have some bearing on the pathology of the higher centres of nervous activity in man. Obsessional neurosis and paranoia might prove to be pathological states of the corresponding cells of the cerebral cortex—in this case in a state of pathological inertness. In the actual experiments two factors emerged as producers of disturbance: overstraining of the excitatory process, and at another time a clashing with the opposite process. Pavlov argues that human neuroses might thus be traceable to irregular development, occasional accentuation of one or other of the emotions, and disease of some organ or of a whole system, which cause the corresponding cortical cells to be temporarily or permanently, excessively and unlimitedly excited. This, he suggests, finally brings about their pathological inertness—an irresistible conception and sensation, which continues to exist long after its real cause has been withdrawn. The same might arise from strong and overwhelming life experiences, since life is an incessant struggle, a conflict of innermost aspirations, wishes, and tastes with general natural and special social conditions. The argument is worked out in detail in connexion with two cases recorded by Kretschmer. The author believes that clinicians, neurologists, and psychiatrists in their respective spheres will inevitably have to take into account certain patho-physiological facts—namely, the complete isolation of functionally pathological (at the aetiological moment) points of the cortex, as well as the pathological inertness of the excitatory process and what he terms the "ultra-pathological phase" in these points when there results a reversal of the positive and negative metronomes.

147 Treatment of Epilepsy

H. I. SCHOU (*Nord. Med. Tidsskrift*, May 19th, 1934, p. 620) has treated about 2,000 cases of epilepsy in the past decade in an asylum in Denmark, and is impressed by the improvement effected in this period. His patients have fewer attacks, less dementia, and fewer serious mental complications than they had ten years ago. Bromine has been completely, and, he states, rightly, replaced by luminal. Its action is most effective during the first three months, after which it becomes weaker. Luminal may be given continuously for ten years or

more in doses of 30 to 40 cg. a day without bad effects. The French preparation of borax—"tartrate borico-potassique," 1 gram, three to six times a day—may cause dyspepsia and loss of hair, but is occasionally remarkably effective, the fits recurring only when the drug is withheld. It seems to be particularly effective in children. Dieting has proved disappointing. Eighty patients were put on a diet containing much meat for three months and then for the next three months on a vegetarian diet without the total number of fits in the two periods showing any difference. But much can be done to reduce the number of fits by curtailing the fluid intake. To drink only 500 to 600 grams a day and to avoid liquid food, fruit, etc., is at first unpleasant, but patients get used to this regime, and by comparing six "dry" months with six "wet" months, the author was convinced of the accruing benefits. Rest in bed for some hours every day is beneficial, as well as the avoidance of mental and physical strains. During menstruation the epileptic should always keep her bed—some epileptics remain free from fits only by keeping to bed. In the eight cases in which the author attempted endocrine gland transplantation no benefits ensued. Failure had also to be recorded in connexion with a ketogenic diet. The artificial induction of fever may abort the fits as long as it lasts, but in the author's experience they recurred when the temperature became normal. The modern institutional treatment of epilepsy enables about 10 per cent. of the discharged patients to remain free from fits for more than half a year, and 25 per cent. to achieve considerable improvement.

148 Neurological Complications of Mumps

C. B. MCKAIG and H. W. WOLTMAN (*Arch. of Neurol. and Psychiatry*, April, 1934, p. 794) report a case of transverse myelitis at the level of the sixth cervical segment which followed an attack of mumps in a girl aged 16. The incidence of involvement of the nervous system in this disease is recorded variously in the literature as from 1 to 100 per cent., and many of the necropsy reports mention the presence of meningitis, but otherwise there is no evidence bearing on the nature of the pathological process. It is not known whether the same agent is responsible for both the parotitis and the neurological phenomena; or whether mumps activates a virus already existent in the nervous system, as has been stated to occur in vaccinal encephalitis. This latter view appears to be negated by the findings on serial and repeated spinal punctures, which suggest that the nervous system is involved in most cases, and also by the observation that neurological signs and symptoms may precede the parotitis. Encephalitis is probably the gravest complication of mumps, but as a rule it is not fatal, although the residual complications may take many months to clear up. The symptoms appear to have a vascular basis, and the presence of multiple foci is indicated in some cases. Extension into the cortex from the meninges is known to occur. Hemiplegia and hemianaesthesia are the commonest sequels, but the list of recorded disabilities includes paralysis of one arm and the opposite leg, emissive or receptive aphasia, agraphia, conjugate deviation of the eyes, ataxia (presumably due to cerebellar involvement), chorea, myoclonus, and herpes. Psychiatric disorders are rare; the most common disturbance is delirium, lasting a few days. The course of a meningitis of this aetiology is usually benign. Repeated spinal punctures and drainage for the purpose of lowering the tension of the fluid to normal levels are indicated. When neuritis is a sequel of mumps it seems more likely that the symptoms are secondary to meningitis, so that the term "meningo-radculitis" would be more applicable. Paralysis may be present with a normal spinal fluid. Of the nerves supplying the extraocular muscles the sixth appears to be the most susceptible, and presumes a meningeal origin. Deafness complicating this disease is generally complete and permanent, but, fortunately, is unilateral in 75 per cent. of the cases. The affected ear may be on the opposite side to that of the swollen gland. The most generally accepted explanation is that there has been a sudden exudate into the labyrinth; if so, the injection of a hypertonic solution of dextrose might prove useful.

Obstetrics and Gynaecology

Pathology

149 The Aschheim-Zondek Test in Chorion Epithelioma

H. SCHWALM (*Zentralbl. f. Gynäk.*, May 26th, 1934, p. 1212) describes a case in which this test enabled radical treatment to be instituted where, on clinical grounds, there was nothing more than a suspicion of chorion epithelioma. In curettage material from a woman aged 41, some ten months after a probable abortion, chorionic cells were found embedded in fibrinoid tissue; the injected animals, in an Aschheim-Zondek test of the urine, showed many corpora lutea. Bleeding persisted, and a second test was positive, but the uterus did not enlarge beyond its previous size—that of a fist. The urine, diluted as much as 1 in 150, gave Grade I reaction in one animal: total extirpation was done on the recommendation of Aschheim's laboratory, and the uterus was found to contain a chorion epithelioma as large as a small apple, with penetration of the myometrium. Implantation of tumour portions gave in three mice a positive, in two a negative, result—a confirmation of the finding that a urine test is more significant than that of implantation of material from biopsy or curettage. Schwalm states that in chorion epithelioma the Aschheim-Zondek test in the urine is invariably positive; in the few reported cases to the contrary either the tumour was diagnosed erroneously or its complete and fortunate removal by curetting accounted for the subsequent negative urinary test. The quantitative relations of the excretion of the gonadotropic hormone in the urine in pregnancy, hydatidiform mole, and chorion epithelioma are not yet worked out, but a positive reaction with 1 in 50 dilution is not uncommon in early pregnancy, and it must be remembered that the test does not remain positive more than sixteen days after abortion, but may not become negative for eighty days after passage of a hydatidiform mole. The persistence of a Grade I reaction after ablation of a chorion epithelioma is not of evil significance, for it is a usual sequela of castration.

150 Labour and Heart Disease

H. KÜSTNER (*Münch. med. Woch.*, May 18th, 1934, p. 741) discusses the conduct of labour complicated by heart disease in the light of his experience with 110 such cases at his maternity hospital in Leipzig. In fifty-six of these it was considered advisable to hasten labour artificially (forceps, version, etc.). As these operations required only a few minutes, ether anaesthesia was comparatively safe. In the remaining fifty-four cases the normal course of labour was not interfered with as there were no complications other than the heart disease and several of the patients were multiparae whose labour was soon completed. Eleven of the 110 died. All these deaths occurred after the successful termination of labour, the strain on the heart not achieving its maximum effect till some time later. The fatal issue a few hours after the completion of labour is also promoted by the elimination of the foetal circulation and the flooding of the mother's circulatory system with too much blood. When, after the completion of labour, the patient suddenly begins to cough and breathe with difficulty, she is liable to die in a short time of oedema of the lungs, which depends partly on flagging of the heart and partly on a superfluity of blood in the circulatory system. In those cases in which the loss of blood during labour was considerable, the author noticed that both labour and puerperium were apt to be most uneventful. He refers in particular to two cases, in one of which venesection (500 c.cm.) apparently saved the life of the patient, while in the other death, from acute oedema of the lungs, occurred as a sequel to the interruption of pregnancy between the sixth and seventh months. The general obstetrical rule to shed as little blood as possible does not therefore apply to the patient who is suffering from heart disease and threatened by acute oedema of the lungs.

151 Elective Localization of Streptococci

C. VIRGILIO (*Soc. Internaz. di Microbiol., Boll. Sez. Italiana*, 1934, vi, 102) has been studying the so-called organotropism of streptococci. According to Rosenow streptococci cultivated by a special technique from an infective focus in a particular localization of the body tend, on intravenous inoculation into laboratory animals, to give rise to disease in the same organ as that from which they were originally isolated. The present author has followed Rosenow's technique, and now reports the results obtained by himself on five hundred rabbits, and by his colleagues on several hundred more. These animals were inoculated intravenously with strains of diverse origin, and at necropsy they were submitted to a rigorous examination, usually both bacteriological and histological, to ascertain the distribution of the streptococci in the body. As controls, strains of streptococci were used that had been isolated from the tonsils of healthy persons. The results are given in tabular form, and on the whole confirm Rosenow's findings. For example, while 93 per cent. of strains isolated from acute, and 88 per cent. from chronic, articular rheumatism gave rise to lesions of the joints, only 67 per cent. of "normal" strains, 55 per cent. of cholecystitis strains, and 38 per cent. of strains from the central nervous system did so. Again, while only 3 per cent. of "normal" strains produced lesions in the brain, 25 per cent. of strains isolated from the central nervous system did so. Strains isolated from gastric and duodenal ulcers, from appendicitis, and from cholecystitis gave rise to lesions of the abdominal organs with far greater frequency than strains of other origin. The author, though acknowledging the fact of elective localization of streptococci, is careful to point out that it is merely one of degree.

152 Staphylococcal Toxin

P. NÉLIS, J. J. BOUCKAERT, and E. PICARD (*Ann. de l'Inst. Pasteur*, 1934, lii, 597) have been studying the preparation and properties of staphylococcal toxin. Of fifty strains studied, only two formed a really good toxin; both of these were of the *albus* variety. No relation was observed between the ability of a given strain to form toxin *in vitro* and the severity of the lesion from which it was isolated. Passage through laboratory animals did not appear to increase the toxicity of a strain. The most satisfactory medium for the production of toxin was that used by Ramon for obtaining diphtheria toxin. The addition of 0.1 per cent. glucose to this medium, which is made from pork and veal, proved advantageous. The best results were obtained by growing the organisms for about a week in a current of air containing 20 per cent. carbon dioxide. The haemolytic titre to rabbit red cells of toxin obtained under these conditions varied from about 1 in 100 to 1 in 1,000. Intravenous inoculation of 1 c.cm. of toxin into rabbits weighing two kilograms proved fatal. Rabbits dying rapidly, due apparently to a direct action of the toxin on the heart, showed nothing characteristic at necropsy. In rabbits, however, that survived for some hours, a serous pericarditis was observed, sometimes accompanied by a peritoneal exudate. Intravascular haemolysis was a constant finding. Microscopically, cellular necrosis was apparent in several organs. The protoplasm of the liver cells was often completely lysed, the nuclei remaining intact. The kidneys showed acute tubular nephritis. Comparative studies of the haemolytic and dermatotoxic titres led the authors to conclude that the effects on rabbit red cells and on the rabbit's skin were due to one and the same toxin. Absorption of the toxin with red cells, followed by centrifugation, deprived the supernatant fluid of both its haemolytic and its dermatotoxic power. The stromata of the red cells, however, on to which the toxin had been absorbed, were found, even after washing, to be both haemolytic and dermatotoxic. Staphylococcal anatoxin was found to combine with antitoxin.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

153 Glycerin Therapy in Renal and Ureteral Calculi

F. LICKINT (*Münch. med. Woch.*, June 1st, 1934, p. 821), who states that stones in the kidney and ureter are on the increase with each decade; enumerates some of the methods of conservative treatment: (1) masterly inactivity, with or without anti-spasmodics (undoubtedly quite a percentage of stones are passed spontaneously); (2) ureteral massage; (3) lavage of the ureters by large quantities of tea, coffee, and mineral waters; (4) stretching of the ureters with special instruments, or with two to three ureteral catheters; and (5) administration of pituitary extract, which increases ureteral peristalsis. He then describes treatment by glycerin as an important conservative measure. Large doses of this substance are excreted in large quantities in the urine. Its therapeutic value in the treatment of calculi of the urinary system is stated to be that: (1) it relieves spasm and lessens pain; (2) it increases ureteral peristalsis due to its dehydrating action. Lickint denies the diuretic action of glycerin, that it acts by increasing the viscosity of the urine, that it has any function as a bland fluid, and that it dissolves stones. It is useless given in small doses, and the author administers 50 grams of pure glycerin thrice daily for three days. He states that he has never observed bad effects from this treatment, and

do not occur. The treatment is the stone is too large to pass down the ureter, and in inflammatory conditions of the kidney. He has used glycerin in twenty cases of urinary calculi. In four cases he gave inadequate doses with resulting failure. In sixteen cases, with large doses of glycerin, he recorded one complete failure; one case passed one stone, but a second one failed to pass into the bladder; in the remaining twelve the stones were passed.

154 Symptomatology and Early Diagnosis of Cancer of the Colon

C. CRAFOORD (*Acta Chir. Scand.*, May 15th, 1934, p. 513) deploras the frequency with which cancer of the colon is overlooked until it is inoperable, and analyses the first symptoms of 160 patients treated in a Danish hospital in the period 1900-30. In as many as thirty of these cases the disease was too advanced to warrant a radical operation. In 101 cases there were vague and general abdominal symptoms which in eighty-three cases were the first to appear. The average interval between the first appearance of these general symptoms and treatment was seven months. In most cases the patients themselves were to blame for this delay, but in several instances they had been for some time under the care of general practitioners and even under observation in hospital without the cancer of the colon being recognized until it had reached an advanced stage. An apology for this state of affairs may be forthcoming in the not infrequent symptomless development of the disease whose first manifestation may be acute intestinal obstruction caused by an inoperable new growth. The author classifies in seven groups the manifestations which first indicated the existence of the disease: (1) general abdominal symptoms in eighty-three, (2) intermittent intestinal obstruction in twenty, (3) acute intestinal obstruction in sixteen, (4) emaciation and debility in thirteen, (5) blood and mucus in the motions in six, (6) constipation in sixteen, and (7) diarrhoea in six cases. It should be noted that these figures refer exclusively to the cases in which each sign or symptom was the earliest evidence of the disease. Much could be done to increase the proportion of operable cases if prompt attention were paid to the above signs and symptoms and the patient submitted to an x-ray examination, which, in the author's opinion, is the "sovereign means" for deciding for or against the diagnosis of cancer of the colon.

155 Ultra-violet Light as a Preventive of Tuberculosis

E. BRUNTHALER (*Deut. med. Woch.*, June 8th, 1934, p. 863) has treated with ultra-violet light in two periods children exposed to tuberculosis or already infected with it. In the first period, 1924-8, he treated in this manner 248 children (up to the age of 15) out of 426 who were exposed to infection. Among the 178 children who, not being given this prophylactic treatment, served as controls, there were as many as eighteen who developed active tuberculosis. Among the 248 given artificial-light baths there was only one child who developed active tuberculosis, which took the form of hilum tuberculosis and ran a mild course, being arrested in a couple of months. The second period, representing another five years, from 1929 onwards, concerns 492 tuberculous children and 313 who were in contact with active cases of pulmonary tuberculosis. Of these 313 contacts, 277 were given prophylactic light baths. At the end of 1933 only one of these children had developed tuberculosis, the disease involving the hilum and running a benign course. Hence the author's conclusion that artificial high-altitude sunlight is a potent preventive of tuberculosis in children exposed to it. He does not give details as to the number and duration of his light baths.

Surgery

156 Prognosis in Skull Fracture

O. SANDERS OLESON (*Ugeskrift for Læger*, May 17th, 1934, p. 528) has conducted follow-up investigations which show that the ultimate prognosis for fractures of the skull is often excellent. In the five-year period 1926-30 forty-nine cases of fracture of the skull were treated at his hospital. In twenty-five cases the diagnosis depended on the radiograph. In thirteen cases the fracture involved the base of the skull and was uncomplicated. There were twenty-one children to twenty-two men and six women. The cause of the fracture was a traffic accident in twenty-two cases, a fall from a height in nineteen, the kick of a horse in six, and other blows in two cases. All the eight deaths occurred within a few hours of the accident. The average stay in hospital of the forty-one survivors was sixteen days. Inquiries were answered by forty of the forty-one. Fourteen of the twenty surviving children were reported as perfectly well; three were still subject to slight headache, nervousness, and lassitude; two still suffered from severe headache, giddiness, and mental dullness; and only one had developed typical Jacksonian epilepsy. Of the twenty adults, ten reported as being quite symptom-free, five had still slight symptoms, and five serious symptoms, which did not, however, in any case entail complete incapacity for work.

157 Errors in Surgical Diagnosis

As the result of a study of the records of the first surgical division of the Roosevelt Hospital for three years, C. W. CUTLER, jun. (*Amer. Journ. Med. Sci.*, June, 1934, p. 810) found that the preoperative diagnosis was wrong in 110 out of 2,340 cases, a percentage of 4.6. Acute appendicitis headed the list with twenty-eight errors in 389 cases (7 per cent. of the whole). Five times acute salpingitis or salpingo-oophoritis was mistaken for this condition, while in five other cases infection of the appendix proved to be chronic and not acute. Three of these latter cases had obstruction, and the diagnostic significance of colicky pains is thus indicated. Four other cases proved to be enteritis, the rather early and significant onset of diarrhoea having been overlooked, sometimes in consequence of the administration of a laxative. Pneumonia was only once mistaken for appendicitis, error being obviated often by a preliminary radiography. In three cases pelvic disease was found. Chronic ap-

pendicitis was diagnosed 213 times, with five errors, three of these lying in the field of pelvic diagnosis. Attention is drawn to the use of lipiodol in pelvic examinations, and also the careful investigation of the biliary system in doubtful cases. In 292 hernia diagnoses there were five mistakes, errors of observation involving adenitis, varicocele, hydrocoele, and a psoas abscess being the worst. In nine operations for cholecystitis there was one mistake, a high acutely inflamed appendix closely simulating the clinical picture of a fulminating and possibly gangrenous cholecystitis. There were thirteen errors in 191 operations for chronic cholecystitis, and the importance of not relying on any single diagnostic method in these cases is urged. In eight out of sixty-four cases regarded as duodenal ulcer this condition was not found, the final diagnosis being chronic appendicitis in seven and neurasthenia in one. The author attributes the diminishing number of mistakes in this group to the more prevalent employment of medical treatment and to more careful radiography. The diagnosis of perforated duodenal ulcer was made nineteen times, falsely in six cases. Three of these proved to be acute cholecystitis with cholelithiasis, one a volvulus of the intestine with resulting gangrene, one a perforation of a carcinoma of the sigmoid, and one an angina or coronary occlusion.

158 Treatment of Suppurative Arthritis of the Knee

J. DE FOURMESTRAUX (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, June 2nd, 1934, p. 757) states that simple arthrotomy suffices when the effusion is confined to the anterior portion of the knee without deep fistulae or condyloid perforations. This should be followed by active (in preference to passive) mobilization of the joint according to Willems's method. The pain caused by these movements, and those consequently rendered possible, can be obviated by local anaesthesia of the knee. Active movements cause expression of the effusion, and act as an efficient means of drainage. The anaesthesia should be extensive so as to act on the terminal branches of the external and internal popliteal nerves and the sympathetic; cocaine injections (0.5 per cent. solution) should therefore be made into the external lateral ligament, with infiltration of the crural biceps and diffusion under the fascia lata, and into the internal lateral ligament with diffusion under the rectus, sartorius, and semitendinosus. Movements can be made many times daily; they usually again become painful after forty-eight hours, when the treatment is renewed till the joint is completely free of fluid and dry. Three cases are recorded to demonstrate the efficacy of this method. Despite Picot's war experience that amputation is necessary in cases of streptococcal infection of the knee, de Fourmestaux maintains that his treatment should be employed whatever might be the infecting micro-organism. The prognosis is much graver in arthritis diffused to the posterior of the knee, and especially in cases of suppurative osteo-arthritis.

Therapeutics

159

Hot and Cold Compresses

A. BRAUCHLE (*Med. Welt*, May 26th, 1934, p. 729) discusses the indications of application of hot fomentations and cold compresses. In those cases in which one is in doubt, a hot fomentation should first be applied, which can then be changed if necessary, and followed by a cold compress left on for one to two hours. Hot fomentations relieve pain and cramp, loosen sticky secretions, and soften the part. They are indicated in local rheumatic pain; in migraine, applied to the back of the neck or site of greatest pain; in catarrhal conditions of the teeth, tonsils, glands, and ears. They are helpful in catarrhal processes of the upper respiratory tract and bronchi, in asthma and emphysema; in pleurisy and pneumonia, to lessen pain and loosen secretions. In angina pectoris moderate pain is lessened by them, acute attacks may be accentuated by them. Pain and cramp are lessened

488 2

in all forms of spasm of unstriated muscle. Cold compresses are indicated in headaches of nervous origin; in haemorrhage into the brain; in toxic conditions of the thyroid; in cardiac arrhythmia; in haemorrhages into the lungs, stomach, or intestine. In the case of inflammation which is performing no useful function—for example, pericarditis—cold compresses are also of value. Conversely, when localized febrile reaction denotes an attempt on the part of Nature to cure the condition, hot fomentations are indicated, as they increase the circulation and remove the dead bacteria and metabolic waste products. Brauchle emphasizes the importance of relying on the subjective physical feelings of the patient, and of changing a hot fomentation for a cold compress if the patient does not feel better or even worse after it.

160

Gas Gangrene

G. E. KONJETZNY (*Klin. Woch.*, June 9th, 1934, p. 831), describing nine cases of gas gangrene under his care in the last four years, stresses the value of prophylactic treatment—namely, careful cleansing of all parts in serious accidents, with, when necessary, wide amputation of affected limbs. He denies that anti-gas-gangrene serum is valueless. The serum may not prevent the incidence of gas gangrene (it did not in four of his cases), but it lessens the fatality of the disease. There was only one death in his cases, none occurring in seven which followed street accidents. In five of the seven street accident cases amputation was avoided by the administration of anti-gas-gangrene serum, which was given in doses of 20 to 80 c.cm. subcutaneously or intravenously.

161

Bee Venom in Rheumatism

According to R. SCHWAB (*Münch. med. Woch.*, May 25th, 1934, p. 793) the efficacy of cutaneous injection of bee venom in rheumatic and neuralgic conditions has been widely recognized. He finds that inunction of an ointment containing the poison, together with salicylic acid to soften, and microscopic crystals finely to excoriate the skin, is equally effective and less painful than injection in acute and chronic articular rheumatism, muscular rheumatism, sciatica, and neuralgias. From the fact that remote was as successful as local inunction, it is concluded that the venom acts by immunizing at the same time against the apian and rheumatic poisons. Local reactions were earlier in non-rheumatic than rheumatic subjects.

Dermatology

162

Leather Dermatitis

H. BEERMAN (*Arch. Derm. and Syph.*, May, 1934, p. 671) records five cases of this rare condition, and comments on its complex aetiology. The specific factors in his cases were tanned leather (probably due to some synthetic tannin), and in one instance the vat dye. Beerman remarks that the literature on the subject contains examples of specific irritations resulting from almost every substance used in leather manufacture. Fungus infections, he thinks, probably predispose to this condition by extending the sensitivity of the body to other agents in addition to trichophyton, while injury to the skin caused by the mycotic inflammatory process facilitates the penetration by other irritating substances. On the other hand, an allergic dermatitis, such as that of leather, may predispose to, or reactivate, a fungus infection. In one of the author's cases dermatomycosis of the hands was followed by a hatband dermatitis. Three months later severe dermatitis occurred on the parts of the feet covered by the shoes, and there was an associated interdigital fungous maceration. During the foot trouble, however, there was no recrudescence of the forehead condition, although a later recurrence of the leather dermatitis of the feet was complicated by a return of the dermatomycosis in the locality. It appears that focal infection may bring out a local sensitivity, or may help to maintain

a leather dermatitis, but only temporary relief is secured by removal of the offending focus. Certain clinical peculiarities emerged in the course of observation of these cases. It was clear that persons varied in the intensity of their response to the same irritant, in the same concentration, and acting for the same length of time. Contrary to expectation it was found that all hat leather need not cause irritation in all sensitive persons, though in a very sensitive subject reactions of varying grades to all leathers might be anticipated. It was shown that the irritating substance was soluble in ether, was not present in all leathers, and was not absorbed through the intact skin, unless in sufficient concentration to excite a reaction in a very sensitive person. The author concludes that this lends support to the view that the various irritating substances do not act directly, but possibly excite the production in the skin of some common substance, which in its turn produces the dermatitis.

163 Haematoporphyrinuria and Impaired Liver

Function in Hydroa Vacciniforme

E. URBACH and J. BLÖCH (*Wien. klin. Woch.*, April 27th, 1934, p. 527) describe two cases in which hydroa vacciniforme was combined with porphyrinuria, porphyrinaemia, and impaired liver function. The first patient, a chronic alcoholic aged 50, had had syphilis eight years previously, and function tests pointed to chronic pancreatitis, hepatic cirrhosis, and latent diabetes. His skin was hypersensitive to sunlight, especially the rays of longer wavelength. He responded to, but could not tolerate, raw liver treatment, was not relieved by antidiabetic or insulin-dextrose therapy, but was improved in all respects by a course of neosalvarsan and bismuth. In the second patient (a woman aged 40) the hydroa of the exposed parts preceded by six months the porphyrinuria, and a latent hepatopathy was shown by function tests; improvement in the cutaneous and urinary morbid conditions, as well as in abdominal crises, which had been accompanied by increased porphyrinuria and indicanuria, followed prolonged rest and a diet rich in milk and carbohydrates. Urbach and Blösch believe that neither isolated tests with non-dissociated sun rays nor tests with artificial luminous sources suffice to determine the sensitizing rays: only from tests with coloured glass filters can protective ointments be chosen which will, temporarily at least, cure the eruption.

164 Sodium Thiosulphate Treatment of Dermatitis

Herpetiformis

In four cases E. STEINER (*Derm. Woch.*, June 2nd, 1934, p. 682) has had rapid and conspicuous success in treating dermatitis herpetiformis by ten intravenous injections (three each week) of 1 gram of sodium thiosulphate: at the same time 0.5 gram was given orally thrice daily (twice daily on the day of an injection). Externally, only a 1 per cent. menthol dusting powder was used. Sodium thiosulphate treatment of Duhring's disease was introduced by Wirz, who postulated a metabolic sulphur derangement. Steiner suggests, however, that the action of sodium thiosulphate is chemical, antagonizing tissue iodine. He points out that in dermatitis herpetiformis there is special sensitiveness to iodine, taken internally or applied externally: it gives an intense cutaneous reaction, and often leads to pyrexia and general prostration. Sodium thiosulphate reduces free iodine in solution.

165 Treatment of Scalp Ringworm with Thallium

Acetate

One hundred and thirty-one children aged from 2 to 10 were depilated with thallium acetate by LOUSTE and RABUT (*Bull. Soc. Franç. de Derm. et de Syph.*, March, 1934, p. 484), four of them being treated twice. The cases dealt with were microsporon ninety-two, trichophyton twenty-nine, and favus fourteen. The dose ranged from 7 to 5.5 mg. per kilogram of body weight, and was

given at a single draught. The time taken for depilation to begin was irregular, varying from four to fourteen days, the greatest number beginning on the eleventh day. In 5 per cent. of cases there was no depilation at all. Often the fall of hair was incomplete, bands being left in the frontal and occipital regions, and it was found that there was a tendency for the diseased hairs not to be loosened. Regrowth began in from eight to fifteen days, and was complete in from three to six weeks. Complications encountered were: rise of temperature on the first or second day (as high as 103° F. in one case); muscular pains in the lower limbs, varying from a feeling of heaviness to acute pain necessitating rest in bed; septic folliculitis of the scalp during the second month (20 per cent. of cases); transient albuminuria during the second week (10 per cent. of cases); and loss of appetite, jaundice, erythema of the face, dilatation of the pupils, and oedema of the eyelids. In the cases treated a second time after intervals of from four to seven months there were no complications of note. Louste and Rabut considered their results to be poor, as they had 53 per cent. failures.

Obstetrics and Gynaecology

166 Expression of Placenta: Modification of Crédé's Method

W. KARNICKI (*Gynéc. et Obstét.*, May, 1934, p. 437) points out that most of the historical methods aim at expressing an already detached placenta. If it lies in the vagina Crédé's method is effective; but for the cases in which there is no retroplacental haemorrhage, and therefore no detachment, after waiting for three hours the following manœuvres are suggested. First, the fundus is palpated to find the soft and prominent portion (usually one cornu, often the right) which denotes the site of the placenta. Secondly, the centre of this area is massaged between two fingers until contractions occur whereby detachment and retroplacental haemorrhage is initiated. Thirdly, massage is done radially outwards from this starting-point until the uterine outline has become symmetrical, which indicates complete detachment. Fourthly, pressure is applied with the right hand on the area thus softened in the direction of the genital canal until the placenta is expressed. As complete detachment has been previously secured, this pressure is exerted upon clot only, so that tearing of the membranes is avoided. Further, with the left palm placed above the symphysis, the thumb, and two first fingers make counterpressure on the fundus. This straightens the birth canal and also prevents inversion. The method fails with an actually adherent placenta.

167 Low Cervical Caesarean Section

W. J. STEVENS (*Canadian Med. Assoc. Journ.*, May, 1934, p. 498) argues that since the mortality rate in the intra-peritoneal retrovesical Caesarean section is so much lower than that in the classical method a more universal adoption of this procedure, with a curved transverse incision and a double flap closure would seem reasonable. After infected and prolonged labours this low section is particularly indicated, since the lower uterine segment resists infection better than the fundus. The danger of peritonitis is very much lessened, and any infection is restricted to the most dependent part of the abdomen, where it is well situated for localization and evacuation. There are fewer post-operative discomforts, and there is less tendency to adhesions, since the intestines and omentum are seldom seen or handled during the operation. More protection is afforded to sutures in the passive lower segment, and they are also subjected to less strain from muscular activity. This promotes the formation of a stronger scar, and a consequent lessened liability to uterine rupture in subsequent labours. Stevens points out that the adequately long transverse semilunar incision of 15 cm. or more is restricted to the thinner, avascular, lower uterine segment, where the muscles and blood

vessels run transversely. With reasonable care in delivering the head it is possible to reduce the otherwise unavoidable trauma, and much less haemorrhage is entailed than in the classical operation. He admits, however, that the low method is somewhat more complicated, and takes rather longer to perform. He adds that it is essential to remember that Caesarean section is still to be regarded as very hazardous, and not lightly to be undertaken. There is room for improvement in its technique, as well as in the critical assessment of favourable and unfavourable indications. For example, in urgent emergencies, such as accidental haemorrhage due to acute and complete placental separation, or in bad operative risks, a classical Caesarean section, with or without hysterectomy, is best.

168 X-Ray Diagnosis of Foetal Deformity

J. GRANZOW (*Zentralbl. f. Gynäk.*, June 9th, 1934, p. 1330) specifies the grounds on which diagnosis, before labour, of foetal deformity is desirable: dystocia, as in hydrocephalus, may be foreseen; considerations of foetal survival, as in anencephaly, may be eliminated from the principles of management; and premature induction may in some cases be justifiable. Clinical signs which should lead to suspicion of foetal deformity, and therefore to radiography, are hydramnios, accompanied by failing foetal pulse, and lively foetal movements. In doubtful cases a second picture taken after rupture of the membranes may be conclusive. Abnormalities of the skull are the most susceptible of x-ray detection, and here lateral photography is useful. Limb deformity, especially shortening, may be simulated by false projection, the limb and the film lying in non-parallel planes. A case is mentioned in which repeated films showed one arm only; no mention was made of this to the mother, and the infant proved to be quite normal. The shadow of one arm had been masked by the maternal spine. As a radiological sign of death of the foetus, overriding of the cranial vault bones—Spalding's or the tiled-roof sign—is reliable.

Pathology

169 Excitability of Human Plain Muscle in Disease

A. LÜWEN and H. J. LAUBER (*Bruns' Beitr. z. klin. Chir.*, May 19th, 1934, p. 447) find that the neuromuscular apparatus of excised strips of non-striped human muscle retains its excitability for twenty-four hours. Stomach muscle responds to adrenaline by elongation, the response being less in muscle from the ulcerated stomach than in that from the stomach associated with duodenal ulcer; this may be taken as evidence of sympatheticotonus in the ulcer stomach. The shortening in response to electric stimulation is less in muscle from a case of gastric ulcer than from one of gastric cancer. Electrical excitability of strips of gastric muscle is diminished by novocain, bile, trypsin, or bacterial toxins. Strips of gall-bladder muscle lengthen in response to adrenaline, and after electric stimulation quickly shorten at first, then slowly returning to normal. The electric response may be diminished in preparations from the morbid gall-bladder. The responses of the normal and pathological ureter are similar to those of the gall-bladder.

170 Urinary Excretion of Citric Acid

CLEMENT SCHUCK (*Journ. of Nutrition*, June 10th, 1934, p. 679) found that when 1,000 c.cm. of orange juice or grape juice were added to a basal diet there was an increased citric acid excretion in the urine. In subjects given orange juice the increase was slightly greater than in those who had received grape juice, but the ratio of the amount of citric acid excreted to the amount ingested was very much higher in the cases when grape juice was administered. With one patient the increase represented 20 per cent. more than the citric acid contained in the grape juice, indicating a metabolic source for the excreted

citric acid. There was a general increase in the organic acid excretion as a whole, but only 40 to 60 per cent. of the increase was derived from the citric acid in the orange juice, and of the 35 to 40 per cent. in the grape juice cases only a very small part could have come from the grapes, most of it having a metabolic origin. It is concluded that the organic acids representing products of metabolism may be the result of the alkalinizing effects of the fruit juices. The same author (*ibid.*, p. 691) tested the effects of the ingestion of citric acid, sodium citrate, and sodium bicarbonate. She found that citric acid excretion was not dependent on the ingestion of this acid, while the total organic acids and citric acid excreted as a result of the ingestion of sodium citrate amounted to two or three times the excretion on the basal diet. Sodium bicarbonate brought about an increase in the pH of the urine and a decrease in titratable acidity, accompanied by a small increase in total organic acids and a considerable increase in citric acid excretion. Further evidence is thus afforded for the view that citric acid plays a part in acid-base balance regulation.

171 Determination of Blood Cholesterol

J. KEMLET (*Journ. of Lab. and Clin. Med.*, May, 1934, p. 883) has devised a rapid method of determining cholesterol in whole blood, serum, or plasma. In this technique 0.2 c.cm. of blood (whole, plasma, or serum) is deposited and allowed to dry on an ashless 7 cm. filter paper; when dry the filter paper is extracted with 10 c.cm. of chloroform for two hours. This solution is compared colorimetrically with a standard cholesterol solution by the Liebermann-Burchard reaction. An accuracy of 9 mg. per 100 c.cm. is claimed. For routine laboratory methods this should prove invaluable, as it is simple and quick, and can easily be done in duplicate if greater than clinical accuracy is required.

172 Isolation of a Polysaccharide from *Br. abortus*

G. FAVILLI and G. BIANCALANI (*Lo Sperimentale*, June, 1934, p. 337, record the isolation of a polysaccharide substance from the bovine type of *Br. abortus*. Previous attempts, though successful with *Br. melitensis* and *Br. paramelitensis*, had failed with *Br. abortus*, practically the whole of the polysaccharide being lost during the process of purification. By modifying this process the authors have now succeeded in getting rid of the protein without losing the polysaccharide. Their method was briefly as follows. A typical smooth strain of *Br. abortus*, isolated from the stomach of a bovine foetus, was grown for three days on liver agar. The growth was washed off with saline, filtered through paper, centrifuged, and the bacterial deposit weighed. To every 10 grams of the deposit 100 c.cm. of saline were added. This suspension was placed in a boiling-water bath for four to five hours, centrifuged, and the deposit again taken up in saline and heated. The extraction with hot saline was repeated three times. The extracts were mixed, filtered through paper, reduced to a twentieth of their volume, and treated with five to six times their volume of absolute alcohol. This resulted in the formation of an abundant gelatinous whitish yellow precipitate giving both the carbohydrate and the protein reactions. After being reprecipitated twice with alcohol from an aqueous solution, it was dissolved in water and treated with an 0.6 per cent. aqueous solution of uranium acetate slightly acidified with acetic acid. The resulting precipitate was removed by filtration. The filtrate was treated with sodium phosphate to remove the uranium, and the phosphate was then precipitated as the ammonium-magnesium salt. The filtrate was treated with three to six volumes of absolute alcohol, and the resulting precipitate dissolved in water and reprecipitated two or three times with absolute alcohol. The final material obtained was a white powder, very soluble in water, failing to give any of the protein reactions, giving a strong Molisch reaction, containing 3 per cent. nitrogen, and being precipitated in high titre by sera prepared against *abortus*, *melitensis*, and *paramelitensis* strains.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

173 Radioscopic Examination of Recruits

S. P. BOTENGA (*Nederl. Tijdschr. v. Geneesk.*, June 2nd, 1934, p. 2463) states—that fluoroscopic examination of 1,101 recruits yielded the following results. In six cases where no physical signs were found in the lung radioscopic was the only means by which tuberculous lesions, both incipient and advanced, were detected. In nine cases the pulmonary changes were also obvious on percussion and auscultation. In forty-four cases the radioscopic picture gave a clearer view of doubtful findings, and in eight cases radioscopic alone showed the presence of tuberculous lesions both active and inactive in persons who had been declared unfit for other reasons. In twenty-nine cases the radioscopic picture indicated that the recruit should be kept under observation and be regarded as conditionally fit for service.

174 The Family History in Pulmonary Tuberculosis

K. SCHBERTH (*Wien. klin. Woch.*, May 25th, 1934, p. 643) asserts on an examination of 600 cases that a person exposed to tuberculosis usually becomes infected only if his family history is tainted with the disease. At a low estimate, 64 per cent. of patients with pulmonary tuberculosis have tuberculous relatives. The tuberculous taint may be transmitted by "conductors"—thus in a case of healthy persons begetting tuberculous children, the taint may have been conducted on the mother's side through a tuberculous grandmother. Schberth says, "An aunt who years ago had apical tuberculosis is more important in the pathogenesis of tuberculosis than a bed companion with active disease." He states that no tuberculous patients and no persons with a tuberculous family history should be allowed to beget children, and that if in such marriages women become pregnant, therapeutic abortion should be carried out. When both parents are tuberculous, most of the children will develop the disease, and there is no rule indicating which of them are likely to fall a prey to the disease. Adults with untainted family histories who are exposed to tubercle—for example, a healthy woman marrying a tuberculous man, doctors and nurses in sanatoria—rarely become infected, and if they do the infection is usually slight. The author advises that partners contemplating matrimony should make sure that the grandparents and their offspring on both sides are healthy. It is difficult to get facts further back than the third generation, and the chances of taint are remote. Every member of the two generations is of equal importance, for the taint is not necessarily transmitted directly, but may be transmitted, for example, via an uncle. In those cases of tuberculosis in which there is no family taint it may be assumed that the disease is due to a massive infection which has occurred in youth.

175 Duration of Immunity following Vaccination

W. P. DEARING and H. S. DAVIDSON (*Journ. Amer. Med. Assoc.*, June 16th, 1934, p. 1998) studied the duration of immunity to small-pox as indicated by the results of vaccination in 557 medical students who had previously been vaccinated and in nine who had never been vaccinated but who had had small-pox. Of 337 students vaccinated ten years or less after previous vaccination only one gave a primary take, fifteen (4.6 per cent.) accelerated takes, and 321 (95 per cent.) an immediate reaction. Of the 168 students vaccinated from ten to nineteen years previously only six (4 per cent.) gave primary takes, fifty (29 per cent.) accelerated takes, and 112 (67 per cent.) immediate reactions. After twenty years thirty-five of fifty-two reactions (67 per cent.) were immediate, thirteen (25 per cent.) were accelerated, and 8 per cent. gave primary takes. Thus immunity conferred

by a single vaccination usually lasts longer than six to ten years. Vaccination of the nine students with a history of small-pox gave four primary takes, four accelerated takes, and only one immediate reaction. Small-pox therefore does not protect so well against cow-pox as vaccination.

176

Goitre in Otago

F. FITCHETT, C. E. HERCUS, and F. G. BELL (*Aust. and New Zeal. Journ. Surg.*, April, 1934, p. 318) record a six-year study of thyroid disease in Dunedin Hospital, comprising 368 cases. Simple and toxic goitre occurred in approximately equal proportion, but many of the simple cases presented features of "borderline" toxicity. A high familial incidence was found. The authors condemn the arbitrary division of thyroid disease into primary and secondary, urging that the pathological changes which induce toxicity are the same whether they occur in a previously healthy or in an already diseased gland. They suggest four groups, namely: (1) simple goitre of the colloid or nodular type; (2) the thyrotoxic class, including primary and secondary Graves's disease; (3) hypothyroid states of myxoedema and cretinism; and (4) malignant thyroid diseases. The authors' investigations showed that the results of surgical treatment in toxic goitre were excellent, comparing favourably with those in other important disease groups, such as the biliary one. The operative mortality in these toxic cases was 3.7 per cent. An unduly high incidence of recurrent laryngeal nerve lesions came to light. The classical form of post-operative myxoedema was noted in three out of 319 operations in all classes, and tetany occurred in three cases in the same series. Biochemical findings indicated that the blood iodine content was higher in primary Graves's disease than in simple goitre, and that the iodine contents of blood, urine, faeces, and gland were all lower than normal in simple goitres. The authors conclude that the histological picture merely represents innumerable variations of one and the same pathological process of involution and hyperplasia, and that it is impossible to correlate this picture accurately with the clinical classification.

Surgery

177

Tonsillectomy

E. WIRTH (*Med. Klinik*, June 1st, 1934, p. 725) enumerates the indications of tonsillectomy as follows: (1) recurrent tonsillitis, (2) peritonsillar abscess, (3) chronic inflammation of the tonsils, (4) disease in other organs believed to be due to tonsillar infection, and (5) acute tonsillitis and peritonsillitis with complications. Tonsils with simple hypertrophy unrelated to chronic inflammation or mechanical disturbances of speech or respiration should be left alone. Acute tonsillitis is no longer a contraindication to tonsillectomy, but on the whole it is better to wait for eight to fourteen days after the acute inflammation has subsided. The same holds good for peritonsillar abscess, especially when simple incision fails to empty it fully. In patients with haemophilia, diabetes, tuberculosis, nephritis with high blood pressure, and in those with rigid blood vessel walls, tonsillectomy should not be advised. The operation should be performed under local anaesthesia, which is usually complete and lasts for twenty to thirty minutes. The anterior pillar of the fauces should be removed if there is difficulty in shelling out the capsule. Ambulant post-operative treatment is not recommended, and patients should be kept in hospital for five days and off work for a fortnight. Wirth advises tonsillectomy under local anaesthesia and luminal in children under 12 with few exceptions. Infants should get a general anaesthetic. Post-operative haemorrhage may occur with the most perfect technique, but was

serious in only 0.2 per cent. of cases. Pain usually lasts for two to four days after operation. Respiratory complications are uncommon and usually not serious. Exogenous infection of the wound is more to be feared than autogenous, and slight rise in temperature is common; but marked sepsis is rare. The author denies the allegation that tonsillectomized patients are more prone to infections of all sorts, especially those of the upper respiratory tract. Rarely, patients complain that they are more liable to catch cold, or that there is some disturbance in speaking or singing, but failures may usually be explained on the grounds that ineradicable changes have occurred in the nasopharyngeal cavity due to previous chronic disease.

178 Recurrence of Bladder Papilloma

H. LORGE (*Zeit. f. Urol.*, 1934, v. 310) quotes the report of Scheele from the combined literature that after removal of vesical papilloma through a cystotomy wound recurrence occurs in over 60 per cent. of cases. He concludes that there is evidence of special danger after this operation of occurrence of: (1) diffuse papillomatosis, with very numerous histologically benign growths appearing rapidly after a considerable period of freedom, (2) recurrences in the scar which show definite malignancy and often take the form of solid carcinoma, and (3) other carcinomatous recurrences. An analysis is given of forty-eight cases treated by Suter by electrocoagulation. There were sixteen cases of recurrence of the papilloma, but of these one-half at least were cured by repetition of the treatment, and only one was carcinomatous. Thirteen of the recurrences occurred less than three years after electrocoagulation treatment; as in the case of the primary papilloma preference was shown for the paratrigonal area. Lorge points out that although the vesical mucosa shows in many cases indubitable evidence of a "diathèse néoplastique," it is logical to assess the results of treatment according to the appearance of metastases and their response to treatment. No method of treatment excludes recurrence. Cystotomy is undesirable as favouring scar-implantation metastases. Snare operations are insufficiently radical and lead to truly local recurrence; after electrocoagulation recurrences, however, never affect the scar, and are relatively infrequent. Suter did cystotomy in six cases only, in which electrocoagulation was contradicted by haemorrhage preventing cystoscopic vision; recurrence occurred in five.

Therapeutics

179 Acetylcholine in Peripheral Vessel Occlusions

A. GOLDMAN and K. OSSERMAN (*Med. Record*, June 6th, 1934, p. 579) report three cases of peripheral vessel occlusions treated with acetylcholine. They quote the literature to the effect that the value of this drug lies in the absence of subjective discomforts and its relative safety in patients of any age, regardless of the general physical condition or associated debility. It is, however, not a dependable medication, its effect is transient, and it must be injected intramuscularly. In one of the authors' cases the patient had probably a partial occlusion of the bifurcation of the internal iliac artery; it seemed that the injection of acetylcholine dilated the terminal vessels, and so improved the circulation and relieved the upper congested part. Its effect on the pain was very definite. The second patient had previously had a leg amputated for arteriosclerotic gangrene; three years later paralysis of the other leg occurred, with subsequent ulcer formation. The pain was much reduced by acetylcholine injections, but amputation was later necessary. The third patient had arteriosclerosis of the glans and stocking type of both upper limbs, with hypertension, arteriosclerosis, aortic atheroma with cardiac decompensation, leg ulcer, and sternal calcifications. The employment of acetylcholine cleared up the arteriosclerosis, and the exhibition of digitalis removed the oedema of the legs and the sternal calcifications. The

authors add that the injection of this drug once a week, as usually recommended, is useless, the optimal dose being one ampoule twice a day. The drug's action and its excretion are rather rapid; it is considered worth trial in peripheral vascular disturbances, especially when these are complicated by debility.

180 Vaccination against Typhus

G. BLANC, M. NOURY, M. BALTAZARD, J. BRUNEAU, and J. BARNEQUOD (*Bull. de l'Acad. de Méd.*, May 1st, 1934, p. 582) reported last year a series of successful vaccinations of the human subject against typhus fever. Their vaccine was derived from maceration of the tunicae vaginales and spleen of guinea-pigs infected by murine typhus, and conferred immunity against Toulon and Casablanca strains as well as against the historic virus. These workers have now satisfied themselves that no increase of virulence is shown by the murine-Casablanca type (the source of the vaccine) after fourteen months' preservation and sixty successive passages through guinea-pigs. The serotol-splenic extract is active in dilutions of 1 in 1,000, so that vaccine material for 1,000 persons can be got from one guinea-pig; but paper filtration reduces considerably its potency. The vaccine is a living virus; it is without danger, but confers its immunity at the expense of an infection which is ultra-benign or imperceptible.

181 Pepsin Therapy in Gastro-duodenal Ulcers

In a previous report M. DEBRAY and A. ROY (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, June 11th, 1934, p. 816) showed the marked benefits resulting from pepsin therapy by intramuscular injections in gastro-duodenal ulcer, but that about 20 per cent. of the patients did not respond to this treatment. On the hypothesis that these failures were due to a sensibilization of the gastric mucosa to pepsin and that treatment should be applied more directly to this tissue, the authors have employed intramucous membrane injections in such cases. Owing to the inaccessibility of the gastric mucosa, these were made into the mucosa of the cheek. A solution of pepsin (0.05 gram per c.c.m.) was used, the first dose being 1 in 10 c.c.m., followed by doses of 2 in 10 and 3 in 10 c.c.m. A series of twelve injections monthly (three per week) were given; the frequency and dosage of subsequent series were governed by the digestive tolerance of the patients and the radiological results. The injections, which must be made deeply into the mucosa, cause the formation of a small bulla. Most patients tolerate these injections perfectly; in some, a slight pain at the injection site and swelling of the cheek occur which, however, disappear in one or two days. Brief notes of eight illustrative cases are given; seven of these were markedly improved or apparently cured; no radiological evidence of ulcer was obtained in the non-responsive case. Debray and Roy state that the pain and vomiting disappear in the same time as after intramuscular injections. They consider that, owing to the minute doses injected, the effects cannot be attributed to the medication, but that a veritable desensibilization of the gastric mucosa was produced; the local reactions, which lessened as treatment progressed, constitute an argument in favour of this theory.

182 Hepatic Extract in General Paralysis

F. JEDŁOWSKA (*Arch. di Patol. e Clin. Med.*, March, 1934, p. 560) records his observations on thirty-four cases of general paralysis, tabes, and dementia praecox which had undergone malaria therapy and were in consequence in a state of profound anaemia. He found that daily subcutaneous injection of small doses (2 c.c.m.) of liver extract for a period of ten days caused a rapid restoration of body weight and return to normal in the number of red cells and haemoglobin value. The return to normal conditions was much more rapid and obvious than that obtained by the usual methods, and was complete from ten to fifteen days after commencement of treatment, when controls were still in a state of profound anaemia.

Disease in Childhood

183 Vitamin C in the Nursling

P. ROHMER, N. BEZSSONOFF, and E. STOERR (*Bull. de l'Acad. de Méd.*, June 19th, 1934, p. 871) record attempts to determine the need of vitamin C in the dietary of infants. Their study is based on urinary tests, and definitely proves that the healthy normal nursling can, unlike the adult, synthesize vitamin C in considerable quantities. This function, particularly active during the first months of life, decreases towards the eleventh month, and is definitely lost after the first year. Synthesis of the vitamin is physiologically effected from a substance of unknown nature—"provitamin"—which occurs in raw human and boiled cows' milk in sufficient amounts to satisfy the infants' needs. Hence, orange or lemon juice is unnecessary during the first months, but nourishment containing the provitamin is important. The considerable quantity of the vitamin synthesized by the normal infant indicates its great need of this substance. All lowering of the synthetic function due to an infectious or other cause produces troubles, the cure of which lies in the supply, sometimes large, of vitamin C. After the sixth month the power of synthesis begins to decrease; therefore, from this period an addition, more and more indispensable as the end of the first year is approached, of this principle is indicated.

184 Congenital Athetosis

J. BEAUFAYS (*Zentralbl. f. Gynäk.*, June 2nd, 1934, p. 1279) describes a case in which a healthy mother, aged 21, gave birth to a slightly premature infant whose left arm was at once noticed to show little motility; next day athetosis was noted therein, with tonic flexion of the index and hyperextension of the other fingers, alternating with reversed respective positions. A diagnosis of haemorrhage in the corpus striatum was considered, but next day the condition was symmetrically bilateral; this, together with a tendency to opisthotonos, both of which persisted, established the existence of congenital athetosis. Athetosis is rarely noted at so early a stage, and is due to areas of degeneration scattered in the corpus striatum, the inhibitory action of which on the globus pallidus is diminished. Typical features of this case were: the premature birth (probably accelerated by forcible intra-uterine athetotic cramps); maternal perception of unusually active foetal movements; a protracted asphyxial tendency after birth, due to affection of the motor control of respiratory movements; and diminution of athetosis when the infant was laid on the belly.

185 Chloral Hydrate in Paediatrics

According to E. D. ANDERSON (*Minnesota Med.*, April, 1934, p. 184) chloral hydrate, in common with other drugs, is inadequately employed in the diseases of children. In the exhaustion following severe infantile colic, even though the cause is obscure, it can be given by mouth in 1-grain doses before each feeding, and will in most cases afford immediate relief, while bad sleeping habits can be checked by giving it per rectum at bedtime for two or three nights. In attacks of cyclical vomiting and in the vomiting due to acute upper respiratory infections, marked dehydration or acidosis may be arrested by the rectal administration of doses large enough to put the child to sleep, and these may be repeated if necessary at intervals of four to six hours so as to ensure sleep for eight to twelve hours. At the end of this time nausea and vomiting will often have been brought to an end. If in the course of an acute illness there is extreme restlessness due to toxæmia rather than to severe pain, such as in acute pneumonia, the introduction of chloral by the rectum will often have good results. It may also be used before the performance of certain diagnostic and therapeutic procedures, such as spinal punctures, blood transfusions,

and the injection of subcutaneous or intraperitoneal fluids. In a possible case of acute appendicitis the administration of an adequate amount of the drug by the rectum will induce muscular relaxation without affecting muscle spasm, and permit more careful examination. It may also be given after an operation when the child is beginning to recover from the anaesthetic; fear and physical discomfort will be removed by the induction of sleep, and on awakening finally there will be much less nausea and distress. This procedure is said to be particularly effective after tonsillectomy, and to promote convalescence markedly. Anderson has found it necessary to give larger doses than are usually recommended in the textbooks. To control convulsions or induce sleep, rectal doses of 5 grains are advised in infants under 6 months old, from 5 to 7½ grains in infants of 6 to 12 months, from 7½ to 10 grains in children aged between 1 and 2 years, and from 10 to 20 grains in older children. Even higher doses are required in some cases of convulsions.

186 Endocarditis in Still's Disease

L. SAIMOVICI (*Thèse de Paris*, 1934, No. 389), who records five illustrative cases in children aged from 3 to 12 years, one of which is original, states that endocarditis is a rare occurrence in Still's disease. It may assume the form of a malignant attack with a protracted course or a malignant attack of rapid course and streptococci in the blood. Saimovici's case was that of a boy, aged 7 years, who had been the subject of a febrile disease for four months. During the first three and a half months he had suffered from subacute rheumatism closely resembling Still's disease, and it was only in the last fortnight that he developed symptoms of a fatal infective syndrome consisting in anaemia, haemorrhages in the skin, and enlargement of the spleen indicating malignant endocarditis, the presence of which was confirmed by the necropsy.

Obstetrics and Gynaecology

187 Prophylactic Intervention in the Second Stage of Labour

J. R. GOODALL (*Surg., Gynecol. and Obstet.*, May, 1934, p. 882) argues that, with experienced hands and sound judgement, prophylactic intervention in the second stage of labour and suturing reduce the amount of damage to the abdominal wall, involve minimal trauma to the supports of the uterus and the bladder, ensure a completely repaired pelvic floor and the restoration to the normal of any previous obstetrical damage, and effect a very considerable reduction in the number of stillbirths. Such intervention, moreover, reduces fatigue and prevents exhaustion, while it relieves the patient and shortens labour. In the first stage of labour the approach of the uterine isthmuses to the pelvic wall renders the normal uterine supports excessively lax, especially the pubo-uterine and the sacro-uterine ligaments. When the cervix is fully dilated the uterine ends of these ligaments are stretched to five times their previous size, and consequently thinned as a whole. As the presenting part descends, the whole force of the contraction and retraction of the upper segment against the lower vagina and perineum is borne by the uterine attachments, and a tendency develops to tearing away from the cervix, causing small interstitial haemorrhages. The author describes his procedure to diminish the various risks. It includes manual acceleration of any incomplete rotation, drawing down of the head with forceps if necessary, incision of the perineum, and rapid removal of the placenta. A special plan of suturing repairs the damage and prevents subsequent prolapse. The method is painless in most cases, but three types of cases do not heal well—namely, those in which the head has been allowed to rest too long on the pelvic floor, severely toxic cases, and cases of prolonged dystocia which have become infected before

the completion of labour. When multiparae come for delivery with an obviously damaged vaginal floor and a marked degree of cystocele, the author incises the perineum as in his usual procedure, and extensive denudation and perineorrhaphy are performed. He claims also that his foetal mortality rate has been reduced by 75 per cent. The majority of stillborn children have died during the second stage of labour, owing to impeding of the circulation through the placenta, spasm of the tired uterus, and the growing frequency of the pains. Goodall believes that much of the foetal death rate attributed to forceps is really due to the delay in their application, and that such prophylaxis as he indicates will be effective in most cases.

188 Senile Involution of the Mammary Gland

R. GATTA (*Arch. Ital. di Chir.*, May, 1934, p. 529), as the result of the examination of the breasts of thirty-five women, all but nine of whom were over 40, comes to the following conclusions. In senile involution of the mammary gland there is a gradual disappearance of the fibillary connective tissue, which is replaced by adipose tissue. Definite limits cannot be assigned to this involution, which begins directly after the menopause, but sometimes does not become complete until extreme old age. During the involution, side by side with the regressive process, the parenchyma presents in every case proliferations which become particularly numerous after the menopause. The dilatations of the alveoli and lactiferous ducts which develop after the menopause are to be attributed to the direct activity of the epithelium and not to a sclerogenic action of the connective tissue. They must be distinguished from the cysts due to stasis, which are few in number and often absent, but become more numerous after the menopause. Eosinophil cells are found in the female breast after the menopause, being derived from the normal cells of the gland, of which they represent a final stage. The appearance presented by the breast during its involution partly resembles that of cystic fibrosis, but there are always differences in the intensity of the proliferative processes which allow the two conditions to be distinguished.

189 Manual Extraction of the Placenta

J. SEJRSLE (*Ugeskrift for Læger*, June 7th, 1934, p. 589) finds that among 21,568 confinements at his maternity hospital in Denmark there were seventy cases in which the placenta was extracted by the hand, thirty-six cases in which a retained cotyledon was thus removed, two cases in which the hand was introduced for the removal of membranes, and three cases in which intrauterine palpation was undertaken. Among this total of 111 cases there were nine deaths, but only three of them could be traced with any justification (and to a limited degree) to the introduction of the hand into the uterus. Complete retention of the chorion occurred in 106 cases, one of which terminated fatally from puerperal fever. Among the remaining 105 cases there were fifty presenting some complication or other, such as fever, but the average duration of the patients' stay in hospital was only between fifteen and sixteen days—a state of affairs suggesting that complete retention of the chorion has little influence on the puerperium. The author concludes that, though retention of the membranes may often give rise to fever for some days, such retention should not be taken too seriously, and should not as a rule be an indication for manual extraction. On the other hand, if there are doubts as to the retention of part of the placenta itself, or if there is haemorrhage, it is well to explore with the hand and, in the process of such exploration, to remove any membranes which may be retained. The retention of a placental polypus is such a serious complication that, when in doubt, it is better to palpate the cavity of the uterus and, too often than not often enough. Turning to the literature, the author finds that manual extraction of the placenta has been undertaken in from 0.3 to 1.27 per cent of all confinements. The latter figure is from a hospital in which 111 cases of this nature were made since

1928. It is apparently not only the growing frequency of abortions in Russia which is responsible for this high ratio, but also the greater enterprise shown in the conduct of confinements.

Pathology.

190 Biological Properties of Ultra-short Waves

G. IZAR and P. MORETTI (*Klin. Woch.*, May 26th, 1934, p. 771) summarize as follows their findings, published in Italian journals, concerning short (highest frequency) waves of 1 to 50 metres, and believe that their action is due to electrical rather than thermal effects. Radiation of the animal kidney with waves of 8 metres diminished the blood urea without increasing that of the urine. Human blood sugar content is unaffected by radiation of the upper abdomen, but as a rule the erythrocyte content is temporarily diminished, the leucocyte count temporarily increased. Certain bacteria are killed by 4 or 8 metre waves, and unaffected by longer ones. Human agglutinins may lose their activity, but complement in animal serum is, in general, not destroyed, after application of the shortest waves. The writers now report that 4 to 15 metre waves increase definitely the catalytic activity of colloidal copper with respect to hydrogen peroxide.

191 Ascorbic Acid in the Chick Embryo

E. MARTINI and A. CONSIGNORE (*Biochim. e Terap. Speriment.*, May, 1934, p. 169) point out that vitamin C is found in practically all animal tissues, though in very varying amounts in different organs. In the guinea-pig the amount appears to depend strictly on the diet, while in animals such as the rat and the hen ascorbic acid can be demonstrated in the tissues even after long periods of vitamin C deficient diet. In order to find out whether these animals are liable to synthesize ascorbic acid, the authors carried out an experiment on developing chick embryos. The technique used to demonstrate the presence of this substance was one worked out by themselves, and depended on the reducing action of a weakly acid solution of ascorbic acid on methylene-blue under the influence of strong illumination. Eggs of white Leghorn hens were incubated at 38° to 39° C., and were examined at suitable intervals, the embryos being dissected out and ground up with sand in trichloroacetic acid. The extract, after treatment with an alkaline solution, was then tested by the methylene-blue technique. During the first three days of incubation no ascorbic acid could be demonstrated, but on the fourth day traces were found, and the amount continued to increase till the twelfth day, when 0.17 mg. was found per gram of embryo. During the next few days the amount decreased, and then became stabilized from the fifteenth day onwards at about 0.09 mg. per gram of embryo. The ascorbic acid was found only in the embryo itself. Glutathione, on the other hand, which was estimated by the iodine technique, was found distributed through both the embryonic and non-embryonic parts of the egg. The authors assume that the methylene-blue-reducing substance found in the extracts was ascorbic acid, and suggest that this substance must be synthesized in the developing chick embryo.

192 Natural Immunity in Syphilis

W. SIDOROWICZ (*Thèse de Paris*, 1934, No. 386) records ten cases in persons aged from 22 to 30 who, in spite of numerous exposures to virulent syphilitic infection, did not contract the disease. The occurrence of such cases raises the possibility of the existence of immunity to syphilis. There is, however, no experimental evidence in confirmation of this hypothesis. The suggestion that these refractory cases were due to the presence of hereditary syphilis was negatived by the fact that the individuals in question did not present any dystrophies or stigmata of that disease, and repeated serological tests were invariably negative.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

193

Occult Cardiac Insufficiency

In the first number of the *Revista Argentina de Cardiol.* (March-April, 1934, p. 11) F. COSSIO and L. BERCONSKY demonstrate the frequent existence of cardiac inadequacy in cases where its more manifest signs are non-existent. They noted that the absence of dyspnoea (both "effort" and paroxysmal), of physical and intellectual fatigue, of diminution of the differential tension and gallop rhythm, functional, mitral, or tricuspid inadequacy, venous hypertension, congestion of the lung bases, "cardiac liver," oedema of dependent parts, and exudation into serous cavities is held by clinical teachers to be sufficient evidence of perfect heart-muscle competence. Analysing twenty-seven cases of varied cardiopathy which were free from these manifestations, the writers found that in 80 per cent. the work of the cardiac pump, and thus its output, was diminished. All were examined under the strictest basal conditions while at rest in bed. Pulse and respiratory rates, arterial tension, venous pressure, circulatory speed, vital capacity, difference between the oxygen content of arterial and venous blood, respiratory and circulatory "minute volumes," systolic volume, lactic acid percentage in venous blood, and dimensions and electrocardiographic condition of the heart were all taken. They explain the absence of dyspnoea as due to an increased concentration of oxyhaemoglobin and an increased supply of O_2 in the capillary network, both counterbalancing the diminution of blood supplied to the tissues. Visceral congestion is absent owing to the lessening of blood stasis following upon a slight diminution of the cardiac output. In all patients with structural alterations in the cardiovascular system—even though there may be entire absence of dyspnoea or visceral congestion—an increase of the contraction rate when engaged on a definite effort, a reduction of the differential pressure, and positive cardiac enlargement should point to the probable existence of a diminution of the output of the organ. If to these be added increased rapidity of the blood stream and increased differential ratio between the venous and arterial oxygen with reduced vital capacity, one may be convinced that the power of the heart as a pump has deteriorated. To obviate the conversion of occult to apparent cardiac incompetence, digitalis is essential.

194 X-Ray Diagnosis of Pulmonary Tuberculosis

B. KATTENTIDT (*Münch. med. Woch.*, June 15th, 1934, p. 912) much prefers the x rays to auscultation and percussion in the diagnosis of pulmonary tuberculosis, and he analyses his experience with the routine x-ray examinations (screening) of 30,000 students in Munich since 1929. In support of his dictum that "percussion and auscultation are almost a complete failure, even in open active tuberculosis," he notes that among 10,000 students submitted to auscultation only two were thus found to be suffering from open tuberculosis. On the other hand, in another group of 10,000 students thirty-five were found on screening to be suffering from open tuberculosis. In a group of 1,526 persons sixty-nine were found on auscultation to be suspects; but screening showed thirty-five of these sixty-nine to be perfectly normal, and as for the remaining thirty-four, the scarring of their lungs was comparatively slight. Yet in the same group screening revealed five open and three active but closed cases of tuberculosis, and as many as 193 cases of pulmonary disease about which nothing had been heard on auscultation. Even the most extensive tuberculosis may be compatible with a capacity for great physical exertion, and there may be no symptoms such as cough to betray it. About three-quarters of all the cases of ignored pulmonary tuberculosis are not to be detected by auscultation, and can be discovered only by the x rays. In Munich the average interval between the development of the first focus

of disease and its diagnosis is three years. The author insists that when the community is educated to the point at which routine screening of the lungs is systematically repeated on everyone, the diagnosis of infectious active pulmonary tuberculosis will have been hastened by years. At the present time in Munich one case of open active tuberculosis is to be found to every 200 persons between the ages of 18 and 25. In every fifty such persons there is one with extensive tuberculous scarring, in every fifteen there is one with slight scarring in need of watching, and in every five there is one with negligible tuberculous scars. The author insists on the great skill and experience required in the correct interpretation of what is seen on screening.

195 Mode of Infection in Weil's Disease

P. H. VON THIEL (*Nederl. Tijdschr. v. Geneesk.*, July 7th, 1934, p. 3115) states that, though there is general agreement that *L. icterohaemorrhagiae* invades the human organism by the skin, especially when it is damaged, as well as by the mucous membrane of the digestive tract, it has not hitherto been known by which route infection occurs most often and most readily. The author accordingly carried out experiments with rats and guinea-pigs, which proved that, although infection by the mouth is possible, several millions of spirochaetes could be swallowed by these animals without their contracting the disease. Infection was found to be conveyed much more readily by the nasal route and also by the conjunctival mucous membrane. In all probability, therefore, water inhaled by the nose is much more dangerous for swimmers than swallowed water.

196

Dangers of Bronchography

Although bronchography is valuable in the diagnosis of certain conditions, especially bronchiectasis and bronchial stenosis, F. LICKINT and HIPPE (*Med. Klinik*, July 13th, 1934, p. 937) state it is only indicated in exceptional cases when all other diagnostic methods have failed. Bronchography is contraindicated in diseases of the heart and blood vessels, in acute inflammations of the upper respiratory tract, in hyperthyroidism, and in patients who are nervous or have an idiosyncrasy to iodine. The authors quote several cases in which the iodine acted as a plug in parts of the lower respiratory tract, causing death. They state that the instillation of iodine in tuberculous patients is fraught with danger, as it may activate latent disease. After bronchography most of the iodine is coughed up, but minute quantities may remain for several months, producing untoward results—granulations in the lungs, iodism, and sharp rise in temperature. The most common danger of bronchography is infection of the respiratory tract, and the authors describe a case of bronchopneumonia which occurred after the procedure. That it did not terminate fatally they regard as unusual. Bronchography should not be undertaken in nervous patients, as in them it has been known to produce grave shock, collapse, and epileptiform fits.

197

Atypical Forms of Serum Disease

N. SCHLISSER (*Thèse de Paris*, 1934, No. 408), who reports ten illustrative cases in patients aged from 6 to 22 years, states that the complications of serum treatment are very frequent, but are usually mild in character. There are, however, certain rare atypical forms, the prognosis of which may be very grave. These include orchitis and orchio-epididymitis, generalized adenopathy, gastro-intestinal symptoms, paralysis and amyotrophy, acute suprarenal insufficiency and sudden death, and acute articular rheumatism and cardiac complications. Prophylaxis consists in only using the intravenous and intrathecal routes in cases of absolute necessity, employment of refined serum, and the use of the ordinary methods of desensitization. As regards treatment, the best results are secured by adrenaline, ephedrine, pancreatic extract, and magnesium hyposulphite.

Surgery

193

Urethrography in Nurslings

According to I. MIHALOVICI (*Journ. d'Urol.*, June, 1934, p. 516) radiography of the male urethra and its adnixa is as practicable in the nursing as in the adult. For the contrast substance he employs a 50 per cent. solution of thorotrast, and injects 7 to 8 c.cm. under gentle pressure, the infant being placed in a slight right lateral position with the left leg flexed on the flexed, abducted thigh, and the right leg extended. The plate is taken at the time of the injection, not, as in adults, at the moment of micturition. A radiograph is presented which shows a congenital stricture in an infant 2 months old, and one of a normal child, aged 3 weeks. The latter demonstrates that in the newborn the urethral bulb is formed, and that during average filling of the bladder the lower vesical wall is almost in a straight line.

199 Biliary Fistula following Gastrectomy

O. FRANCKE and N. FALCOIANI (*Bull. et Mém. Soc. Nat. de Chir.*, June 30th, 1934, p. 893) point out the post-operative complications which may follow a gastrectomy, and consider that injury to the bile duct is one of the most serious. Attention is drawn to the advisability of making a careful examination before mobilizing the duodenum, as if the bile duct is not involved in the ulcer a gastro-duodenal resection can be undertaken without great risk. But in certain cases, when the bile duct has been partially eroded by the ulcer and a spontaneous chole-docho-duodenostomy has been formed, it is better to let the condition persist. It has been found that the biliary fistula is not always discovered at the time of operation, and the bile does not begin to flow until some days after. A case is reported in which it was found at operation that a duodenal ulcer was adherent to the pancreas, gall-bladder, and bile duct, and the freeing of the parts and subsequent anastomosis was carried out with some difficulty. Post-operative conditions were normal for two days, but on the third day there was an abundant flow of bile from the wound where the drain had been. The patient's general condition was deteriorating, and twenty-eight days after the first operation a further laparotomy disclosed a mass of adhesions which fixed the liver and the transverse colon to the anterior abdominal wall. There was also a band of adhesions round the gastro-jejunal anastomosis, in which was seen an opening as big as a 50-centime piece, from which a large quantity of bile was flowing. As it was impossible to make an anastomosis between the fistula and the intestine, it was considered advisable to make one between the gall-bladder and the jejunum. The opening of the fistula could not be closed owing to the friability of the tissues, and it was plugged with compresses. After a stormy convalescence and the appearance for a few days of a smaller fistula the patient made a good recovery. It is suggested that the fistula was produced by necrosis of the wall of the bile duct.

200 Osteomyelitis of the Scapula

G. BRANCATI (*Arch. Ital. di Chir.*, May, 1934, p. 575), who records two illustrative cases in a boy and a girl each aged 9 years, states that osteomyelitis of the scapula is not an extremely rare condition, and should be considered in every case of violent inflammatory processes of the shoulder and back. Its rational treatment requires operation in two stages. The first consists in incision of the soft parts containing pus as early as possible, while the second stage consists in resection of the necrosed part of bone or sequestrectomy. The interval between the incision of the soft parts and the resection must be determined by the local and general conditions in each case, but must not be too long, so as not to delay the time needed for healing of the wound. Functional capacity may be restored even after extensive operations in cases in which care has been taken to preserve the periosteal sheath.

Therapeutics

201 Malaria Therapy in Dementia Paralytica

F. L. H. MACDOWELL (*Journ. Royal Navy Med. Service*, July, 1934, p. 222) cites statistical evidence in favour of his commendation of malaria therapy in dementia paralytica. In fifty cases of this disease dealt with at the Royal Naval Hospital, Great Yarmouth, before this treatment was employed 30 per cent. of the patients died within a year of admission, 46 per cent. within two years, 10 per cent. within three years, 8 per cent. within four years, 4 per cent. within five years, and 2 per cent. within six. None showed any stage of remission, and all became bed-ridden and died miserably. Of twenty-four cases subjected to malaria therapy the disease was well advanced in twenty. There were only seven deaths in the series; four of these patients showed no improvement and died within six months after the termination of the treatment, while three had good remissions lasting six, five and a half, and two years respectively. Two of these patients were capable of useful employment until a short time before death. Twelve cases showed good mental and physical improvement (50 per cent.); six had a marked degree of physical amelioration without mental change; one patient improved mentally without corresponding physical advance as regards the ataxic symptoms. The change for the better became apparent usually within a few weeks after the cessation of the pyrexia, while in some instances an amelioration of the mental symptoms was obvious during the fever. Increase in weight was immediate, and an important index as regards prognosis. The author believes that the more gradual the gain in weight the more favourable will be the result; rapid gain in weight goes with less permanent improvement. No marked serological changes were recorded.

202 Vaccine Treatment of Abdominal Actinomycosis

In treatment of actinomycosis, which in his district is usually met with as an abdominal and chiefly ileo-caecal affection, E. NEUBER (*Wien. klin. Woch.*, June 8th, 1934, p. 708) has had good results from vaccinotherapy. He finds that in the wasted patients allergic reactivity is in abeyance, so that a preliminary stimulant treatment is required. In this, injection of gold salts (solganal) is found particularly effective. In some cases malariotherapy, followed by stimulant and dietetic treatment, is a useful preliminary. The vaccine is preferably autogenous and freshly prepared; it is given intracutaneously in increasing doses, in the greatest dilution which will produce reaction in those suffering from actinomycosis but not in healthy subjects. A case is illustrated of lasting cure, with 9 kilograms increase in weight, after seven weeks' treatment by injections at four or five days' intervals.

203 Calcium Ortho-Iodoxybenzoate in Arthritis

T. WHEELDON (*Ann. Int. Med.*, June, 1934, p. 1510) has treated 282 cases of arthritis in the last two years with calcium ortho-iodoxybenzoate; the therapeutic results were most satisfactory, and there were hardly any unpleasant effects. Four tablets, each of half a grain, were administered daily by the mouth. The author gives the warning that no real improvement is manifest in less than a month. The clinical improvement is described as having been excellent in 50 per cent., fair to good in 36 per cent., and slight or none in 14 per cent. The average age of the patients was 53. A remarkable feature was the improvement noted in hypertensive and heart conditions; this is attributed to the amelioration of the general condition, but is said to be utilisable as a criterion of the effect of the drug. Joint swellings were reduced and the range of motion was increased, but the relief of pain was less evident. It is pointed out that salicylates or other analgesic drugs can be exhibited concurrently without fear of incompatibility. Laboratory investigations indicated an increase in the indican output and a lowering

of the sedimentation rate. The author is inclined to doubt whether the benefit obtained is due to any bactericidal effect or improvement of the permeability of membranes. He thinks the important factor is the drug's stimulating action on the peripheral circulation, especially in the affected joints. Patients who had been chronic invalids were restored in some cases to wage-earning employment or the resumption of household duties. The patients were also treated by the removal of foci of infection, exercises and apparatus to improve the muscular movements, dieting, measures against constipation, and the local treatment of affected joints. The average length of treatment was sixteen months.

Ophthalmology

204 Carotid Sympathectomy in Ocular Degenerations

A. MAGITOT (*Bull. de l'Acad. de Méd.*, June 12th, 1934, p. 816) points out that carotid sympathectomy, which differs from resection of the cervical sympathetic cord or of the superior cervical ganglion, consists of decortication, anterior and posterior, of some 2 cm. of the sheath of the common carotid artery. The carotid ganglion is of necessity excised. Together with Desvignes, Magitot has traced the effect of unilateral and bilateral carotid sympathectomy on the general blood pressure and that of the central retinal artery, as shown by ocular sphygmography, in which pulsation of the retinal arteries is provoked by graduated pressure on the globe. Unilateral sympathectomy is followed by slow oscillations, lasting some days, of the retinal arterial pressure; bilateral sympathectomy (one side being tackled ten to twenty-five days after the other) after an oscillatory phase by a bilateral and long-lasting increase of that pressure, somewhat more marked on the side of the first intervention. The effects on pressure in the retinal arteries are not concomitant with those on humeral blood pressure. Magitot describes six cases in which bilateral carotid sympathectomy was done as treatment for insular softening of the retina or optic neuritis of non-central origin. Temporary improvement occurred in a man, aged 38, with familial optic atrophy. Notable and apparently lasting benefit followed in two cases of optic atrophy in subjects who had suffered from syphilis and malaria. In a man, aged 56, with insular retinal degenerations, vision improved from 1/25 to 4/10. In a female, aged 54, with old-standing chorio-retinitis due to congenital syphilis and recent optic atrophy, the acuity altered from 1/50 to 2/10 and from 0 to 1/20 on the respective sides. Complete restoration of vision was obtained in a case of toxic retrobulbar neuritis, probably due to carbon bisulphide poisoning. Magitot notes, as the chief encouraging sign, that a rise in the retinal arterial pressure is accompanied by improved visual function: in the weeks following operation the two vary *pari passu*, but later oscillation and even diminution of retinal arterial pressure may occur without regression of the gain in sight.

205 Intracapsular and Extracapsular Operation for Senile Cataract Compared

D. K. PISCHEL (*Amer. Journ. Ophthalmol.*, April, 1931, p. 326) cites many conflicting reports on the comparative excellence of the two operations. Such reports deal only with immediate effects, and contain amazingly wide interpretations of a good operative result. Thus some consider 24 per cent. of vitreous loss normal, and others 6/36, or even less, a good visual outcome. A useful conclusion was drawn by one writer, who obtained the same immediate visual result with the combined, the simple, and the intracapsular operations. The last were, however, all selected cases, while the combined was used for all poor risks. The present writer examined a series of cases which had been operated on in Meller's clinic at least two years previously. Forty-five "perfect" intracapsular operations, performed on an average two years and six months before examination, were compared with fifty extracapsular

operations, of an average history of three years and seven months, which included all cases except those started as an intracapsular. Results showed 6/8 or better vision in 91 per cent. of the former group and in 94 per cent. of the latter. In five of the former vision was permanently lost, while in the latter in no case was useful vision or the prospect thereof lost. Thus there were more bad results in a selected series of intracapsular than in an unselected series of extracapsular operations.

206

Apparent Optic Atrophy

F. H. ALDER (*Arch. of Ophthalmol.*, June, 1934, p. 942) states that it is well known that the vision may remain normal for several months (in one case seven years) after the appearance of "optic atrophy." The loss of vision is thus not proportionate to the degree of pallor seen, though in most cases the vision is soon lost when the disk is dead white, and once lost is never regained. In certain toxic atrophies (methyl alcohol and some arsenicals) retention or recovery after total blindness of central vision is not uncommon. Further, the maintenance of the pupillary reactions and marked contraction of the nasal fields are characteristic of these toxic cases. These points are of importance in differentiating the atrophy of tabes from that of anti-syphilitic remedies. The explanation of the preservation of central vision with apparently complete atrophy in tabes may be that the condition is analogous to peripheral interstitial neuritis. The nearer the lesion is to the globe the sooner is central vision lost. A case of delayed loss of vision was found to have a chiasmal lesion at post-mortem. One must not be dogmatic about the state of the nerve fibres from the colour of the disk, which may be rendered pale by anaemia, diminution in the number of capillaries on the disk, overgrowth of glia, and, finally, actual loss of nerve fibres. Where the vision is temporarily lost in a pale disk the condition may be one of Cushing's "physiological block," which later becomes relieved, those fibres which have survived taking up their function again.

Obstetrics and Gynaecology

207

Paralysis in Eclampsia

H. SCHWANEN (*Zentralbl. f. Gynäk.*, June 16th, 1934, p. 1394) contrasts the frequency of an intracranial focus of bleeding or softening as a post-mortem finding in eclampsia with the rareness of paralysis as a clinical symptom. In explanation he finds that paralysis occurs mostly in very severe cases, in which coma leads quickly to death, so that the palsy may be overlooked; that neurological examinations are apt to be incomplete, attention being concentrated on management of the labour and circulation; and that confusion may occur with cerebral embolus. In thirty-four cases from the literature and three personal cases of eclamptic paralysis the mortality was about 50 per cent.: the palsy usually took the form of hemiplegia or monoplegia, but in one of Schwanen's cases there was evidence of meningeal haemorrhage and paralysis of the abductors. In over one-half of the cases the eclampsia was unaccompanied by convulsions. It may, he states, be concluded that the intracranial bleeding had interrupted the motor tracts—a view confirmed by certain cases in which the convulsions as they occurred affected the non-paralysed side only.

208 Determination of Foetal Size in Utero by X Rays

S. CLIFFORD (*Surg., Gynecol. and Obstet.*, June, 1934, p. 959) measures the occipito-frontal diameter of the foetal head *in utero* by stereographic radiograms. Applying "the law of uniform foetal growth ratios," as worked out by Scammon and Calkins, whereby they deduce the age in lunar months, he has constructed a graph which shows the average body weight in the last four months *in utero*, corresponding to an estimated occipito-frontal diameter. The calculations are based on measurements of 479 new-

born infants. The information is of service in deciding the date at which the infant is viable in cases where induction is called for because of maternal conditions. Interesting figures emerge. During lunar months seven and eight the foetus increases by five or six ounces per week—that is, from one to four pounds; but during lunar months nine and ten the increase is eight to twelve ounces per week, so that even a week's delay into the ninth month is of great value. The mortality of infants of five to six pounds was less than 3 per cent.; in weights lower than five pounds it was between 28 and 29 per cent. In the last two months assurance could be given of minimum weight only. While below four pounds, corresponding with 10 cm. occipito-frontal measurement, the actual weight can be forecast.

209

Pregnancy after Paralysis

H. H. WARE (*Journ. Amer. Med. Assoc.*, June 2nd, 1934, p. 1833) reports three cases of the occurrence of pregnancy in women suffering from paraplegia. In the first case complete motor and sensory paralysis below the second dorsal segment of the cord had followed a febrile attack three years previously. There was incontinence of urine and faeces. Pregnancy gave rise to no discomfort, but, owing to the abdominal muscles being flabby and the foetal breech presenting, Caesarean section was performed without anaesthesia, a healthy child being born. Apart from a few days of pyrexia, recovery was normal. The second patient had sustained a fracture-dislocation of the first lumbar vertebra, and laminectomy did not relieve the ensuing paralysis. Pregnancy followed about three years later, being uneventful except for slight nausea and vomiting during the first three months. The membranes ruptured spontaneously at term, and after considerable delay delivery was completed with forceps painlessly. In the third case the paralysis had been due to a fall which caused a compressed fracture of the first lumbar vertebra and of the transverse process, with almost complete severing of the cord. Four years later the patient became pregnant. Under procaine anaesthesia, later reinforced by nitrous oxide and oxygen, low Caesarean section was performed without complications of any magnitude. Ware concludes, therefore, that labour can occur in paralytic women, and that labour is painless. No instinctive use is made of the accessory muscles, and uterine contractions were shown to be weak in the one patient delivered from below. He believes that Caesarean section and sterilization should be performed in these cases, sometimes without an anaesthetic. The uterine and abdominal incisions heal normally. The author's three patients were unable to nurse their children.

Pathology

210 Effect of Testicular Extract on Tuberculous Infection

R. M. THOMAS and F. DURAN-REYNALS (*Proc. Soc. Exp. Biol. and Med.*, June, 1934, p. 1201) report some curious observations on the effect of testicular extract on the progress of tuberculous infection and reinfection in guinea-pigs. The increased permeability of the tissues caused by testicular extract is now well known, and it was to be expected that the incorporation of this substance with the inoculum would lead to a considerable increase in the size of the primary lesion. This in fact occurred. The testicular extract was prepared by mincing bull testicle in two volumes of saline, straining through cloth, and filtering through a Berkefeld V candle. One group of guinea-pigs was injected intradermally with a mixture of 1 c.c.m. of testicle extract and 10 c.c.m. of a suspension containing 0.1 mg. moist weight of human tubercle bacilli. Another group was injected with 0.1 mg. of bacilli suspended in 2 c.c.m. of saline. In the testicular group the resulting lesions measured 7 to 8 cm. long and 5 to 6 cm. broad, while in the control group small nodules formed, varying from 1.5 to 2 cm. in diameter. In a

second experiment the inoculations were made subcutaneously. The testicular group, when killed sixty to seventy days later, showed not only more extensive primary infection but a much greater amount of generalized tuberculosis than the control group. This was probably due to a greater spreading of the organisms in the primary lesions, and not to any systemic action of the testicular extract, since the injection of this extract alone into guinea-pigs that were already tuberculous did not appreciably affect the course of the disease. Rather different results, however, were obtained in reinfection experiments. Two groups, each containing eighteen tuberculous guinea-pigs, were reinjected four to six weeks after the primary infection, the reinfecting dose containing testicular extract in one group but not in the other. In the testicular group the local lesions following reinfection were four to five times as large as those in the controls, but when the animals were sacrificed four to six weeks after reinfection the lesions in the testicular group were found to be not nearly so advanced as those in the control reinjected or the control non-reinjected groups. The effect of testicular extract was apparently to favour primary and delay secondary infection.

211

Staphylotoxin and Staphylocoagulase

R. VANBREUSEGHEM (*C. R. Soc. de Biol.*, 1934, 116, N. 22, 650) assembles the evidence collected by different workers to show that while the various cytotoxic activities of the staphylococcus—that is to say, its effect on red blood cells, platelets, leucocytes, and tissue cells in general—are due to one and the same toxin, the coagulating effect of this organism on oxalated plasma is due to an entirely different substance. Staphylotoxin is destroyed in half an hour by exposure to a temperature of 58° C.; staphylocoagulase withstands heating to 100° C. Chamberland candles allow the toxin to pass through, while retaining the coagulase. The toxin is strongly adsorbed by red blood corpuscles; the coagulase is not. In Ramon's medium incubated in an atmosphere containing 20 per cent. CO₂, toxin is formed abundantly, while the coagulase is formed only if the culture is incubated under ordinary aerobic conditions. In Ramon's medium containing 0.1 per cent. glucose the yield of toxin is better than in the medium without glucose, but the yield of coagulase is negligible unless the reaction is kept constantly alkaline. Acid has a deleterious action on the coagulase, and leads to its partial destruction. Both by its properties and the conditions necessary for its formation the coagulase appears to be distinct from the toxin.

212 Differential Staining of Myelin in Macroscopic Sections

E. PONS TORTELLA (*Rev. Méd. de Barcelona*, June, 1934, p. 515) stresses the ease with which the grey nuclei may be effectively stained in many ways, whereas the staining of the white matter is difficult and the processes by which it is effected are few and lengthy. The technique required by the methods of Weigert and Spielmeier is long and not precise, though the results are often beautiful; hence the writer, inspired by the success obtained by Ortega, who stains myelin in histological sections with ammonio-silver carbonate, succeeded with the same salt in evolving a most effective and rapid process of staining it in macroscopic sections. His method is as follows. Take the thinnest possible sections of brain preserved in formalin. Wash well in running water. Place in water acidulated with sulphuric acid for half to one hour. Rinse rapidly in distilled water. Immerse in solution of ammonio-pyridine-silver carbonate until the myelin is thoroughly stained. Place in 4 to 5 per cent. formal for fifteen minutes. Reduce with 5 per cent. hyposulphite of soda and mount in gelatin. The entire process takes but two or three hours. The grey nuclei remain unaltered, while all myelin is deeply stained. If the acid bath be withheld, both grey and white matter are stained. The writer holds that the acid forms with the iron of the grey nuclei a sulphate which prevents the fixation of the silver carbonate.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

213 Diphtheritic Myocarditis

I. NATIN and C. DARIN (*La Semaine Médica*, June 14th, 1934, p. 1789) emphasize the value of electrocardiography in assessing the condition of the heart muscle during and after diphtheria, and hint at the impossibility of accurate prognosis when this is neglected. They attach great value to the syndrome described by Marfan as an indication of the presence of "malignant" diphtheritic toxæmia, but believe that with endocardiographic examination many of its elements may be forestalled. These are: persistent pallor, apathy and listlessness, paralysis of the soft palate, hypotension, and tachycardia, which are succeeded in order by increased liver dullness, increased cardiac dullness, weakening of the heart sounds about the eighth or tenth day, and, finally, vomiting, often accompanied by bradycardia. Early and massive doses of antitoxin afford the sole preventive treatment, with absolute rest for as long as the electrocardiogram indicates. To prevent heart-block, camphor and adrenaline intravenously is recommended, but if there is ventricular fibrillation, as evinced by multifocal extrasystoles, often in salvos, adrenaline must be omitted. Digitaline, if pushed, will cause auriculo-ventricular block. Ouabain (strophanthin) is preferable to digitaline when repeated electrocardiographic examination is impracticable. If there is heart-block, caffeine and adrenaline should be used, and if sudden death is feared, owing to the occurrence of ventricular fibrillation during complete auriculo-ventricular dissociation, intracardiac injection of adrenaline is advised.

214 Primary Rheumatic Carditis in Adults

Commenting on the rarity, nowadays, of meeting with attacks of acute rheumatism in the adult, either with or without arthritis, C. DIMITRACOFF (*Arch. des Mal. du Cœur*, June, 1934, p. 337) reports on two patients, aged 47 and 48, with rheumatic pericarditis, and one, aged 48, thought to have rheumatic carditis. In the first case there was a pericardial effusion of considerable size; this quickly subsided with rest and large doses of salicylate; an electrocardiogram was taken some months later, when the patient was well and at work, and the author interprets the rather low voltage waves in the curve as indicating myocarditis. In this patient there had been no previous manifestation of acute rheumatism. The second case was similar to the first, except that there was no x-ray evidence available of pericardial effusion; there was, however, intense pericardial friction. The electrocardiogram showed changes in the T-wave such as have been reported by others as occurring in pericardial effusion, but which are rarely seen in rheumatic carditis without effusion. The third, a man aged 48, complained of epigastric pain, which was accompanied by fever and soon followed by dyspnoea and gross heart failure. These symptoms, together with typical electrocardiographic changes, very strongly indicated a diagnosis of coronary occlusion, but the author's diagnosis of rheumatic carditis was based on the appearance of slight joint pains in the course of the illness, and on an improvement which followed administration of salicylates.

215 Epidemic Pneumonia

A. A. RASMUSSEN (*Ugeskrift for Læger*, June 28th, 1934, p. 691) gives an account of an epidemic of pneumonia in the Faroe Islands in the autumn of 1933. All the twenty-six cases (only two in males) occurred within twenty days, and the explosive character of the epidemic was suggestive of typhoid fever, but the Widal was negative in the four cases thus tested. The examination of the scanty sputum provided no clue, and the clinical picture was too well defined to warrant the diagnosis of influenza.

Besides, there were no colds or influenza-like illnesses observed during the epidemic. The disease began suddenly, with high fever, shivering, and severe headache. In some cases there was nausea, with vomiting and pain in the back. There was no cough or expectoration, no pain in the chest, no dyspnoea, and no cyanosis, and the pulse was not very rapid. During the first few days, up to a week, there would be no stethoscopic signs over the lungs. Then crepitation would be demonstrable over the base of one lung, whence it would extend to other parts, to the accompaniment of dullness and bronchial respiration. The other lung was not infrequently involved, the extension of the physical signs from one lung to another being marked by a rise of the temperature. There were no catarrhal symptoms referable to the upper respiratory passages, and no history of a cold such as often precedes croupous pneumonia. The temperature remained high for two to four weeks, showing small remissions and falling by lysis. In the neighbouring districts the epidemic claimed forty-two victims, and of the total of sixty-eight patients only seven were males. The remainder were almost exclusively adult women, middle-aged or elderly. Of the seven patients who died, three were pregnant women. The author does not identify this disease with croupous pneumonia, and the name he gives it is "primary epidemic alveolar pneumonia."

216 Chronic Nephritis without Hypertension

U. DE CASTRO (*Arch. di Patol. e Clin. Med.*, May, 1934, p. 644), who records an illustrative case, states that arterial hypertension is an almost constant symptom in chronic diffuse glomerulonephritis. Exceptions to the rule do, however, occur, and several cases have been reported, especially in recent years, of chronic nephritis with a normal blood pressure, which has lasted for a long period and continued up to death. In some instances the patient dies of uræmia with a normal blood pressure, or even hypotension, and without marked evidence of myocardial insufficiency. De Castro's patient was a woman aged 51, who had undergone subtotal removal of the uterus and adnexa at the age of 23. About a year before death she began to suffer from feverish attacks, pain in the spine and limbs, general weakness, anaemia, and vomiting. The blood pressure was never higher than 125 mm. Hg, and in the last stage the systolic pressure was 95 mm. and the diastolic 73 mm. Hg. The necropsy showed a remarkably smooth appearance of the surface of the kidneys in spite of their considerable reduction in size, predominance of some of the small renal arteries, and an absence of changes in the intima, a slight degree of generalized hypertrophy of the heart, and a normal condition of the suprarenals.

Surgery

217 Operative Treatment of Hallux Valgus

H. G. ULLMANN (*Deut. med. Woch.*, June 22nd, 1934, p. 932) deplors the profusion of different operations for hallux valgus, as it is apt to give the erroneous impression that not one is satisfactory. Since 1924 thirty-four patients, representing fifty-nine cases of hallux valgus, have been operated on at his hospital, the procedure being that recommended by Hueter in 1877 and modified by Mayo in 1908. After all the diseased skin over the affected joint has been excised, the head of the first metatarsal bone is resected, and the gap thus made is filled in by the flap of soft tissues cut so that its base is on the proximal side of the wound. The shortening entailed by the bony resection is essential to any successful operation for hallux valgus, as it helps to compensate for the shortening of certain muscles provoked by this condition. The fact that all the author's cases healed by first intention may be credited to the excision of diseased

skin. The patients were allowed to get up eleven to fifteen days after the operation, with plaster-of-Paris splinting. After a couple of days shoes were worn with supports, and three weeks after the operation the patients were discharged. From four to six weeks after the operation they were again fully fit for work. The last symptoms disappeared between one and a half and three months after the operation. From one to six years later thirteen patients (twenty-one cases) were re-examined. With only one exception all were completely rid of their symptoms, both active and passive movements being perfectly satisfactory. In the case of the one exception, movement was limited by shortening of the extensor tendon and slight dorsal flexion of the big toe. The cosmetic effect was excellent in eighteen cases. A patient who had been operated on on both sides had developed a slight valgus displacement soon after the operation, because, as she admitted, she had promptly returned to unsuitable shoes. She was, however, completely free from symptoms.

218 Habitual Dislocation of the Peroneal Tendons

According to R. LOHE (*Zentralbl. f. Chir.*, May 19th, 1934, p. 1154) dislocation of the peroneal tendons at the outer ankle is rare, and their anchoring to the periosteum by the retinaculum superius is so effective that occasionally their dislocation is accompanied by cleavage of the periosteum from the fibula. When dislocation with tearing of the retinacula occurs it is apt to become repeated after slight trauma or in forcible extension of the ankle, and treatment by simple suture and/or immobilization is ineffective. Habitual dislocation of the peroneal tendons has been successfully treated by suture with fascial strips, bridging by grafts of bone and periosteum, or fixation by a transplanted tendon of the palmaris longus. Lohe recommends and has practised section of the peroneus longus tendon at the ankle, its displacement from the anterior to the posterior border of the peroneus brevis, round which it is wound, and then sutured to the periosteum of the inner surface of the os calcis. In cases in which in addition to the peroneus longus the peroneus brevis tendon becomes habitually dislocated he suggests implantation of the latter, after passage around the former, in a similar situation.

219 Congenital Torticollis

G. DE N. HUGH, jun. (*Surg., Gynecol and Obstet.*, June, 1934, p. 972), states that in rare cases congenital torticollis is bilateral, with forward inclination of the cervical spine and head. There was no sexual predisposition in the cases he reviews (twenty-seven boys and thirty girls). The right side was affected in thirty-one cases and the left in twenty-six. Various theories of aetiology include heredity, constitutional defect, arrested development, birth injury, infective myositis, and ischaemic fibrosis. Abnormal intrauterine position or increased intrauterine pressure is widely believed to be a causative factor. The condition is described as a sclerotic interstitial myositis, with Zenker's waxy degeneration producing dense induration and shortening. This is usually limited to the sternomastoid muscle, but in severe cases the platysma, scaleni, and splenius capitis may be shortened. The lesion is usually noted at birth or soon after, and it has been found that non-operative treatment results in correction in a large proportion of cases under one year. In older cases open division of the sternomastoid muscle is the usual method of operative treatment, followed by a period of fixation and subsequent massage and exercises. In this series the operative procedure consisted of division of both the sternal and clavicular origins of the muscle, with a subcutaneous tenotomy of the insertion when necessary. It was found that complete excision of the sternal head of the sternomastoid causes an asymmetry of the neck, with loss of normal contour and prominence of the sternal extremity of the clavicle. This can be obviated by plastic lengthening of the tendon. Full active and passive over-correction of the deformity was obtained in all cases, and facial asymmetry was usually complete in about three years.

Therapeutics

220 Antirabic Virus Vaccine in Treatment of Sciatica and Migraine

J. HAGUENAU, L. CRUVEILLIER, and S. NICOLAU (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, May 21st, 1934, p. 671) report further trials of treatment in morbid conditions of the nerves by injections of neurotropic virus. They use the virus vaccine employed for prophylactic treatment of rabies at the Pasteur Institute, giving a course of daily injections for fifteen or more days. In patients with chronic arthritis of the hip or vertebral rheumatism, in pains after herpes, in trigeminal or facial neuralgia, and in tabes or general paresis the treatment was practically useless. In five out of seven cases of severe sciatica, however, which has proved refractory to other treatments, the virus vaccine injections led to speedy cure. Twelve bad cases of migraine were treated; cure was obtained in six and partial amelioration in two. The writers are satisfied that apart from relief of symptoms the majority of patients showed after their treatment a slow but striking improvement in general health; in several instances a patch of alopecia was found to disappear, and the hair and beard of a diabetic patient regained their colour.

221 Gonorrhoeal Arthritis treated by Antigonococcal Serum

L. MATEOS (*Rev. Med. de Barcelona*, June, 1934, p. 483) publishes an interesting series of cases of gonococcal arthritis treated by intravenous injection of antigonococcal serum (10 per cent. in slightly hypertonic saline), and concludes that this is the treatment of election owing to its speed and efficacy and the absence of any dangerous complications or sequelae. Though he met with early "congestive crises" and lumbar pain at times, these yielded at once to an injection of adrenaline. Delayed serum reactions were frequent, though they rapidly disappeared when adrenaline with calcium chloride and magnesium hyposulphite were administered. Complete cure invariably followed. Here is the simple technique which the author employed. The patient, fasting, though otherwise unprepared, receives intravenously 20 c.c.m. of serum in 200 c.c.m. of saline from a double-channelled irrigator provided with a controlling key. This operation should take half an hour, and is repeated forty-eight hours later with 30 c.c.m. of serum in 300 c.c.m. of saline. With like intervals two other injections are given of 40 c.c.m. of serum in 400 c.c.m. of saline. No other treatment is necessary. Three or four hours after each injection there is a rigor, with some elevation of temperature, which disappears next day. After the final injection there is occasionally serum erythema with arthralgia, both of which yield rapidly to calcium chloride.

222 Splenotherapy in Tuberculosis

J. C. BAYLE (*Bull. et Mém. Soc. Méd. de Paris*, June 8th, 1934, p. 385) advocates splenotherapy in all forms of pulmonary and surgical tuberculosis. This treatment produces a rapid disappearance of the anaemia, alleviation of the cough and dyspnoea, regression of the calcareous lesions, diminution and ultimate disappearance of the bacilli, and a rapid increase in weight and vitality. For subcutaneous or intramuscular (the more active) injections, a mixture of two parts of a glycerin extract of the total gland and three parts of physiological serum is employed, and for oral administration a saccharo-glycerin extract. Bayle combines both methods, giving daily three soup-spoonfuls of the latter preparation, and four injections weekly of the former in 5 c.c.m. doses for adults, and in children 1 c.c.m. for each year of age above 5 years. This treatment is administered for three weeks, and is then suspended for a period. The injections are free from danger, and cause no febrile or anaphylactic reaction. This method is said to be of value in cases in which pneumothorax is contraindicated or impossible, and is a useful adjuvant when this intervention has been performed.

Laryngology and Otology

223

Function of the Sacculæ

D. W. ASHCROFT and C. S. HALLPIKE (*Journ. Laryngol. and Otol.*, July, 1934, p. 450) record the results of experimental work on electro-physiological lines directed towards the elucidation of the problem of saccular function, the animal employed being the frog. While no response was obtained from the saccular nerve in response to movements of tilting or rotation, vibration brought about a marked reaction, showing that in this animal the end-organs concerned in the sense of hearing are situated in the sacculæ. It is thought by the authors that their experimental results support the suggestion of Tait that in man the sacculæ is concerned with the reception of bone-conducted sound. If it is possible to establish the truth of this suggestion the resonance theory of hearing is somewhat discounted, and localization of disturbance in the cochlea, although it may occur, would no longer have the supreme psychological significance expressly attributed to it by the resonance theory. Both the frog's sacculæ and the cat's cochlea exhibit the common attribute of frequency reproduction, and there is thus good evidence for the belief that in the peripheral mechanism of pitch perception both cochlea and sacculæ are commonly concerned, at any rate for the lower frequencies. Regarded from the viewpoint of phylogeny it seems likely to the authors that the cochlea in its primitive macular form would possess the simple telephone mechanism shown to exist in the sacculæ of the frog. That this primitive mechanism would be lost in the course of development seems improbable to the authors, although the appearance of an extraneural tuning mechanism would lead to a spatial representation of frequency. It is thought likely that both telephone and resonance mechanisms are concerned in the psychological process of pitch discrimination.

224 Laryngo-fissure in Laryngeal Carcinoma

L. H. CLERF (*Arch. of Otolaryngol.*, June, 1934, p. 653) has subjected a series of fifty-eight consecutive cases of cancer of the larynx treated by laryngo-fissure to analysis from the standpoints of age, sex, death from post-operative complications, death from intercurrent diseases within three years of the operation, recurrence, and recovery without recurrence for a period of more than three years after operation. There were fifty-four male and four female patients. One was in the third decade of life, two in the fourth, fifteen in the fifth, twenty in the sixth, fifteen in the seventh, and five in the eighth. Five died from complications developing after the operation, a high mortality rate of 8.6 per cent. Four between the ages of 65 and 70 died from cardiac and renal complications (one having coronary thrombosis), while the fifth, who had diabetes mellitus, died on the eighth day from bronchopneumonia and diabetic coma. Deaths from intercurrent diseases after the operation numbered six, and in none of these patients was there any demonstrable evidence of recurrence. There were eight cases of recurrence, of which seven terminated fatally, irrespective of irradiation or laryngectomy. The eighth patient was subjected to laryngectomy, and there was no evidence of recurrence more than three years later. In six of these cases the growth was graded as of an intermediate type, and it might be suggested that laryngectomy would have been a more suitable primary operation. Clerf thinks it doubtful whether all the cancer would have been removed thus, unless the hyoid had been excised with the larynx. He points out that in five cases the growth was incompletely removed, in one the recurrence between the hyoid bone and the base of the epiglottis might have been successfully treated by a radical operation if it had been discovered sufficiently early. In another case there was an unexpected extension of the growth to the thyroid gland; and in the last the metastasis had involved the deep cervical lymph nodes without recurrence in the larynx. Fear of the whole series could not be traced, and thirty-five have remained free from signs of recurrence for periods

ranging from three to five years so far. On the basis of recurrence in eight cases and freedom from recurrence in thirty-five the rate of failure can be stated as 18.6 per cent. Laryngo-fissure is commended, therefore, in laryngeal carcinoma, except in cases where metastasis has occurred, or the growth has invaded the thyroid cartilage, or it is impossible to remove sufficient of the surrounding normal tissue. It should not be employed, moreover, in cases of cancer of the epiglottis or of the aryepiglottic fold, or in lesions originating in the infraglottic portion of the larynx.

225

Surgical Treatment of Aural Vertigo

Drawing an analogy from the surgical treatment of facial neuralgia, A. HAUTANT (*Bull. de l'Acad. de Méd.*, June 26th, 1934, p. 933) considers that this method is indicated in those cases of essential vertigo, characterized by incessant, violent crises, which are refractory to all medical measures. Any displacement or change in pressure of the intralabyrinthine liquid reacts upon and excites the nervous elements. Removal of even a minute quantity of the endolymphatic fluid suffices to destroy the normal excitability of the vestibular apparatus, and, by destroying the peripheral stimulus of the latter, attacks of vertigo are almost always ameliorated and frequently cured. The method consists in trephining the semicircular canals, employing the mastoid route; this involves no danger, and, if unsuccessful, does not aggravate the vertiginous condition. Hautant has performed this operation in thirteen cases, with cure in seven and improvement in four. Short notes on three cases are given.

226 Diphtheria Bacilli in Chronic Nasal Infections

R. SCHROEDER (*Ann. d'Oto-laryngol.*, May, 1934, p. 487) discusses the significance of the appearance of diphtheria bacilli in the nose and throat of patients suffering from chronic nasal infections. In a series of 126 patients with such infections diphtheria bacilli were detected in thirty-nine, but in no instance did the clinical symptoms justify a diagnosis of chronic diphtherial rhinitis. He finds it necessary to admit, therefore, that such an appearance of diphtheria bacilli in the nasal cavities in a state of chronic inflammation is merely a secondary phenomenon. Diphtheria antitoxin was given in four cases without any lasting effect on the rhinitis. In only 10 per cent. of the cases with diphtheria bacilli in the nasal secretions were the organisms discovered in the throat concurrently. As an alternative to the isolation of these diphtheria carriers he urges the active immunization of all their contacts against diphtheria, and emphasizes the danger of infection to the community from these often unsuspected sources.

Obstetrics and Gynaecology

227

Uterine Carcinoma

G. LECLERC (*Presse Méd.*, June 20th, 1934, p. 993) presents a study of cancer of the uterine body based on forty-four personal cases—pre- and post-menopausal. In the former the diagnosis is difficult, as metrorrhagias due to causes other than cancer are very frequent. The latter group comprises forty of the cases described. Leclerc does not agree with Faure and others that a persistent haemorrhage after the menopause is necessarily pathognomonic of cancer, but affirms that, while malignancy should always be suspected when it occurs without cervical symptoms, the diagnosis should be infallibly established. Hysteroscopy, uterine radiography after injection of lipiodol, intrauterine digital exploration, and curettage are cited as diagnostic measures; the first three are dismissed as giving reliable information in only a few cases. Leclerc rules on curettage: this is perfectly harmless if done skilfully with a soft curette; it can be performed without anaesthesia and without dilatation, or merely sufficient dilatation to permit of the introduction of the curette. Hysterectomy is the elective treatment for these cancers; radium is recommended only when inter-

vention is impossible or contraindicated. The gravity of this operation (Leclerc's mortality figure was 18 per cent.) emphasizes the need of correct diagnosis. In twenty-eight cases cured by operation there were nine recurrences and nineteen survivals of from three to fourteen years. In subjects with good resisting powers total abdominal hysterectomy is advocated; in others, the subtotal or vaginal. In doubtful cases Leclerc performs the total in two stages: first, a subtotal is done, with removal of the uterus, and, if a diagnosis of cancer be established, the cervix is secondarily excised.

228 Retention of the Membranes

From the results noted in 317 cases of partial and twenty of total retention of the membranes after delivery, J. L. WODON and R. DE GUCHTENEER (*Bruxelles-Médical*, June 17th, 1934, p. 1047) draw the following conclusions. In partial retention, no intrauterine intervention (curettage, injections) is justifiable. This condition causes no haemorrhage or other grave complication. There was no morbidity (the criterion of this was taken to be the occurrence of an axillary temperature of 37.5° C. once during the first eight days post partum) in 60 per cent. of the cases; in 30 per cent. the temperature did not exceed 37.5° C., and in 8.8 per cent. it reached 38.9° C. In only 1.2 per cent. was the latter temperature exceeded, a figure not higher than that occurring with complete expulsion of the foetal adnexa. In cases of total membranous retention followed by an early temperature of at least 38.5° C., curettage may be performed, though not absolutely necessary; this intervention appears to be of value only if performed before the fifth day of the post-partum.

229 Treatment of Salpingo-peritonitis

J. ELGART reports treatment of fifty cases of incipient salpingo-peritonitis (*Journ. Obstet. and Gynaecol. British Empire*, June, 1934, p. 396) by his method, with no fatality and no diffuse peritonitis. In acute abdomen combined with vaginal discharge he first performs appendectomy, and then examines the Fallopian tube. If pus can be expressed he disinfects with iodine, ligates the tube, and severs it 0.5 cm. beyond the ligature. This prevents escape of pus into the abdominal cavity, is followed by subsidence of inflammatory symptoms in two or three days, results in a patent lumen, and allows for restoration of function by subsequent salpingostomy if desired.

Pathology

230 Monocyte Histology in Malignant Disease

O. C. GRUNER (*Journ. Lab. and Clin. Med.*, June, 1934, p. 917) describes certain filamentous, spirillar, and geniculate structures which are discernible in leucocytes, especially the monocytes, in a high percentage of cases of malignant disease, and are also found in occasional cases which are clinically non-malignant. They are demonstrable only by Pappenheim's panoptic method or by Leishman's stain. Care must be taken not to wrinkle the cells in spreading the film, nor to confuse these structures with azure granules. Such intracellular structures were found in 132 out of every 1,000 mononuclear cells in malignant disease of the alimentary tract, but less frequently in sarcoma and in oesophageal cases. In patients under radium treatment they were much less common and more difficult to find. Gruner discusses their significance, having satisfied himself that patients with malignant disease do, as a rule, have their blood loaded with such abnormal cells. It was found that the blood varied in its content of these structures at different times of the day. He concludes that the nucleo-irritative products vary in amount independently of the defensive tissue reaction. He points out that, while chromoidal extrusions are common in circulating blood, especially in malignant disease, they are also numerous in healthy persons on a diet rich in purines. But these extrusions

never attain the length of the filamentous structures, being of drumstick or spiculated form. The structures might perhaps be taken as an index of chromoplastic activity, which would be in harmony with a popular view as to the nature of malignant disease. They may reflect the outpouring of cytotoxic and cytotoxic products from the neoplasm, an event which need not necessarily be continuous and need not occur in all stages.

231 Tuberculin Sensitivity in Childhood Tuberculosis

J. A. JOHNSTON, P. J. HOWARD, and J. MARONEY (*Amer. Rev. of Tuberculosis*, June, 1934, p. 652) record observations based on 213 children with primary tuberculous infections followed in hospital for two years, and on more than 500 children followed in the out-patient department for six years. Serial dilutions of old tuberculin were given intracutaneously at monthly intervals, the threshold being taken as the highest dilution to which any local response was elicited. The same batch of tuberculin was used throughout. Changes in sensitivity were studied in relation to the x-ray appearances in the lungs and the blood picture. Generally speaking, in the first stage of the infection the x rays showed parenchymatous infiltration, and the tuberculin sensitivity increased. During the second stage, when the parenchymatous infiltration began to clear but the hilum region enlarged, tuberculin sensitivity was at its height. In the third stage, as the hilum nodes diminished in size and began to calcify, tuberculin sensitivity gradually fell. In none of the hospital patients did the tuberculin reaction become completely negative, but thirteen of the out-patient group eventually failed to respond even to 1 mg. The changes in the blood were more variable. As a rule the total leucocyte count was normal, but a steady fall in polymorphs and monocytes occurred, accompanied by a rise in lymphocytes. The most consistent finding, however, was a definite shift to the left in the Schilling-Arneth index, followed, as involution of the local lesion occurred, by a shift to the right. The authors conclude that the maximum level of tuberculin sensitivity corresponds to the maximum involvement of the lymph nodes. The steady rise in sensitivity is a feature not of extension but of absorption of the parenchymal lesion.

232 Serological Diagnosis of Weil's Disease

W. GAETGENS (*Med. Welt*, June 16th, 1934, p. 825) states that in the neighbourhood of Hamburg the number of cases of Weil's disease recognized in each of the last two years exceeded that of the period 1927-31. Further experience has confirmed the diagnostic value of serological tests, and has shown that the complement-deviation test is at least as valuable as those of agglutination and lysis. Its antigen prepared from the spirochaetes is highly specific, and is stable for at least twelve months. The complement-deviation and other serological tests are only exceptionally positive during the first week of illness, but nearly always positive towards the end of the second week. Gaetgens agrees with Uhlenmuth and Zimmermann that agglutination or lysis in a serum diluted to 1 in 200 confirms clinical suspicion of Weil's disease: agglutination in a titre of 1 in 100 is highly suspicious. He finds that in the complement-deviation test a positive result in dilution 1 in 100 is fairly conclusive, in dilution 1 in 50, or even 1 in 10, definitely suspicious.

233 Human Influenza and Canine Distemper

A. EICHORN and N. J. PYLE (*Journ. Amer. Med. Assoc.*, June 23rd, 1934, p. 2082), after confirming the findings of Smith, Andrewes, and Laidlaw with regard to the inoculation of ferrets and the post-mortem changes in these animals, found that inoculation of the human influenza virus induced immunity in ferrets to the virus of canine distemper. There thus appears to be a possible relationship between influenza in man and the distemper virus in dogs. The writers are at the present time conducting experiments to determine the possibility of cross-immunization with the virus of influenza and the virus of distemper in dogs.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

234. Secondary Pellagra in Asylums

G. V. BREDMOSE (*Hospitalstidende*, June 12th, 1934, p. 694) has joined in the hunt for cases of pellagra in asylums in Denmark, recently set on foot by Hess Thaysen, whose investigations have shown that pellagra, secondary to protracted gastro-intestinal disease or an inadequate diet, is not rare among the insane. By January, 1934, the comb-out of Danish asylums had yielded as many as twenty cases of pellagra; and the author adds seven more to this number by scrutinizing the records of his asylum in the ten-year period 1924-33. Five of the patients were women, and five had died suffering from well-developed, active pellagra. In the last two cases the patients benefited from the comparatively early recognition of their disease and from treatment with vitamin B₂ preparations (bevit and spinatin) and a dietary including eggs, milk, cream, and maltose. Under this treatment marked improvement was effected as far as the pigmentation, hyperkeratosis, and spinal symptoms were concerned. But there was no improvement in the mental condition, and the author is inclined to think that no such thing as a special pellagra psychosis is demonstrable. Pellagra may occur in any form of mental disease, not as a direct sequel to it, but as the result of refusal to eat or prolonged gastro-intestinal disturbances which interfere with the absorption of the pellagra-preventing vitamin. The investigations hitherto conducted in Denmark suggest that 0.3 to 1 per cent. of the inmates of Danish asylums suffer from pellagra.

235. Infection Risks from Children with Open Tuberculosis

G. WILDER and F. STÜRMELING (*Munch. med. Woch.*, June 29th, 1934, p. 976) draw attention to the growing importance attached to children as sources of tuberculous infection, since several investigators have found that the contents of the stomachs of tuberculous children, withdrawn by the stomach pump, often contain tubercle bacilli. To examine this problem from another angle, they introduced six guinea-pigs into the tuberculosis section of a children's hospital in Munich, letting tuberculous children play with the animals in bed. A couple of guinea-pigs were kept as controls (out of contact with the tuberculous children). The other guinea-pigs were removed from the section during visiting hours, so as to avoid their infection by tuberculous visitors. This experiment was continued uninterruptedly for three months, and the guinea-pigs were then kept by themselves in stables for another three months. During this period they were repeatedly tested with tuberculin administered by the intracutaneous route. There was never any positive tuberculin reaction, and when the guinea-pigs were killed no evidence of tuberculosis was found. Yet at least two of the children had cavities, and in several cases an intercurrent attack of whooping-cough made the children cough much. Though this experiment was negative, the authors are disinclined to conclude from it that tuberculous children do not spread tuberculosis.

236. Abscess of the Lung

H. STARCK (*Deut. med. Woch.*, June 8th, 1934, p. 857) believes that within the last few decades abscess of the lung has become quite common after being so rare that a clinician's experience of it might well be limited to a single case. Now he may have seen over a hundred such cases, and Professor Starck has observed twenty-three cases, which, with only two exceptions, have occurred since 1930. As women are as subject to this disease as men, it can hardly be traced to war-time gassing. A more plausible hypothesis incriminates the successive waves of influenza which have swept over the world since 1918, and which may have paved the way for abscess of the

lung. Though the textbooks distinguish between abscess and gangrene of the lung, the difference is assuredly one of degree only; the simple abscess of the lung merges without any great change into gangrene when anaerobic germs enter the field and render the sputum putrid. Fever is seldom absent, but there is no characteristic temperature curve, and it may not exceed 38° C. throughout an illness lasting for months. Indeed, one of the author's patients has suffered from a pulmonary abscess for two years and a half without any rise of temperature. The disease may be fatal in a few days or run a chronic course, lasting for years; even when there are no complications, and the abscess is a benign, metapneumonic lesion, the illness is apt to last three or four months. The prognosis is most uncertain; at any moment there may be a surprise. As a rule the central and perihilar abscesses fare better than the peripheral abscesses, but the factors of greatest prognostic importance are the general health, the heart, and circulatory system. When the abscess is perihilar or central an artificial pneumothorax is indicated. Of the author's twenty-three patients four were operated on (two deaths and two recoveries). There were five deaths from sepsis. The recoveries under conservative treatment numbered thirteen, and one patient was still under treatment.

237. Thrombo-angiitis Obliterans and Typhus

D. KISZELNIK (*Thèse de Paris*, 1934, No. 513), who records a personal case in a patient aged 23, maintains that thrombo-angiitis or Buerger's disease is not an exclusive appanage of the Jewish race, but is encountered in all countries where typhus is endemic, such as the Balkans and Soviet Russia. In view of the affinity of typhus infection for the vessels and the frequency of thrombo-angiitis obliterans in these countries where typhus is endemic, it is probable that a number of cases of Buerger's disease are due to an attenuated or inapparent form of typhus, for which a careful search should be made by clinical examination and the Weil-Felix reaction.

Surgery

238. X-Ray Diagnosis of Chronic Appendicitis

L. KRENS (*Wien. klin. Woch.*, June 22nd, 1934, p. 778), as proof of the utility of x rays in the diagnosis of the "chronic appendix," cites the finding that the addition of radiography to the pre-operative investigations diminishes the proportion of normal appendices found from about one in four to about one in ten, in cases coming to operation for supposed chronic appendicitis. Of 234 patients who appeared clinically to have this disease, alterations of the appendix could be shown radiologically in two-thirds of them. Only 10 per cent. of the appendices which had been invisible on screening proved to be normal. No single appendix was free from disease which radiologically had showed abnormal filling (partial filling, adhesion, tenderness); this group was composed of twenty-one patients. According to the practice of Czega, the patients received about a teaspoonful of magnesium sulphate with the contrast meal, and were examined eight, twenty-four, and forty-eight hours afterwards; the screening was repeated (with a different aperient dose) if the appendix was imperceptible.

239. Treatment of Syndactylism by Epithelial Inlay

J. ESSER and RAOUX (*Rev. de Chir. Plastique*, May, 1934, p. 21) point out the difficulty of successful operative treatment in cases of syndactylism, particularly owing to the insufficiency of skin available to close the wounds after separation of the fingers. Skin grafts are successful in some cases, but the technique is delicate and difficult, and the formation of scar tissue and granulation may prevent free movement of the fingers. The method of treatment

advocated by the author, and called "epithelial inlay," has been in use by him for eighteen years, and has given remarkably good results. The fingers are first separated up to the interdigital space, so as to leave the web at the normal level when the operation is completed. After careful haemostasis an impression of the wound is taken with a Stent mould, which is similar to that used by dentists when taking impressions of the teeth and jaws. The mould is disinfected externally by sublimate solution, and is soaked in hot water to soften it before it is applied to the interdigital space. After a few minutes the mould hardens, and the impression thus taken is covered with a dermo-epidermic graft, which must be of sufficient size to cover both the web and the two lateral wounds. The graft is then placed between the fingers and is held firmly in place by bandages. The mould is removed after ten days, and it has always been found that the graft has taken so successfully that the wound is completely covered by epithelium without sign of granulation. The mould is dried and replaced for a few more days. This method of treatment is considered to be superior to that of any other type of plastic operation, being simple to carry out, and giving good results in all types of syndactylism.

240 Sarcoma complicating Paget's Disease

Paget observed the frequent occurrence of sarcoma in the disease bearing his name, and Leri noted that this malady predisposes to gout and cancer, especially osseous cancer: several cases are recorded in the literature. J. HAGUENAU, L. GALLY, and P. DAUM (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, June 4th, 1934, p. 786) present details of a case of Paget's disease in which an osteo-sarcoma of the right knee with metastases in the cervical vertebral region developed. Death supervened in six months after the first appearance of pains in the knee. In most cases these tumours appear after the age of 50, and much more frequently in males, and they invariably develop on bones presenting, at least radiologically, the characteristics of Paget's disease, and never on normal ones. Histologically, they most frequently resemble ordinary sarcoma; in one case, however, myeloplaxic tumours occurred, and in another von Albertini noted that the marrow of the affected bones was converted into a tissue of fusiform cells, sarcomatous in appearance, and he suggests the possible formation in "pagetic" bones of a presarcomatous tissue capable of true sarcomatous degeneration. The present authors believe that this complication is too infrequent to permit of this hypothesis, and consider that these cases are analogous to those neoplastic degenerations following chronic irritation. The prognosis of these sarcomata is rapidly fatal and no treatment is of any avail.

241 Fracture of the Styloid Process

O. KAPEL (*Hospitalstidende*, June 26th, 1934, p. 786) finds that in certain fractures, such as those of the os naviculare manus and of the styloid process of the radius, inadequate immobilization may prevent bony union and ultimately lead to a painful wrist with chronic arthritis deformans. When immobilization is not continued long enough pain returns on movement, and it may then be waste of time to practise massage and active movements. A chauffeur, aged 49, fractured the styloid process of the right radius while cranking up a car. For three weeks the wrist was immobilized, and thereafter he was treated with massage and movements. As his wrist remained painful he was referred to the author, who secured it in plaster-of-Paris, in a position of slight dorsal flexion, with the fingers perfectly free. The patient was thus still able to do gardening. The plaster was changed every eight weeks and worn altogether for seven months, after which the movements about the wrist and fingers were perfectly free and painless. The successive x-ray examinations when the splint was changed showed progressive healing of the fracture. The author argues that if movements and massage had been continued when he took over this case the patient would have had an always painful joint, with arthritis deformans and progressive invalidism before him.

Therapeutics

242 New Method of Artificial Respiration

S. JELLINEK (*Wien. klin. Woch.*, June 29th, 1934, p. 808) criticizes the older methods of artificial respiration, and states that the more or less brutal compression of the chest usually employed is physiologically unsound. The circulation in the lungs, as well as the coronary circulation, benefits from the normally present negative intrathoracic pressure, and compression, besides impairing these functions, produces sudden resistance to the muscularly weak right side of the heart. It further damages the lung parenchyma, especially the respiratory epithelium, and if sufficiently brutal may produce fracture of the ribs, rupture of the liver, and laceration of the diaphragm. The good results achieved by older methods do not minimize their danger. Jellinek describes a new method depending on "concussion" of the thorax. The patient is put on his back, with an improvised support between the shoulder blades. The tongue is automatically fixed by the patient's second and third fingers, which are introduced into the mouth and press on the tongue behind the teeth. This automatic fixation keeps the respiratory passages clear. The patient's upper arms are grasped by the fingers, the thumbs resting on the acromial end of the clavicles. With a strong rapid movement the shoulders are pressed against the shoulder-blade support and let go after one second. This pressure is repeated rhythmically at two to three second intervals. X rays showed that all three diameters of the chest increase in size, while manometric readings demonstrated that suction was induced—that is, that active inspiration is aided.

243 Animal Carbon Injections in Infections

H. GAUDIER and DÉMAREZ (*Bull. de l'Acad. de Méd.*, July 3rd, 1934, p. 45) record excellent results in twenty-five cases of very varied infections (urinary and uterine infections, acute articular rheumatism, pneumonia, etc.) following intravenous injections of animal carbon (Saint-Jacques's method). Doses ranging from 2 to 5 c.cm. of a 2 per cent. solution of the finely pulverized substance were injected in series of two or three injections at various intervals. The injections are painless, are not followed by secondary fever, and cause a lowering of the temperature and marked clinical improvement. The authors emphasize the complete innocuity of this method.

244 Remedy for Mycotic Eczema of the Feet

S. LOMHOLT (*Ugeskrift for Læger*, June 21st, 1934, p. 655) of the Finsen Institute in Copenhagen has recently conducted encouraging experiments with para-oxy-benzoic acid-ethyl-ester—sold by the firm of Leo as "mycoeten." It was prepared by two engineers who had investigated various means of preserving foodstuffs against moulds. They requested the author to test it in cases of interdigital eczema of the feet provoked by the *Epidermophyton interdigitale*. After testing it in about 100 cases, some of them controlled by simultaneous tests with various other remedies applied to the other foot, the author was greatly impressed by its efficiency and lack of toxicity. Mycoeten can be applied as a 5 per cent. alcoholic solution or in ointment form, with the following composition: ung. plumb. oxid. grams 60, liquid paraffin, mycoeten, and salicylic acid aa grams 3. The composition of this ointment is designed to promote maceration of the skin, which favours penetration of the drug, while at the same time the acid reaction inhibits the growth of the fungus. The author has found the therapeutic action of this ointment considerably enhanced by the addition of hydrargyrum amidochloridum (5 per cent.). Patients with an idiosyncrasy to mercury should, however, beware of this addition. The ointment is odourless and white, and its application is almost invariably followed by the prompt disappearance of itching and other symptoms. Every evening, the feet are washed with soap and water to which a little soda has been added, and loose tags of skin are removed. The toes are carefully dried and then bathed with the

alcoholic solution of mycoeten. When this has dried a thin layer of the ointment is applied. This procedure is repeated next morning. The stockings are disinfected with methylated spirits and are then dusted with a talcum powder containing 5 per cent. mycoeten and 5 per cent. salicylic acid. In slight cases, and for purely prophylactic purposes, the ointment can be dispensed with and only the alcoholic solution of mycoeten used. It is applied once or twice a day on a pad of cotton-wool to the interdigital spaces. Though the same treatment can be applied to the hands it is apt to be less effective.

245 Convalescent Scarlet Fever Serum and Antitoxin

P. S. RHODS and B. M. GASUL (*Journ. Amer. Med. Assoc.*, June 16th, 1934, p. 2005), from comparative observations on the protective value of convalescent serum and commercial scarlet fever antitoxin, come to the following conclusions. Cases have been observed in which the usual dose of scarlet fever convalescent serum administered to susceptible individuals failed to afford passive protection to the disease. On the other hand, the ordinary commercial scarlet fever antitoxin always afforded complete passive protection against scarlet fever in susceptible persons. Unless an unusually potent convalescent serum is used patients will receive more immune bodies from the therapeutic dose of scarlet fever antitoxin than from convalescent serum given in the usual dosage. Convalescent serum distributed through a serum centre costs much more per antitoxic unit than commercial antitoxin.

Radiology

246 Radiotherapy in Vasomotor Disorders of the Extremities

Owing to the action of x rays on the sympathetic nervous system, R. GILBERT and L. BABANTZ (*Rev. Méd. de la Suisse Romande*, July 25th, 1934, p. 725) have made use of them in vasomotor and trophic diseases of the extremities, such as intermittent claudication, Raynaud's disease, etc. Paravertebral irradiations of the sympathetic ganglia and deep plexuses, either alone or combined with irradiation of the peripheral endings, have given excellent results. The authors have employed this method in eleven cases, five of which are here recorded. With a semi-penetrating moderately filtered irradiation, total doses of 500 to 800 r, spread over two to three weeks, are given in bi- or tri-weekly irradiations; 175 r is given per field at each treatment. If results are not obtained, the series is repeated after an interval of two or three weeks. Spinal irradiations are first given, and, if improvement be tardy, peripheral ones are added. For diseases of the upper extremity, irradiations are made over the cervical and two first dorsal vertebrae, and for those of the lower limbs over the tenth dorsal to the first lumbar vertebrae.

247 X-Ray Treatment of the Thyroid and Thymus

While admitting that x-ray therapy can show a high percentage of successful results in the treatment of overactivity and of enlargement of the thyroid and thymus glands, H. DAVIES (*Brit. Journ. Radiol.*, June, 1934, p. 362) believes that, if cases of thyrotoxicosis were more carefully grouped and operation were regarded as the method of choice in the secondary type with x-ray treatment in the primary type, the results would be still better. Primary thyrotoxicosis occurring in the young adult is attended by an appreciable operation risk and an operation cure of only about 80 per cent., whereas the later x-ray therapy can be shown by large series of cases to be just as effective. Davies considers that the indication for x-ray treatment in thyroid disease is overactivity of the secretory epithelium, while in the thymus not only has such secretory overactivity to be considered as an indication, but also simple enlargement due to overgrowth of the lymphoid tissue. A point to be emphasized is that recurrence in primary cases treated by opera-

tion is as high as 6 to 7 per cent., and this must be taken into account when considering the statistics of successful results in x-ray treatment as compared with operation. Where care is exercised, the risk of skin damage should be nil and the risk of myxoedema negligible. Moreover, x-ray treatment has the advantage that it can be graded, whereas at an operation the amount of thyroid tissue removed is final. The author has treated with x rays three cases of myasthenia gravis with enlargement of the thymus associated with enlargement of the thyroid and some hyperplasia. In one instance there was definite improvement after one month, persisting for eighteen months. In the other two cases there was immediate and striking improvement, but the sequel is unknown. The amount of radiation required to produce a good effect in the thymus is small. In view of the close connexion which has been shown to exist between the lymphoid tissue of the thymus and thyroid and other conditions, the thymus should receive careful attention when treatment is being undertaken.

248 Encephalography under Nitrous Oxide Anaesthesia

R. W. WAGGONER and L. E. HIMLER (*Amer. Journ. Roentgen. and Rad. Ther.*, June, 1934, p. 784) record thirteen cases of encephalography in which nitrous oxide anaesthesia obviated all subjective symptoms while the fluid was being removed, without preventing a quick return of consciousness. This anaesthetic was found also to diminish the severity of the post-encephalographic reaction. The pulse rate, blood pressure, and respiration rate were recorded every few minutes, and no adverse manifestations were noted, whereas without an anaesthetic the pulse frequently becomes weak and thready after about 50 c.cm. of spinal fluid has been removed. The only objection is the additional expense involved. The increase in initial intracranial pressure consequent upon its use does not appear to be a contraindication. The age of the patients in the authors' series ranged from 3 to 56 years. The average time required for drainage of the fluid was slightly under one hour. The authors add that no cases with choked disks or posterior fossa tumours have been included so far, although two with frontal and temporal tumours were clearly localized by this method. These two patients were up and free from headache in less than forty-eight hours.

Obstetrics and Gynaecology

249 Symphysiotomy

W. HAUPT (*Med. Welt*, June 23rd, 1934, p. 863) records that at Bonn in the past fifteen years thirty sections of the bony pelvis have been done, in comparison with 585 Caesarean sections. He believes that the former operation still has definite, if limited, indications. It should not, in general, be done if the conjugate in the flat pelvis exceeds 7.5 cm., or in multiparae—although Zarate included thirty-two primiparae in his series of 100 operations, with one fatality only. According to collected mortality statistics, symphysiotomy, in rightly chosen cases, has a considerably better maternal and a slightly better foetal outlook. Technically, Haupt recommends that the division be done with the guidance of the left index in the vagina, pushing the urethra sideways, and the left thumb pressing the clitoris outwards. The pre-urethral ligament is respected, the arcuate ligament as a rule divided. The division of the cartilage is accompanied by slight abduction and external rotation of the thighs; so soon as it has been slowly completed, with gradual pulling of the pubes, the thighs must be adducted and rotated internally to avoid injury of the sacrospinous joints. In general, labour is completed, after downward pressure of the head into the pelvis, by forceps. The labes are afterwards tied together by a handkerchief, and a pelvic girdle is applied, the crossed anterior ends of which are led over pulleys at the sides of the bed, and subjected to traction for some eight days, sandbags at

being applied outside the hips. In twenty-three personal cases the mortality comprised one only—an eclamptic case. Bleeding and injuries were negligible: four infants did not survive.

250 Aetiology and Treatment of Pregnancy Pyelitis

F. v. MIKULICZ-RADECKI (*Zentralbl. f. Gynäk.*, June 30th, 1934, p. 1506) expresses his astonishment that the importance of ureteral, or rather pelvirenal, catheterization in the treatment of pyelitis in pregnancy is not generally recognized. It is still doubtful, he thinks, whether pressure of the enlarging uterus is an important favouring factor, and whether the renal parenchyma is affected: certainly the vesical mucosa is rarely inflamed. Pyelitis in pregnancy demands as concomitant factors: (1) urinary infection, usually by *B. coli*; (2) stasis in the ureter—this is due, v. Mikulicz-Radecki believes, to angular kinking, with or without torsion, of the lax, spinally slung, uppermost section of the ureter. (Atonicity of the ureter during pregnancy is a proved physiological condition. Acute kinking of the ureter during pregnancy, in the absence of urinary infection, leads to acute pain and rigidity, without morbid urinary findings: acute appendicitis may be closely simulated, but catheterization of the ureter will usually relieve the pain and settle the diagnosis.) In pyelitis of pregnancy the best treatment is found in catheterization and irrigation of the renal pelvis. Many apparent failures are due to omission to pass the catheter sufficiently high.

251 Atrophy of Female Genitals after Castration

F. RÓZSA (*Thèse de Paris*, 1934, No. 350), who records nine illustrative cases in women aged from 33 to 55, states that surgical castration in women may be followed by trophic disturbances which may affect the whole or part of the genital tract remaining after the operation. Subtotal hysterectomy is succeeded by atrophy of the cervix and diminution of the secretion of the glands of the cervix, while the vulva and vagina undergo a sclerotic retraction similar to the kraurosis vulvae of old age. The trophic disorders of castration are mainly due to removal of the ovary and the complete disappearance of its internal secretion. The preservation of a single ovary or the activity of an ovarian graft appears to be sufficient to protect the patients from these trophic changes without the uterus being preserved. Treatment is mainly preventive. In some cases it is possible to keep a part of the uterus or one of the ovaries. When atrophy of the genitals has taken place the treatment must be general by administration of ovarian extract and local by dilatation with the speculum or dressings. When the atrophy is associated with leucoplakia the affected tissues should be excised as freely as possible so as to prevent cancer of the vulva.

Pathology

252 Factors Predisposing to Infection with *Cl. septicum*

GRIZEL R. BORTHWICK (*Brit. Journ. Exper. Path.*, June, 1934, p. 153) has carried out experiments on guinea-pigs to determine the conditions favouring infection with the anaerobic spore-bearing organism, *Cl. septicum*, from the alimentary tract. Cultures of this organism rarely set up infection when fed to normal guinea-pigs—for example, in a series of thirty animals tested not a single death occurred. Adjustment of the gastric contents to pH 7.6 did not seem to favour infection, only one out of twenty-one guinea-pigs dying. Similarly, adjustment to pH 5, which was found to be the most favourable H ion concentration for the activity of the toxin, had little effect in favouring infection: only three out of twenty-one animals died. On the other hand, inhibition of peristalsis by previous administration of narcotine led to the death of fifteen out of twenty-one animals when the pH of the gastric contents was not adjusted, and to the death of

fifteen out of twenty animals when the pH was adjusted to 7.6. Previous exposure to cold led to the death of nine out of twenty animals when the pH was not adjusted, and to the death of sixteen out of twenty when it was adjusted to 7.6. Cooling of the culture to 0° C. had much less effect; only four out of twenty-two animals died under these conditions. It appears, therefore, that the two most important factors predisposing to infection are stasis of the gastro-intestinal tract and exposure of the animals to a low temperature. It was thought that exposure to cold might act by inhibiting peristalsis, but experiments failed to lend any support to this view. The feeding to guinea-pigs of toxin alone, in 8 to 10 c.c.m. quantities, proved harmless, nor did the administration of narcotine or the adjustment of the gastric contents to pH 5 or pH 7.6 render it active. This suggests that the toxin is not absorbed from the intact mucosa of the stomach or intestine.

253 Effect of Supersonic Waves on Bacteria

A. C. H. YEN and SZU-CHUN LIU (*Proc. Soc. Exp. Biol. and Med.*, June, 1934, p. 1250) have studied the destructive action of supersonic waves on a number of different bacterial species. The waves, which consist of actual molecular vibrations, were produced by means of an oscillating current, the quartz plate being adjusted to vibrate at 1.5×10^6 times per second. The bacterial suspensions to be exposed were placed in a test tube, 15 mm. in diameter, containing a glass cooling-coil to prevent the temperature rising above 20° C. Plate counts were made before exposure and at intervals up to ninety minutes during exposure. There seemed to be a more or less continuous variation in the susceptibility of the different species of bacteria to the supersonic waves. The anthrax bacillus, for example, seemed to be very little affected. A definite reduction occurred in the numbers of *B. subtilis*, and a still greater reduction in those of a group of nasopharyngeal organisms, including Pfeiffer's bacillus, *N. catarrhalis*, and *Str. haemolyticus*, together with *Staphylococcus aureus*. *B. coli* and *B. typhosum* were completely destroyed in ninety minutes, while *proteus* X 19 and Shiga's dysentery bacillus survived for only forty-five to sixty minutes. The mechanism of action of the supersonic waves was not determined, but studies on the opacity of the suspensions suggested that actual cellular disintegration was occurring with the liberation of protein which subsequently underwent coagulation.

254 Outbreak of Botulism

A. STRØM (*Tidsskr. f. d. Norske Lægefor.*, June 15th, 1934, p. 633) gives an account of a small epidemic of botulism traced to an infected ham. In the middle of December, 1933, a servant girl fell ill, her most troublesome symptom being paresis of the accommodation of the eyes, lasting between one and two months. The next two cases on the same farm developed at Christmas, the illness lasting only a week or two. Early in February three of the farm's workers left it temporarily, and after a couple of days one of them had to return home, feeling ill. His place was taken by another worker, who after a couple of days became very ill, his illness lasting several weeks, and his symptoms including paresis of the muscles of accommodation, the abductors, the intestines, and the bladder. In practically every case the disease began with diarrhoea and vomiting, which lasted twenty-four hours. A couple of days later dryness of the throat and giddiness were complained of, the pupil reflexes were absent, constipation was severe, and the patients were mentally sluggish. Though all recovered some were very exhausted, and the pulse in a couple of cases was up to 120. Suspicion fell on a couple of hams which the three workers had taken with them on leaving the farm. Samples of these hams and of eight others not yet cut into were sent to the State Institute of Hygiene in Oslo, where experiments on mice and guinea-pigs, supplemented by culture tests, demonstrated the presence of the *B. botulinus* in one of the first two hams. The mode of infection of this ham could not be discovered.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine.

255 Epidemiology of Whooping-cough

C. HÜNERMANN (*Deut. med. Woch.*, June 29th, 1934, p. 978) has made a practice during the past two years of getting all the children in the whooping-cough section of his hospital to cough on to Bordet-agar-blood-culture plates, and he has succeeded in thus finding the Bordet-Gengou bacillus both in the catarrhal stage of the disease and during the first four to six weeks of the convulsive stage. After this interval repeated cough tests failed to demonstrate this bacillus—an observation from which the author concludes that whooping-cough is infectious only during this interval. A search for carriers of the Bordet-Gengou bacillus proved negative in the case of children showing no sign of disease. But in a certain number of cases this bacillus was found in children subject to a more or less obstinate cough in which there was no whooping element. It would appear, therefore, that even in children who have never received prophylactic vaccination against whooping-cough this disease may still exist in such a light, abortive, and atypical form that its true nature would be overlooked in the absence of a bacteriological examination.

256 Primary Mumps Orchitis

C. M. HOOGENBOOM (*Nederl. Tijdschr. v. Geneesk.*, July 14th, 1934, p. 3275) records the case of a man, aged 37, who developed right orchitis, epididymitis, and deferentitis nineteen days after his daughter had developed mumps. He had had no injury to the testis, and there was no evidence of gonorrhoea. Six days later his two sons showed bilateral parotitis, and on the following day he developed left parotitis himself. Complete recovery took place without any testicular atrophy.

257 Odd Reactions to Tuberculin

H. HOFF (*Wien. med. Woch.*, July 14th, 1934, p. 811) records the case of a 54-year-old patient who responded to therapeutic injections of tuberculin with attacks of trigeminal neuralgia. They occurred even when the dosage of tuberculin was most timid. Another patient, aged 34, responded to therapeutic injections of tuberculin by suddenly seeing bright-coloured rings which rapidly approached him. He would then fall and lose consciousness for a few minutes, and would feel very tired after recovering from such an attack. It should be noted that he had been subject to similar attacks before treatment with tuberculin was instituted. In a third case, that of a woman aged 35, injections of tuberculin were followed by slight tetanic convulsions.

258 Aortic Stenosis

S. McGINN and P. D. WHITE (*Amer. Journ. Med. Sci.*, July, 1934, p. 1) record conclusions drawn from a review of 4,800 cardiovascular cases seen in private practice and 6,800 hospital post-mortem examinations. This material produced 123 cases of aortic stenosis proved by necropsies and 113 clinical cases. In the post-mortem series aortic stenosis occurred nearly as often as mitral stenosis, but was less frequent in the clinical series owing to the difficulty of recognizing slight degrees during life. The authors think it justifiable to make this diagnosis when a loud, harsh systolic murmur is heard in the region of the second right intercostal space and is transmitted to the neck in the absence of pronounced aortic dilatation due to syphilitic aortitis or marked hypertension, especially when there is evidence of other valvular deformity or a history of rheumatic infection. An aortic systolic thrill, a diminished or absent second aortic sound, a plateau pulse, and an aortic diastolic murmur are important corroborative findings, but are not essential to the diagnosis, being late signs. The presence or absence of calcareous changes in the aortic cusps is said clinically to be rela-

tively unimportant as compared with the aortic stenosis itself, except in so far as it alters the degree of stenosis or aids in the x-ray diagnosis. Patients with pronounced aortic insufficiency in addition to aortic stenosis had a shorter terminal illness and died younger than did the cases where stenosis predominated. The authors are satisfied that all grades of aortic stenosis exist, with varying symptoms and signs, much as in the case of mitral stenosis. The aortic form, even of considerable degree, is common, particularly in males; is often caused by rheumatic infection; is less serious than aortic regurgitation of high degree; and is sometimes associated with considerable hypertension. It is often overlooked, and special search should be made for it, even in the lesser grades, because of the progressive nature of the lesion and the frequency with which it is associated with congestive heart failure.

259 Thoracic Trauma and Pulmonary Tuberculosis

Citing numerous cases from the literature and two personal cases, N. N. STOICHIȚA (*Presse Méd.*, June 30th, 1934, p. 1051) states that pulmonary tuberculosis can be caused by thoracic contusions. Penetrating wounds are not usually followed by this complication, since as a rule they mortally injure the heart or large vessels, thus causing fatal haemorrhage. Infection of the contused pulmonary area through the respiratory passages or by bacilli circulating in the blood has been advanced as a possible pathogenic factor. Distension of the lung, due to a reflex occlusion of the glottis preventing expiration, is the essential cause of the rupture during trauma. The injured tissue with the consequent haematoma forms an excellent medium for the development of the Koch bacilli. In most cases the thoracic contusion activates a latent tuberculosis; occasionally it aggravates an active one. The onset of post-traumatic pulmonary tuberculosis may consist of haemoptysis, or it may be pneumonic or pleuritic. The site of the lesion usually corresponds to the injured area. In most cases the clinical signs appear in three to six months after the trauma, and the evolution of the disease is, as a rule, rapid and grave.

Surgery

260 Tuberculosis of the Knee in Adults

H. WALDENSTRÖM (*Hygiea*, June 30th, 1934, p. 401) has come to the conclusion that operative treatment is indicated in every case of tuberculosis of the knee in adults as soon as it has been diagnosed with certainty. In the past the results achieved in different quarters in the treatment of this disease have varied greatly with the correctness of the diagnosis, the successes being directly proportional to the mistaken diagnoses. A clinical examination, supplemented by an x-ray examination, is, he states, inadequate. The correct diagnosis can with certainty be made only by an expert microscopical examination of the capsule of the joint and of an effusion in it. After aspiration, this fluid should be injected into a guinea-pig or two. If the guinea-pig test is negative, a snip of the synovial membrane should be examined by an expert for tubercle bacilli and typical tubercles. It is well to defer such an exploratory excision of the capsule of the joint for some time in order that the tuberculous disease, if present, may have extended to the whole of the joint, otherwise an exploratory excision may yield an island of still healthy tissue. During the past ten years the author has applied these criteria to twenty-five persons over the age of 17. In twenty of these cases tuberculosis was diagnosed on the strength of an exploratory excision, and in the remaining five on that of a guinea-pig test. Both tests were employed in six cases. In as many as nineteen of the twenty-five resection was performed, in all but two instances after protracted conservative treatment had proved

futile. Whatever the treatment, there are only two alternatives—ankylosis, or retention of some degree of mobility. The former can be achieved much more rapidly by an operation than by conservative treatment, and if it assures the retention of movement there is always the prospect of a relapse, even years after an apparent cure, as a result of a long walk or other excessive claim on the joint's functional capacities.

261 Traumatic Aneurysm of the Subclavian Artery

W. LEE, C. MITCHELL, and A. PEACOCK (*Ann. of Surg.*, July, 1934, p. 87) point out that, though the onset of aneurysm of the subclavian artery is so gradual as to obscure the diagnosis, yet a correct one can usually be made when there is a history of trauma, signs of swelling, expansile pulsation, a bruit, and an increasing severity of symptoms. Conservative treatment is sometimes advocated, but is not so successful as operation, particularly in cases of traumatic aneurysm. Good operative results depend on prolonged and safe anaesthesia, adequate exposure, repair of the vessel, and post-operative care. Avertin, with ether inhalation, has proved a satisfactory anaesthetic. The two routes of exposure are: the anterior, in which the location and type of incision are variable; and the posterior, which passes through the posterior mediastinum and may be used in cases involving the first portion of the left subclavian artery. With the anterior approach a partial resection of the clavicle is necessary to gain adequate exposure. Operative technique must depend upon the condition encountered, and may consist of ligation, excision, or endo-aneurysmorrhaphy. Post-operative complications consist of primary or secondary haemorrhage, shock, collapse of the lung, gangrene of the extremity, and infection. Complete rest, by means of a cast, bandage, or splint, is absolutely essential after operation, and large doses of sedatives are necessary. A record is given of 128 cases of traumatic aneurysm of the subclavian artery, and one case is reported which originated from the first portion of the artery and was successfully excised, the opening in the artery being closed with lateral sutures.

262 Treatment of Hydrocephalus

T. J. PUTNAM (*New England Journ. Med.*, June 28th, 1934, p. 1373) describes a method of treating hydrocephalus by coagulation of the choroid plexus. The ventriculoscope used carries a tiny bronchoscope light and electrodes for diathermy. Through a trephine hole the apparatus is passed into the lateral ventricle and down to the fossa in which the plexus lies. The current is turned on and carefully limited coagulation ensues, the tissue within the field of operation turning from red to white. Avertin anaesthesia is usually employed, but the patient generally moans slightly when the coagulation begins. The reaction to the operation is slight, and directly proportional to the amount of haemorrhage. The infant is often able to resume its feedings in two or three hours. Each ventricle is dealt with separately, an interval being introduced between the two operations. The author states that endoscopy with coagulation has been performed twelve times in seven unselected cases of hydrocephalus, the age of the infants ranging from one to eighteen months at the time of the operation. In most of the cases hydrocephalus had been the sequel of operations for meningocele. Two patients died, but it is doubtful whether either death could be ascribed to the operation. The procedure seemed to have no ill effects on the mentality. Two patients had a few convulsions in the subsequent fortnight, but no other complications were observed. Putnam remarks that, considering the otherwise almost hopeless outlook in hydrocephalus, the immediate results of this treatment appear encouraging. The relief of the intracranial pressure was always manifest, bulging of the fontanelles was terminated, and the diameter of the head was decreased in all cases except one. There would seem to be at least as much hope of permanent benefit as in the more immediately dangerous operation of removing the choroid by open operation.

Therapeutics

263

Dietetic Treatment of Obesity

According to G. A. HARROP (*Journ. Amer. Med. Assoc.*, June 16th, 1934, p. 2003) a diet having as its basis bananas and milk is an effective way of treating obesity, and is commended on the grounds of simplicity, low cost, ready availability, palatability, high satiety value, and low salt content. The strict diet consists of six large bananas and 1,000 c.cm. of skimmed milk, taken in three or four meals, which are spaced according to the individual preference. The caloric value of this is estimated as being 940. A salad of a quarter medium-sized head of lettuce, or of an equal quantity of cabbage, is a useful and valuable supplementary at one meal during the period of strict dieting. In about ten days to a fortnight there is a loss in weight of four to nine pounds in persons who are moderately active, and who continue their usual routine. Reduction to four bananas daily is well tolerated by many, and the results are said to be more striking; weakness and severe physical discomfort must be avoided. Fluids without food value, including tea and coffee but without milk and sugar, are freely permitted, but salt is avoided in order to obviate retention of fluid in the body. At least six large glasses of fluid must be taken daily in addition to the milk. After about a fortnight the diet is modified by the gradual substitution of one or two bananas by one or two eggs and a little butter. Green vegetables may also be taken with butter poured over them, though not used in the cooking. Then lean meat, fish, or poultry can be added, but no pork or thickened gravy. The strict and modified diets are alternated, each continuing for about a fortnight at a time. The limit to which weight reduction can be continued is given as one or two pounds a week, or five to ten pounds a month. Some hunger and weakness at the start of the treatment are not uncommon, and need not be considered as deterrent, being replaced at the end of a week by a feeling of well-being. Weight loss in excess of two or three pounds a week indicates an undue loss of water, except when the diet has been markedly curtailed. The larger losses at the beginning of treatment represent the displacement of water from the tissues, and this should be explained to the patient to prevent alarm. The author adds that although the nitrogen intake is low on this diet the nitrogen balance was maintained fully in six cases observed, and only slightly reduced in four others.

264

Application of Vitamin A to Wounds

Z. HORS and S. SANDOR (*Deut. med. Woch.*, July 6th, 1934, p. 1018) report from their hospital in Ujpest observations on the action of an emulsion and an ointment of high vitamin A content on wounds liable to become septic, and in cases of phlegmon, tendo-vaginitis, carbuncle, lymphadenitis, etc. The same treatment was also applied after operations for appendicitis, gall-stones, etc., when the wounds were left open. The preparation of vitamin A contained 2,000 international units per c.cm., and the name given to it by the firm of Richter in Budapest was "vulnovitan." The investigations were conducted in a surgical hospital, but the authors make no reference to any control tests. After immobilization had been effected by splints, extension, etc., and the neighbourhood of the wound had been cleaned, the emulsion or ointment was applied, and a layer of gauze, saturated with the oil, was secured in place. Six to eight days later, when the dressings were changed, there was a lively growth of granulation tissue showing no inflammatory reaction. The system previously adopted of irrigating the wounds, chiefly in a bath, was found to be injurious in association with this new treatment. It not only facilitated the escape of discharge from wounds already septic, but it also inhibited secondary infections by the promotion of granulation tissue, the growth of which was apt to be even too luxuriant. When this happened, mild antiseptic dressings had to be applied

alternately with the vitamin A dressings. The authors suggest that the success recently achieved by Löhr in the local treatment of wounds with cod-liver oil may depend on the same principle that they have exploited.

Anaesthetics

265 Lumbar Anaesthesia with Pantokain-L

O. UITER (*Finska Läkarsällskaps Handlingar*, May, 1934, p. 428) has studied the effects of lumbar anaesthesia with pantokain-L in a Finnish hospital in which, since the autumn of 1933, 162 out of 1,350 major operations were performed by this means. In 144 cases the anaesthesia was perfectly satisfactory, and in fifteen cases—nervous patients for the most part—it was necessary to supplement with a little ether, the dosage of which was only 10 to 30 grams—that is, enough to have a merely psychic effect on the patient by virtue of the smell. In only three cases was the anaesthesia a failure, possibly because anatomical anomalies prevented the deposit of the anaesthetic in the desired place. A blood pressure of 100 mm. of mercury or less was considered a contra-indication for this form of lumbar anaesthesia: when this rule was broken, a preliminary injection of "racedrin" was given to prevent a further fall of the blood pressure. A smaller dose of racedrin was given when the blood pressure was normal. In at least two cases complications associated with the anaesthetic were traced to the neglect of a preliminary measurement of the blood pressure, and the author is most emphatic as to the necessity of such measurements. A quarter of an hour before the administration of the pantokain-L, morphine and hyoscine should be injected subcutaneously; they hasten the action of the pantokain-L and render the patient less nervous during the operation. The severe headache supposed to follow pantokain-L anaesthesia was never observed by the author, who connects his freedom from this complication with his adoption of the Trendelenburg position, with the head so low that the spine forms an angle of 5 to 10 degrees. Several of the patients could not have taken a general anaesthetic because of their advanced age, high blood pressure, fatness, or pulmonary complications. This selection of the unfittest for pantokain-L anaesthesia must be taken into account with the admission that the complications among the author's cases were perhaps more frequent than after an ether anaesthesia. Convalescence was, however, remarkably satisfactory on the whole, particularly in connexion with that gas retention which is apt to follow laparotomies. The author is most appreciative of this anaesthetic in gynaecological operations, which constituted sixty-two of the total of 162 operations. Pneumonia did not follow one of them.

266 Combined Avertin and Nitrous Oxide Anaesthesia

Based on the results in 600 cases, DESMAREST (*Presse Méd.*, May 19th, 1934, p. 811) advocates combined avertin and nitrous oxide as a most valuable anaesthetic. It should not, however, be given as routine in all cases. Avertin (the French "rectanol") is not a true anaesthetic but only produces a calmer sleep; narcosis must be attained by a complementary narcotic, and as nitrous oxide is the sole physiologically perfect anaesthetic, this is chosen. Contra-indications to this anaesthesia are a bad general condition of the patient (its use is dangerous in debilitated conditions or renal and hepatic diseases) and arterial hypotension. The oculo-cardiac reflex and basal metabolism are valuable guides to correct dosage. These, especially if concordant, indicate the patient's resistance or sensibility to anaesthesia of the base. The duration of the operation also governs dosage—the longer the operation the larger the dose required. Pantopon, given one hour before the avertin enema, is an excellent adjuvant. Nitrous oxide administration should be started twenty minutes after giving the enema. Narcosis during the operation is rarely disturbed. Should respiratory symptoms arise, carbon dioxide should be administered.

Avertin does not cause as great a lowering of blood pressure as was first supposed, and the nitrous oxide usually suffices to restore the equilibrium. If after operation the arterial tension is low and remains so, an injection of ephedrine (1 c.cm.) should be given. Tardy awakening is due to an imperfect elimination of the avertin; such cases should be closely watched and, if awakening does not occur in one or two hours, subcutaneous injections of coramine or cocaine should be given; thyroxine is also useful. Post-operative complications are less frequent with this combined method than with nitrous oxide alone or with ether. Pulmonary complications are seldom noted, and avertin has no unfavourable action on the hepatic or renal functions when these are normal before operation; if renal or hepatic lesions exist, the drug must be used with great caution. Repeated anaesthetics with avertin can be safely given. A further advantage to the use of this combined form of anaesthesia is that it is agreeable to and not feared by patients.

267 Evipan Anaesthesia in General Practice

In order to indicate the suitability of intravenous injections of sodium evipan for inducing anaesthesia in general practice T. S. NICOL and T. M. BELL (*Charing Cross Hosp. Gaz.*, July, 1934, p. 100) record summaries of twelve cases in which it was used for such minor surgery as the opening of boils and abscesses, the removal of nails, needles, and splinters, and the incising of whitlows. An ampoule producing 10 c.cm. costs 2s. 3d. The solution in sterile water is slowly injected into a vein until the patient yawns or loses consciousness, when a further 2 or 3 c.cm. is introduced according to the length of anaesthesia needed. From three to five minutes of full anaesthesia follows, after which the patient may sleep for several hours. Muscular relaxation was poor. Evipan can, it is stated, be administered single-handed, although it is better to have an assistant to hold the arm during the injection, since the patient may sometimes make clonic movements. Slight dizziness may ensue, and patients should not be allowed to go out alone in the succeeding three hours. Other precautions advised are urine testing and inquiry as regards previous nephritis, prevention of the tongue falling back, and the availability of coramine in case of collapse—precautions which apply to any other anaesthetic. There are said to be no unpleasant after-effects.

Obstetrics and Gynaecology

268 Premature Placental Separation

T. L. MONTGOMERY (*Amer. Journ. Obstet. and Gynecol.*, July, 1934, p. 33) finds as the result of a careful investigation of over 4,000 obstetrical histories that the diagnosis of premature separation of the placenta is not infrequently confused in the less severe cases with that of lateral placenta praevia. If the two conditions are carefully differentiated, premature separation of the normally implanted placenta would appear to be a less frequent complication of pregnancy than placenta praevia. The type of treatment and the method of delivery have to be adapted to the circumstances of the individual case. Caesarean section is reserved for those instances in which the cervix is closed, and the contraction of the uterus is ineffective in producing dilatation—where longer waiting implies more bleeding. In the author's series of sixteen cases of definite premature placental separation there was one maternal death, a rate of 6.6 per cent. The foetal mortality rate was 81 per cent. Twelve of the sixteen foetuses were premature. Montgomery considers external violence an infrequent cause of placental separation. Various degrees occur often during the course of labour in consequence of intra-partum attempts at delivery, or of a sudden decrease in the volume of the content of the uterus. The most frequent aetiological factor in premature separation is toxæmia of pregnancy, abdominal trauma accounting

for only an occasional case. Renal toxæmia is more often encountered as a cause than is pre-eclampsia or eclampsia. The author considers that there is no reason to invoke the presence of some new or strange type of toxic disturbance to account for this disturbance. The characteristic lesion in the placenta is hæmorrhage. Interruption of pregnancy often follows, although the presence of old hæmatomas on the surface and in the substance of the placenta in cases of nephritic toxæmia indicates that small hæmorrhages frequently occur without terminating pregnancy. These hæmorrhagic lesions are quite different in structure and aetiology from placental infarctions. Necrosis (infarction) is found frequently in the placenta of both normal and toxic patients. Its presence appears to play no part in the aetiology of placental separation or pregnancy toxæmia.

269

Virginal Leucorrhœa

Reporting research work on leucorrhœa in virgins, R. CRICKSHANK and A. SHARMAN (*Journ. Obstet. and Gynaecol. British Empire*, June, 1934, p. 369) find (1) the non-infective type of secretion to be white, viscid, cheesy, containing Döderlein's bacillus, and having an average pH of 4.4. This type appears along with excess of glycogen deposit in the vaginal epithelium, and is connected with the presence of increased quantities of oestrin. It is found also in the newly born, and very strikingly in pregnancy. The suggestion is made that such non-infective leucorrhœa may occur in virgins (or similarly after marriage) when the normal balance between the anterior pituitary and ovarian hormones is disturbed. Treatment must not be that used locally for infective types, but general. Hormone therapy had not so far proved successful. The use of "antuitrin-S" is suggested for trial. In some cases only was there other evidence of endocrine imbalance. The research is to be pursued with monkeys. (2) Infective virginal leucorrhœa was traced to *Trichomonas vaginalis* in the majority of such cases, the discharge being watery, yellow, and generally irritating. One case of monilia was found. Tubercle is an occasional cause.

270 Abortion in Human Infection by B. Abortus (Bang)

F. WITENSTEIN (*Zentralbl. f. Gynäk.*, July 7th, 1934, p. 1583) describes a case of spontaneous abortion in the fourth month in a female cook who had had a three weeks' illness diagnosed first as influenza, then as typhoid fever, and finally (serologically) as Bang's disease. Abortion in the human (unlike the bovine) infected subject is very uncommon, and may be held to be an unspecific reaction, such as might occur in any febrile disorder. That explanation seems to be contraindicated, in the present case, by the facts that expulsion of the placenta had been preceded by a specific vaccination, and that its removal by curetting was followed by a negative serological test. In the cow Bang's disease is followed by sterility; but Witenstein's patient later became pregnant twice. Allusion is made to Schürer's case, in which a gynaecologist became infected with Bang's bacillus during a curetting.

271

Tertiary Syphilis of the Uterus

P. LIZET (*Thèse de Paris*, 1934, No. 444), who records five illustrative cases in women aged from 19 to 41, states that syphilis of the uterus is much more frequent than is generally supposed. Lesions of the cervix must be distinguished from those of the body of the uterus. The former are usually due to direct infection, while the latter are mostly the result of congenital syphilis. Tertiary syphilis of the body of the uterus assumes the gummatous form, the lesions being mainly vascular or perivascular, with the result that hæmorrhage, death of the foetus, and abortion are liable to occur. In all cases of metrorrhagia of which the cause is doubtful, antisyphilitic treatment should be tried before an extensive operation, curetting, or even radiotherapy is carried out.

Pathology

272

A Modified Aschheim-Zondek Test

A. MANDELSTAM and E. KAPLUN (*Wien. klin. Woch.*, June 29th, 1934, p. 813) state that the ordinary Aschheim-Zondek test for pregnancy has two drawbacks—namely, it takes about 100 hours and requires the relatively large number of five infantile mice. They found that the time consumed could be cut down to fifty hours by the intravenous injection of detoxicated urine into the tail vein. This requires a little practice, and must be done slowly to prevent the occurrence of shock or embolism. Adult mice are used in their modification and three injections of 1 c.cm. urine are given in the first twenty-four hours, and one the following morning. The mice are put in cages which are irradiated with infra-red light from lamps of 40 to 200 watts for two days before the injection and immediately afterwards. Forty-eight hours after injection laparotomy is done through an incision from the back parallel to the spine. In the kidney region a window is made in the peritoneum through which the ovaries are drawn out and inspected with the naked eye or by means of a lens. Macroscopic hæmorrhages into the ovaries can be observed with ease. The ovaries are replaced and the wound closed with two to three stitches. The mice can be used again after one month. The test requires two mice or even only one mouse. Positive results are obtained in 98 per cent. of cases. The advantages of this modification are stated to be: reduction of time; reduction of the number of mice used; accuracy; use of adult mice, which are easily and cheaply obtained, and which may be used again.

273

Cultivation of the Gonococcus

J. W. McLEOD, J. C. COATES, F. C. HAPFOLD, D. P. PRIESTLEY, and B. WHEATLEY (*Journ. Path. and Bact.*, July, 1934, p. 221) describe a method for the cultivation of the gonococcus that has proved of great value in routine diagnosis. The medium used is a 10 per cent. heated blood agar, prepared from broth made according to Wright's method. The essential feature of Wright's method is the addition of the peptone before the meat is extracted; in this way inhibitory bodies, which are normally formed as a result of the oxidation of the peptone during autoclaving, are reduced by substances in the meat. The percentage of agar in the medium is kept as low as is consistent with stability. The plates are incubated at 36° C. for eighteen hours in a closed jar containing air, 8 per cent. of which has been replaced by carbon dioxide. A further incubation for twenty-four hours is carried out under ordinary aerobic conditions. Comparative experiments have shown the beneficial effect of carbon dioxide on the growth of the gonococcus in primary culture. After incubation is complete, a 1 per cent. solution of tetramethyl-*p*-phenylenediamine hydrochloride is poured over the plate and run off immediately. The effect of this solution is, by an oxidase reaction, to turn gonococcal colonies a bright purple colour. Medium-sized convex and translucent colonies which rapidly turn a bright purple, and which consist microscopically of Gram-negative diplococci, are accepted as gonococci. For complete identification, when necessary, the colonies can be picked off, and the organisms studied by fermentation reactions and their ability to grow on ordinary nutrient agar. Occasionally, colonies giving the oxidase reaction and consisting of Gram-negative diplococci have been isolated from the genito-urinary tract which subsequent examination has shown were not true gonococci. Organisms of this type are likely to give rise in 1 to 5 per cent. of cases to erroneous diagnosis if reliance is placed on the smear method alone. Numerous tabulated results are given to show that the cultural method is considerably more delicate than the direct smear method, but it is pointed out that a certain number of cases do occur in which the smear method is positive when no gonococci can be isolated in culture.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

274 Prevention of Serious Arsphenamine Reactions

According to M. SCARF (*Journ. Amer. Med. Assoc.*, June 30th, 1934, p. 2159), who records six cases, a large proportion of fatal or disabling reactions due to the administration of arsphenamine may be prevented by a careful evaluation of symptoms and signs occurring in syphilitic patients under this treatment. One case of aplastic anaemia developed under neoarsphenamine therapy when two injections were given after the appearance of purpura. In one of the two cases of hepatitis, one injection of this preparation was administered after the patient had complained of itching. Haemorrhagic encephalitis occurred as a complication in a case of gonorrhoeal arthritis with a negative Wassermann reaction in which two injections of this drug were given in increasing doses, although an eruption had followed the first one. In a case of aneurysm of the aorta, rupture followed neoarsphenamine therapy, which had been too vigorous, and had not been preceded by a preparatory course of the milder antisyphilitic drugs. A case of transverse myelitis, due to a rare and usually fatal form of Hershheimer reaction, terminated in complete recovery. Scarf argues that, while the occurrence of haemorrhagic encephalitis might have been held to be unpredictable and unavoidable, it may be doubted whether a drug capable of producing such serious sequelae should be used in gonorrhoea or any other disease in which its capacity for good has not been definitely established. Moreover, a maculo-papular rash had followed the first injection, but this indication of intolerance was ignored. The author concludes that the slightest sign of intolerance should receive great attention when arsphenamine products are being administered, and that the risk to the liver should be always borne in mind if itching occurs, and even in the absence of jaundice.

275 Complications of Diphtheria Immunization

L. J. ICHARD (*Thèse de Paris*, 1934, No. 140), who records ten illustrative cases, seven of which occurred in children aged from 26 months to 8 years, and three in adults, states that immunization against diphtheria by anatoxin has given rise to the following series of complications: (1) local inflammatory reactions, such as oedema at the site of injection and non-suppurative adenitis and a general febrile reaction; (2) less frequently, complications resembling serum sickness, such as urticaria and various eruptions with or without arthralgia or myalgia and even paresis of the lower limbs; (3) rarest of all, haemorrhagic complications, such as purpura haemorrhagica and haemorrhagic nephritis. The explanation of these complications is to be found in the individual who is specially sensitive to the proteins of the diphtheria bacillus and not in the anatoxin itself. To avoid such complications the following rules should be observed. As far as possible only young children should be immunized, 18 months being the most suitable age. In the case of children over 7 years of age and adolescents, only those who are Schick-positive should be inoculated. Special precautions should be taken with those showing a pseudo-positive reaction. In such cases Zoeller's anatoxin reaction should always be performed before vaccination. Immunization is contraindicated in cases of pulmonary tuberculosis, cardiac affections, or renal or blood diseases. Convalescents from diphtheria or other acute diseases should not be inoculated, but one should wait until at least two months after recovery.

276 Surgical Operations in Pernicious Anaemia

R. G. HAHN (*Amer. Journ. Med. Sci.*, July, 1934, p. 60) reports a series of thirty-two cases of pernicious anaemia in which operations were required. Discussing the influence of the operation on the disease, he comes to the

conclusion that intensive pre-operative treatment and special care afterwards induce a satisfactory degree of tolerance, and render the patients good surgical risks. He points out, however, that in these cases there seems to be a definite tendency to the precipitation or increased development of neurological symptoms. These must therefore be forestalled by intensive liver therapy beforehand. In the author's thirty-two cases no deaths occurred which could be attributed directly to the operation. In eight cases operated on before the introduction of liver therapy many blood transfusions were necessary in each instance; in the remaining cases blood transfusion was only twice employed. The operations were deferred, if possible, until the red blood cell count had been brought within the normal range. If an immediate surgical intervention was indicated, the operation was performed, and the patient received intensive liver therapy. After the operation it was not found difficult to restore the red blood cell count. There were three deaths, all in cholecystectomy cases, recalling, as the author points out, the possible relationship between biliary and hepatic disease and pernicious anaemia. All had moderate subjective nervous symptoms, and in two these became worse after the operation. Many of the patients in the series had sources of blood loss or infection which rendered operative treatment necessary. The removal of these sources appeared to have a definite therapeutic value, for subsequent blood counts showed an increase in the number of erythrocytes.

Surgery

277 Primary Carcinoma of the Lung

A. YOUNG (*Ann. of Surg.*, July, 1934, p. 1) points out that successful surgical intervention in primary carcinoma of the lung is rarely possible owing to the relative infrequency of a localized tumour being situated well out in the lung parenchyma, and to the difficulty and delay in diagnosis. In over 90 per cent. of cases the disease originates in the region of the hilum and spreads into the lung and the mediastinum, so that surgical extirpation is impossible. It is hoped that in the remaining 10 per cent. earlier diagnosis may be made by means of x-rays. A case is reported of primary carcinoma of the upper lobe of the left lung in a man of 42. The symptoms were pain and stiffness in the joints and a slight cough, with an irregular temperature. X-ray examination showed the presence of a rounded shadow in the upper part of the left chest. Artificial pneumothorax was carried out, and subsequent x-rays showed that the mass was in the substance of the lung and was not adherent to the chest wall. Trap-door thoracotomy, followed by lobectomy, was carried out. The patient's condition was good for about two weeks, but then a limited apical pleural effusion became evident and it was necessary to carry out the excision of the eighth rib for drainage. As the discharge persisted a thoracoplasty was performed, and convalescence was then uneventful. The patient was seen two years later and photographs are shown to illustrate the comparatively slight deformity of the chest and the extensive range of movement of the left upper limb. Local and general conditions were satisfactory in every way.

278 Epigastric Hernia

O. MIKKELSEN (*Ugeskrift for Læger*, July 12th, 1934, p. 748) publishes a study of the forty-three cases of hernia between the umbilicus and xiphoid process observed in his hospital in Denmark in the period 1920-32. The relative frequency of epigastric hernia is indicated by the numbers of other hernias observed in the same hospital and period—206 cases of umbilical hernia, 426 cases of crural hernia, and 2,238 cases of inguinal hernia. The opinion that epigastric hernia is congenital is discredited

EPITOME OF CURRENT MEDICAL LITERATURE

by the observation that it is hardly ever seen in children or adolescents; among the author's cases there were only two children, aged 7 and 12 respectively. The assumption that the origin of epigastric hernia is often traumatic, seems also incorrect in the light of the author's material, which did not include a single traumatic case. He considers the term "epigastric hernia" a misnomer, for which did not the condition is due to a preperitoneal lipoma without any hernial sac. In five cases the onset of the symptoms was stormy, with violent pain in the middle of the epigastrium, whence it radiated to both sides, and with vomiting. In all these cases the diagnosis on admission to hospital was incarcerated epigastric hernia, but in no case was incarceration found on operation. With regard to the interpretation of the symptoms, it should be noted that the pain of epigastric hernia is always independent of the nature of the food; and in the one case in which the patient associated the pain with certain articles of food, it transpired later that he also suffered from duodenal ulcer. The only treatment for epigastric hernia is an operation, and it might have been supposed that it would always prove successful, but the author's own observations and the statistics of other surgeons suggest that a goodly proportion of failures is inevitable. These patients seem often to be subject to other ailments, and among the thirty-three of the author's patients who were operated on, there were as many as five who died soon after discharge, although none of them was old.

279 Treatment of Fractures in Children

Dealing only with fractures in children under 14 years of age, A. MARQUE (*Le Scalpel*, July 7th, 1934, p. 949) describes their treatment under three heads: immediate reduction, with or without radiological control, and application of a plaster cast; progressive reduction by continuous extension; and reduction after surgical intervention with or without osteosynthesis. He considers the last-named to be the surest method of obtaining a perfect reconstitution of the bone. Brief comments, with notes on illustrative cases, are made on the fractures most frequent in childhood. These are the femoral and humeral diaphyses, supracondylar fracture of the tibia, forearm, and clavicle. Reduction, even if radiologically controlled, of its surgical neck, and fractures of the humerus and clavicle. Reduction, even if radiologically controlled, followed by plaster application, is not advocated. Continuous extension should be tried in possible cases; horizontal extension is ineffective. Should this method fail after four or five days' trial, osteosynthesis should be performed.

Therapeutics

280 Irradiation of the Pituitary in Graves's Disease

According to G. ÉTIENNE and P.-L. DROUET (*Bull. de l'Acad. de Méd.*, July 10th, 1934, p. 86) iodotherapy of Graves's disease is not always effective, and must always be protected partial thyroidectomy gives improvements which are not always complete and never include disappearance of the exophthalmos. These authors regard exophthalmic goitre as a malady of the pituitary as of the thyroid gland, basing this view chiefly on (1) the appearance of the exophthalmos, (2) the occurrence in Graves's disease of clinical signs of hyperpituitarism (a contraction of the visual fields for white light and hypophyseal hypertrophy which accompanies congenital or acquired thyroid aplasia), (3) the persistence of clinical signs of hyperpituitarism in Graves's disease in type of the visual fields for white light and colours, and also the presence in the urine of hypophyseal principles, giving a melanophore reaction, and (4) persistence of these two signs after thyroidectomy or increased functional activity in the pituitary of a patient with toxic goitre. It is therefore, they say, logical as well as requisite to associate with the usual treatments means directed to reduction of pituitary activity. They record five cases in which irradiation of the hypophysis was employed, in four as the sole therapy. They noted (1) general gain of strength, with improvement in tachycardia and tremor;

(2) improvement in exophthalmos, which practically disappeared in three cases; (3) a diminution in the basal metabolic rate, which became normal in two cases and subnormal in one; and (4) an enlargement of the visual fields in one case at least. The improvement was accompanied in three instances by considerable reduction of blood pressure, especially the systolic. In general the writers envisage radiation of the hypophysis as a treatment adjuvant to iodotherapy and thyroidectomy, and one which may replace partial thyroidectomy.

281 Breathing Exercises in Treatment of Hypertension

L. G. TIRALA (*Med. Welt*, July 7th, 1934, p. 946) finds that a reduction in systolic blood pressure, which is notoriously difficult to bring about by drug treatment, can nearly always be secured—even to the extent of 50 to 100 mm.—in hypertensive subjects who are made to do deep breathing exercises for five minutes three times a day for three or four weeks. The reduction in pressure is maintained if the exercises are persevered with afterwards. The diastolic pressure also is reduced, but to a less extent. The patient is taught to take deep slow breaths of a predominantly abdominal type ("as if to burst a girdle round the belly") followed by slow expirations during which an "oo" sound is hummed through the closed mouth. Training increases the length of expirations from ten to thirty seconds or more. The exercises are done in the first place in the recumbent position in those with very high pressures. As an adjuvant measure it is sought to lower the diaphragm by clearing the bowel of gaseous and other contents by administration of saline aperients and animal charcoal. The subjective symptoms accompanying hyperpiesis disappear, it is stated, as the pressure drops. Tirala does not hesitate to prescribe breathing exercises in hypertensives in whom morbid organic cardiovascular conditions have become established. The good effects are attributed to (1) increase of the left ventricular output, with reflex vaso-dilatation from stimulation of the aortic depressor nerve; (2) production of a relative alkalosis; and (3) a diminution of tone in the vaso-constrictor centre. Early in the course of treatment the blood pressure sometimes shows a temporary increase.

282 Prostatic Hypertrophy in General Practice

H. BISGAARD (*Hospitalstidende*, July 24th, 1934, p. 20) criticizes the hospital treatment of hypertrophy of the prostate, and emphasizes the benefits enjoyed by the patient who remains at home, up and about, in the care of the general practitioner, whose main solution for retention of urine and allied ailments is the occasional use, for a few days, of an elastic permanent catheter secured in place by the looping on itself of the bladder end of the catheter, the loop being controlled by a fine wire passing through the catheter. The author began his twenty years' experience with hypertrophy of the prostate in a hospital where the patients were kept in bed, their bladders irrigated with silver nitrate. When, in general practice, he noticed how much better this class of patient fared when kept out of bed he began to see in confinement to bed the main cause of congestion of the parts concerned, with consequent obstruction to the normal flow of urine. Silver nitrate he came to regard as actually harmful—as an irritant responsible for increased inflammation of the bladder. As for cystostomy, it may indeed afford temporary relief, but it is the beginning of a long chapter of unnecessary troubles. When, therefore, the prostate cannot be treated directly by prostatectomy, the prostate cannot be treated directly by palliative treatment in x-rays, or diathermy, and only palliative treatment of intelligent ambulant treatment, which possesses the additional merit of not uprooting old folks from their homes, to whose environment and dietetic ways they have become so accustomed that admission to hospital and all that this implies entail a considerable psychic shock. The author illustrates his article with reproductions of the permanent catheter he has devised, and which is made by the Danish firm of Simonsen's and Weel's Efterfølger.

Dermatology

283 Sensitization Tests in Skin Diseases

H. V. MENDELSON (Arch. Derm. and Syph., June, 1934, p. 845) records conclusions drawn from an allergic study of 262 patients with cutaneous diseases. A detailed and careful history was obtained in each case, and the following allergy tests were made: dermal or scratch method, intradermal method, indirect or passive transfer test, and patch test. Most commonly the intradermal method was employed; Mendelsohn considers this more reliable than the scratch method and free from danger when properly performed. The dermatoses included eczema, urticaria, and dermatitis venenata (80 per cent. of the cases), and also prurigo, erythema multiforme, angioneurotic oedema, and neurodermatitis. Cases were selected in which an allergic cause was suspected, and 12,600 tests were performed, of which only 1,237 were positive. Of these, 12,486 were intradermal, the reactions being negative in 11,287. In 114 tests by the patch method thirty-eight reactions were positive. The passive transfer method was used to check eighty-four positive intradermal reactions, but only thirty-six were confirmed as positive. Mendelsohn concludes, therefore, that intradermal tests are of little value in demonstrating the cause of skin diseases. Most of the positive reactions thus obtained are of no practical significance. Positive reactions to food substances or inhalants administered intradermally to patients with cutaneous diseases are far less specific than similar reactions to pollens in patients with hay fever. The indiscriminate subjection of patients with dermatoses to a large number of skin tests is held by the author to be unjustifiable. Far greater aetiological help can be obtained by securing a proper history and making a correct dermatological survey. Mendelsohn holds, however, that patch tests are of decided value, especially in cutaneous diseases due to external irritants.

284 Treatment of Psoriasis

J. GOUIN and A. BIENVENUE (Bull. Soc. Franç. de Derm. et de Syph., April, 1934, p. 678) present a study of psoriasis, based on twenty-four cases, short notes of which are given, which shows that this condition very frequently develops in subjects with a tuberculous diathesis, less often in mixed tuberculosis and syphilis, and only exceptionally in simple syphilis. The leucocytic reactions to the respective specific medicaments (gold salts and anti-syphilitic remedies) were first ascertained. Positive (hyperleucocytic) or negative (leucopenic) reactions were sure diagnostic indications as to the basic origin of the disease and, therefore, as to treatment. Two important factors for the cure of psoriasis are removal of the scales, these acting as a screen against the future treatment, and prolonged exposure to the air and light. The former is obtained by daily washings with soap; actual scraping of the lesions, as in cutaneous tuberculosis, is unnecessary. Exposure to the air and light should be of four hours' duration daily; to shorten this period, ultra-violet rays may be employed. In addition to these measures, internal treatment with gold salts or antisiphilitic specifics, according to the leucocytic reactions, should also be given; in cases showing a mixed origin both remedies should be combined. This form of treatment is not only useless but also dangerous in cases with negative reactions.

285 Successful Treatment of Vitiligo

Vitiligo has long been regarded as an incurable condition, but N. BURGESS (Brit. Journ. Derm. and Syph., July, 1934, p. 313) records the case of a girl, aged 13, in which gold treatment has apparently proved effective. Patches of vitiligo were present above the left eye and on the right temple. To them was applied twice a day a 10 per cent. solution of oil of bergamot. Sanocrysin in 0.05 gram doses was injected intravenously once a week, and the affected parts were exposed to ultra-violet light each

week from an air-cooled mercury vapour lamp. The surrounding skin was protected from the rays, and only the leucodermic areas were left bare. Pigmentation began at the end of three weeks, but the full treatment was continued for another seven weeks. At the end of this time pigmentation was complete, but it was thought advisable to continue the applications of light and oil of bergamot for another three months. There has been no recurrence.

286 Sensitization to Adhesive Plaster

J. V. VAN CLEVE (Urol. and Cut. Rev., July, 1934, p. 439) records two cases, in a man aged 52 and a woman aged 26, in which application of adhesive plaster was followed by severe vesiculo-pustular dermatitis. As a result of patch tests the aetiological agent was found to be orris root, which is the constituent of most commercial adhesive plasters. The writer maintains that a more general use of the patch test would show that many cases of eruption following the use of adhesive plaster would fall into the group of sensitization dermatitis.

Obstetrics and Gynaecology

287 Malignant Ovarian Tumours and Pregnancy

According to P. TRILLAT and A. PUTHOD (Gynéc. et Obstét., June, 1934, p. 513) the presence of a malignant ovarian tumour does not prevent conception, which is, however, very rare. The evolution of pregnancy is disturbed to a remarkably small extent, and there is no evidence of noxious effect on the foetus. Contradictory opinions have been advanced concerning the effect of pregnancy on the tumour development, but it is certain that pregnancy does not stimulate growth of an ovarian tumour in the acute fashion which is the rule in mammary cancer. Two cases are recorded, in both of which the tumour had been well tolerated during pregnancy. In the first it was not suspected until the head was found to be mobile and to remain high after cephalic version at term. The second patient, a four-para aged 27, had noted but not reported abdominal enlargement for three years; the presence of a large ovarian cyst was discovered the day after spontaneous delivery. Concerning treatment the writers believe that a malignant ovarian tumour discovered during the first half of gestation indicates speedy operation at which the foetus need not be considered; in the second half expectant measures are justified until term is near at hand.

288 Menstruation after Conception

K. HEIM (Zentralbl. f. Gynäk., July 14th, 1934, p. 1641) quotes contradictory views concerning the occurrence of menstruation after conception. Zangemeister in 1927 stated that the occurrence of menstrual bleedings, somewhat diminished, during pregnancy is not altogether uncommon (a single period occurring in 0.2 and repeated periods in 0.1 per cent. of cases respectively). Typical menstruations, undiminished, occur in some 0.05 per cent. of pregnancies. Döderlein and others, regarding the question from the medico-legal standpoint of paternity cases, have deemed that menstruation can occur after conception; and some, defining menstruation as cyclical bleeding due to ovulation, and denying that ovulation takes place during pregnancy, would regard "menstruation during pregnancy" as a contradiction in terms as well as a practical impossibility. This argument has, however, been shattered by experimental induction of ovulation in pregnant animals by injection of prolactin or other anterior pituitary preparation. Heim records in detail the case of a physician's wife who seventeen to twenty-five days after conception, fourteen days after the commencement of the preceding menstruation and ten days before that of the next, expelled an ovum which was histologically shown to be 15 to 19 days old. The men-

struation preceding the abortion appeared normal in every way, and Heim has no doubt that this case proves the occasional occurrence of menstruation after conception. Further evidence is seen in a case, also recorded, in which what was regarded as a small cervical polypus, removed eighteen days after apparently normal menstruation, was found to be an ovum; curetting of the cavum gave issue, in addition to decidual areas with necrosis and inflammation, to non-decidual endometrium showing a secretory phase.

289

A New Hypnotic in Labour

F. P. SCHÖRNES (*Deut. med. Woch.*, July 13th, 1934, p. 1054) reports from a maternity hospital in Königsberg his tests with R 239, or "rectidon," which is the sodium salt of the secondary amyl- β -bromallymalonylureids. Administered per rectum, it is a powerful hypnotic, inducing sleep in a quarter of an hour. For the induction of twilight sleep, from 7 to 8 c.cm. are injected through a Nelaton catheter into the large intestine after it has been emptied by an enema. The drug is given as soon as regular labour pains have set in and the os has begun to dilate. If the drug is given at a later stage of labour, care must be taken to introduce the catheter so far that the drug is deposited above the level of the descending head; otherwise a rapid succession of labour pains may force the drug out of the rectum. Even when the patient has been nervous and excited, she ceases to groan and scream fifteen to thirty minutes after the administration of this drug; and, sleeping between each labour pain, she is awakened by it and co-operates actively with it. Multiparae, with past experiences as criteria, were very appreciative of the drug. It has no injurious effect on the labour pains, and though it provokes a certain degree of amnesia, the patients respond intelligently to the instructions given them. No ill effects on the child have yet been observed. But chloroform cannot be dispensed with during the passage of the head, as the retention of reflex excitability is apt to favour injury to the perineum.

Pathology

290 Examination of Fresh Tissues by the Wet-film Method

L. S. DUDGEON and N. R. BARRETT (*Brit. Journ. Surg.*, July, 1934, p. 4) report on the application of the wet-film method of examination of new growths and inflammatory diseases to pathological processes generally, basing their conclusions on a series of over 1,000 cases. Malignant cells were found to be easily distinguishable from their benign prototypes, by their staining more deeply and their nuclei having a greater affinity for haemalum. They varied in size and shape, were larger than normal, and their relative position to the adjacent cytoplasm was in no way constant. The value of wet films was found to be particularly evident in the diagnosis of the various pathological conditions of the lips, mouth, and tonsils. A small piece of tissue could easily be removed under a local anaesthetic, and the diagnosis could often be determined at once. Papillomata of the bladder and renal pelvis were earlier diagnosed as carcinomatous in wet films than in sections. It proved difficult sometimes to differentiate chronic mastitis from a normal breast in a wet-film preparation, but in the former, although the epithelium was scarce, there was revealed a fibrous tissue stroma, groups of enlarged and partly degenerated cells from the cyst walls or dilated ducts staining pink with eosin, and foam cells. The authors point out that a diagnosis of "simple" as opposed to "malignant" is the desideratum in most cases, and this should not be difficult except in proliferative mastitis. In this, however, the epithelial cells were found to be very numerous, small, deeply stained, and arranged in plaques, but with indistinct cell boundaries. The finding

of malignant cells in tissues which were apparently normal in appearance, and at some distance from the original focus of disease, was achieved in a large percentage of cases examined with this end in view. Various errors possible in diagnosis from wet films are recorded, and detailed reference is made to pitfalls that may be expected. A number of instances are given in which the diagnosis suggested from the wet film was more complete or more accurate than that of the corresponding section. This occurred most frequently in the diagnosis of tuberculosis. Most of the mistakes in diagnosis were due to errors in technique.

291 New Method for Detection of Occult Blood

I. BOAS (*Klin. Woch.*, June 30th, 1934, p. 942) describes a new method for the examination of occult blood in the faeces. The reagent is a 0.2 per cent. solution of 2,7-diamino-fluorine-chloral hydrate in 50 per cent. acetic acid. It does not deteriorate with keeping, and remains in the same concentration, thus having an advantage over benzidine and guaiacum. A fine smear of carefully washed faeces is made on a clean slab. Pure acetone is poured on and, after gentle shaking of the slab, it is allowed to stand for five to ten minutes. If the smear contains much colouring matter, decolorization is repeated two or three times with acetone. Five c.cm. of absolute alcohol and ten drops of glacial acetic acid are then poured on the faeces, and the slab is gently shaken to and fro, and then allowed to stand for some minutes. The alcohol is poured off, and 3 to 5 drops of the reagent together with 3 to 5 drops of freshly prepared hydrogen peroxide solution are added to the smear. If occult blood is present the smear turns green or blue with increasing intensity in a few minutes. The cleaner the material and the more haematin present, the greater is the intensity. If the smear is kept in a dark place it retains its distinctive colour for twenty-four hours, after which time it turns olive green. If only minute quantities of haematin are present, a late reaction occurs after ten to twenty minutes. If there is no haematin in the faeces, the green colour occurs only when the smear has stood for some time. Boas lays great stress on the thorough cleansing of the faeces with acetone, which dissolves the faecal colouring matter and concentrates the haematin present. The new reagent is not superior to benzidine in detecting minute quantities of occult blood, but it does not deteriorate, and the smear can be kept for several days.

292 Lysis of Human Blood by Cholera Vibrios

E. ZIMMERMANN (*Zeit. f. Immunitäts.*, July, 1934, p. 495) has compared the haemolytic activities of cholera and El-Tor vibrios on sheep and human blood. A synthetic fluid medium was used, made up with peptone, asparagin, and ammonium lactate, to which 5 per cent. of citrated blood was added. The tubes were inoculated and readings taken every day for four days. Of twenty-eight cholera strains tested on sheep blood only three produced good haemolysis; two others showed traces after three or four days. On the other hand, of eighteen El-Tor strains every one produced haemolysis within twenty-four hours. Tested on human blood twenty-seven of the twenty-eight cholera strains produced haemolysis, mostly within forty-eight to seventy-two hours. Only nine El-Tor strains were tested, and of these, eight produced haemolysis within twenty-four hours, and the remaining one after seventy-two hours. Experiment showed that the cholera haemolysin on human blood was thermostable, being destroyed at 65° to 70° C. within an hour. These strains had all been tested a year or so previously on sheep blood, and the same results had been obtained, suggesting that the reaction towards blood is a fairly stable property among the vibrios. Some of the strains had, moreover, been submitted to lysis by the bacteriophage and to animal passage, without any alteration in their haemolytic powers being produced. The author concludes that most true cholera vibrios are capable of lysing human but not sheep blood, while El-Tor vibrios are able to lyse both types of blood.

Medicine

293

Acute Polyarthrititis

K. MOTZFELDT (*Norsk Mag. f. Laegevid.*, August, 1934, p. 905) prefaces his study of acute polyarthrititis with an analysis of all the rheumatic diseases treated in his hospital in the nine-year period 1924-33. Among the 10,000 cases were 615 of rheumatic disease, acute polyarthrititis heading the list with 140 cases. There followed sciatica with 115, muscular rheumatism with 103, osteoarthritis with ninety-four, chronic polyarthrititis with eighty-four, gonorrhoeal arthritis with thirty-five, lumbago with thirty-two, rheumatic fever (without articular manifestations) with ten, and arthritis urica with two cases. Ninety of the 140 patients suffering from acute polyarthrititis were women. It was most common in the late winter and spring, and between the ages of 20 and 30; it was rare after 40. Of the forty-eight patients with a record of one or more earlier attacks of acute polyarthrititis as many as twenty-five showed signs of heart disease. In only one case was there a history of exposure to cold—that of a boy of 15, who had betted that he could be out all one night in the winter. In no fewer than sixty-two cases (44 per cent.) the disease was associated with tonsillitis, and in ten other cases with a catarrhal infection without tonsillitis. Six patients developed their first attack of acute polyarthrititis after they had undergone tonsillectomy. Since 1926 the sedimentation test has been systematically employed by the author and found invaluable in the clinical control of the disease. The sedimentation rate was never normal in this disease, and during convalescence this test was the only means of ascertaining whether the disease was smouldering or not. Before 1926 the average stay in bed was six weeks; since then it has risen to nine weeks in response to the warnings of the sedimentation test. Electrocardiography has convinced the author that heart disease is an integral component of acute polyarthrititis, for which the best treatment is prolonged rest in bed. He does not regard salicylates as a specific.

294 Fatal Intoxication by Sodium Salicylate

G. PAISSEAU, E. FRIEDMAN, and C. VAILLE (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, July 16th, 1934, p. 1201) record a case (a child aged 10 years) of rheumatic endocarditis in which, after five days' salicylate treatment (2 grams intravenously and 5 grams rectally), symptoms of intoxication, due to an acidoketosis of salicylate origin, together with renal insufficiency, developed. Despite intensive alkalization death occurred three days later. The post-mortem revealed discrete renal lesions and massive fatty degeneration of the liver. Two peculiarities were noted in this case (*ibid.*, p. 1211): a lowering of the cell-plasma chlorine ratio and hyperglycaemia. Insisting on the rarity of death following this medication, the authors suggest an individual predisposition as a factor. They still advocate large doses of the salicylate, but advise that double doses of sodium bicarbonate be given simultaneously. Examinations for acetonuria should be made systematically. The salicylate should be immediately suppressed, and large intravenous and rectal doses of sodium bicarbonate administered at the onset of the intoxication; insulin may be added if hyperglycaemia appears with the acetonuria, and rechlorination instituted if a blood chloropenia be present.

295

Generalized Xanthomatosis

According to K. HERMAN (*Münch. med. Woch.*, July 20th, 1934, p. 1160) the Hand-Schüller-Christian disease, of which Christian was the first to describe the characteristic symptom-complex (skull defects, exophthalmos, and diabetes insipidus), was first recognized by Rowland in 1928 to be a manifestation of generalized xanthomatosis with hypercholesterinaemia. This rare metabolic disease,

of which some seventy cases have been recorded, and which was practically unknown in Europe until six years ago, is characterized by infiltration of certain organs by a special type of granulation tissue, containing cells filled with cholesterol. The gastro-intestinal tract is least commonly affected. The Hand-Schüller-Christian syndrome is simply one specially common group distribution of xanthomatosis. The affection of the skull in "cartographical" areas is characteristic, but is frequently absent, so that diagnosis is difficult. The hypercholesterinaemia may diminish considerably in old-standing cases. The prognosis is worse in juvenile cases, and the average mortality is 30 per cent. No racial or hereditary factor is known with certainty. Herman's case was recognized from (1) ulcerative tumour-like bluish-red cutaneous infiltrations of the thighs, (2) diabetes insipidus, (3) areas of xanthoma on the eyelids, and (4) blood cholesterol increased to 320 mg. Successful treatment consisted in x-radiation of the thighs, injections of hypophysin, and reduction of fat intake.

Surgery

296 Apparent Recurrences after Renal Calculus Operations

F. MORL (*Zentralbl. f. Chir.*, July 14th, 1934, p. 1648) remarks that with improving radiographical diagnosis and less frequent splitting of the kidney at operation mortality in renal calculus has been diminished, but subsequent recurrences have increased. These apparent recurrences—reported by some to reach 50 per cent.—are nearly always due not to new stone formation but to an existent stone being overlooked at operation. Their increased frequency is attributable to (1) the present tendency to place too much reliance on radiology, which in 10 per cent. of cases fails to show a stone or one of several stones which are present; (2) the employment of simple pyelolithotomy in cases not suited to its relatively narrow scope; and (3) digital investigation being done without rubber gloves having been previously discarded. The surest preventive of "recurrence" is x-radiation before the operation is concluded. Next in importance, Morl believes, is the search with the ungloved hand: he relates the histories of four cases in which stones impalpable through rubber gloves were detected by the bare fingers.

297 Causes of Death after Appendicitis

S. MÜLLER (*Hospitalstidende*, July 24th, 1934, p. 34) has analysed the causes of the sixty-one deaths occurring during eleven years among 1,087 patients on whom appendicectomy was performed for acute appendicitis. Among the forty patients whose death was due to peritonitis were twenty-four whose admission to hospital was tardy. In all of the latter there was an interval of forty-eight hours or more between the onset of the symptoms and admission to hospital. In most instances medical aid had been sought too late, but in an indeterminate number the medical practitioner was responsible for the delay. In this connexion the author mentions the tendency of appendicitis to begin acutely and then to run a more or less "subterranean" course for the next two or three days, after which it flares up again. Among the forty peritonitis fatalities there were, however, eleven patients who had been admitted to hospital within the first twenty-four hours. In the remaining five cases of fatal peritonitis the operation had been deferred for some time for various reasons. There were nine deaths from sepsis which in six cases developed after an attack of peritonitis had subsided. There was only one death from subphrenic abscess. Embolism of the pulmonary artery and septic infarct each accounted for two deaths, and pyelophlebitis and emolito cerebri each for one death. There remained five deaths from intestinal obstruction, and in connexion with these cases the author is inclined

to wonder if such fatalities may not be reduced by the avoidance of extensive drainage. He himself has not extended drainage beyond the right iliac fossa, and he is inclined to ask if even such limited drainage may not be excessive and provocative of ileus.

298

Ricard's Amputation

In certain injuries of the foot TONDEUR (*Le Scalpel*, July 21st, 1934, p. 1013) prefers Ricard's to other better-known amputations. This operation, in which the os calcis is conserved, consists essentially of inter-tibio-calcaneum disarticulation, astragalectomy, and the placing of the os calcis in the tibio-fibular mortise, thus forming a new joint; finally the extensor tendons and the plantar muscles are sutured together, and the plantar and dorsal flaps. Astragalectomy lessens the bony mass to be covered and increases the size of the dorsal flap and the relative length of the Achilles tendon. Conservation of the os calcis provides a normal heel and gives absolute steadiness to the stump. Both measures prevent ultimate equinus. The primary incision varies with the extent of the injury; if made at the calcaneo-cuboid articulation, excision of successive layers of the os calcis is necessary; if only 3 cm. in height of this bone is conserved, very good results are still obtained. The advantages of a Ricard amputation are: only slight shortening of the limb and the formation of a painless, mobile, well-covered stump. It is indicated in trauma, in tuberculosis of the medio-tarsal articulations, and in correction of useless stumps. Details of a case with a full description of the operation are given.

299

Cystin Stones

W. POLLAK (*Zent. f. Urol.*, July, 1934, p. 480) draws attention to recent reports of cystinuric subjects who, although excreting cystin in solution, have no cystin sediment in the urine and no stone formation in the urinary tract. Scepticism therefore seems justified concerning cases in which a familial cystinuria is denied because a family history of stone is not obtainable. He describes two cases in which cystin stones cast excellent shadows on the x-ray screen (equally as dense, in one case, as contralateral phosphatic oxalate stones of the same size). These and numerous similar cases from the literature appear to shatter the older statements that cystin stones cast faint shadows or none at all. In one of Pollak's patients cystin stones had existed in the third decade, after the establishment of chronic urinary infection, was followed by repeated production of stones consisting of calcium oxalate, calcium phosphate, and triple phosphates.

Therapeutics

Treatment of Hiccup

300

E. C. NOBLE (*Canadian Med. Assoc. Journ.*, July, 1934, p. 38), discussing the aetiology and treatment of hiccup, draws attention to the great variety of causative factors, and states that various remedies may be effective in different cases. In cases when the hiccup is associated with infection of the upper respiratory passages, the throat may be sprayed with a 2 per cent. solution of cocaine, and a 20 per cent. solution may be applied to the trachea, warm alcohol being slowly dropped into the trachea. The local application to the nasopharynx of menthol or cocaine may also be effective. If it is due to the constant, direct, or reflex stimulation of the phrenic nerve in such cases as mediastinal new growth or diaphragmatic pleurisy, the only therapeutic measures of any avail will be those which depress the sensitivity of the nerve endings or interrupt the central nervous system to such a point that conduction is interrupted, or which involve the actual crushing or severing of the nerve. Drugs worthy of trial but usually in maximum doses, are atropine, luminal and its compounds, bromides, chloral hydrate, morphine and its compounds, heroin, nitroglycerin, and quinine. Noble has had good results with sodium amylal in prolonged hiccup. A dose of 7 to 10 grains is given intravenously, or until the

patient becomes unconscious during its administration. The effect is immediate, and lasts usually from two to six hours, when it may be repeated. On account of its tendency to produce pharyngeal paralysis, the patient must be kept constantly under observation. When hiccup arises from the gastro-intestinal tract, removal of the cause is indicated; the induction of vomiting will often suffice, but, if not, gastric lavage with alkalis should be a routine procedure. This is particularly the case in post-operative hiccup arising early. After lavage, various stomachics or anodynes may be used, such as the tinctures of capsicum or belladonna, chloroform, benzyl benzoate, ginger, peppermint, and chloretone. In the infectious type of hiccup described by Mayo and Rosenow an antibody globulin solution was effective in cases in which a specific organism was isolated. After an initial desensitizing dose, 2 to 5 c.cm. was injected intramuscularly two or three times daily, one dose being found effective sometimes in stopping the symptoms. Caution is advised in the application of surgery involving the phrenic nerve on account of the potential risk of hypostatic congestion following paralysis of the diaphragm.

301

Acetylcholine in Hemiplegic Seizures

By statistics and personal cases F. SCICLOUNOFF (*Pressa Méd.*, July 14th, 1934, p. 1140) shows that acetylcholine therapy greatly improves the chances of cure or marked amelioration in cases of hemiplegic attacks due to recent cerebral softening, and even in those of some days' duration and definitely established. Four illustrative cases are recorded. He injects daily for at least twenty days, or until results are obtained, 10 to 20 cg. of the hydrochlorate. For ten days during each of the three following months preventive doses of 10 cg. are given, and subsequently similar doses every two or three months. Treatment, which is more efficacious in younger subjects, should commence as soon as possible after the seizure, or in the case of idiosyncrasy or intolerance have been noted. Numerous authorities practise this method also in seizures following cerebral haemorrhage and thrombosis. The favourable results obtained are thought to be due to the vaso-dilatory action of the drug on the cerebral arteries, and to its peripheral vasomotor action.

302

Cibalgil Suppositories after Operations

J. BETZNER (*Deut. med. Woch.*, July 13th, 1934, p. 1053) reports from a hospital in Dusseldorf his experiences with cibalgil, which has hitherto been given only by the mouth or by injection. The suppositories he has used have each contained two tablets of cibalgil or the equivalent 0.44 gram dimethylaminophenazone and 0.06 gram dia. A suppository was inserted on the evening of the second day after an operation or accident instead of an injection of morphine. In 90 per cent. of all the cases the patients were rid of pain and other symptoms, but about 40 per cent. missed the hypnotic effect of the injection. To remedy this defect the author inserted a second suppository three hours after the first. The patients then fell asleep about half an hour later, and next morning they did not complain of any symptoms referable to the heart or intestines. There was no excitation phase, nor that intestinal paralysis which is apt to follow the administration of morphine or one of its derivatives, particularly after an abdominal operation. The suppositories also eliminated the risk of morphine addiction. They were successful in all the cases of dysmenorrhoea and other gynaecological ailments given conservative treatment, both headache and pain disappearing in about half an hour. The pain of pleurisy was also relieved, but the results were less satisfactory in cases of biliary colic, for which the intravenous and intramuscular injection of this drug may be more suitable. In chronic diseases such as osteomyelitis and purulent arthritis requiring prolonged treatment, cibalgil in a suppository was found an effective and harmless substitute for morphine. The author publishes a tabular analysis of the 119 cases treated with cibalgil suppositories, whose use was never followed by addiction or other harmful consequences.

303

and begets in the frigid, always provided that this frigidity is not due to an organic lesion. The contents of one capsule, or more rarely of two, were administered by the subcutaneous route daily. As a rule some improvement was noticed in a week or two, but in some cases it was found necessary to administer as many as sixty capsules before a conclusive result was obtained.

308 Cancer following Subtotal Hysterectomy

E. VON GRAFF (*Amer. Journ. Obstet. and Gynecol.*, July, 1934, p. 18) comments total hysterectomy for general use, reserving the subtotal form for selected cases, because he believes that a patient with an amputated uterus is menaced for the rest of her life by the possibility of cancer of the cervix. He cites statistical evidence showing that cancer of the stump was the lesion in 8.3 per cent. of 263 cervical carcinoma cases, and 6.3 per cent. of 344 cases of carcinoma of the uterus, demonstrating therefrom that removal of the stump together with the body of the uterus would have resulted in a considerable decrease in the incidence of cervical cancer. The author believes that undue importance is attached to lacerations of the cervix and cervicitis following childbirth as aetiological factors. He cites evidence that Jewesses are protected by racial immunity against cancer of the cervix—a fact, he thinks, which may explain somewhat the prevailing conflict of opinion as regards the danger and frequency of stump cancer following subtotal hysterectomy. A common concomitant of cervical cancer is the presence of fibroids in the uterus. Failure has attended attempts to prevent stump cancer by destroying the cervical mucosa, because more than 80 per cent. of these cases originate from the squamous-cell epithelium of the vaginal portion of the cervix. Even the most elaborate excision of the mucosa, including the muscular wall, will not prevent it. Nulliparous as well as parous women may be affected, and the age of the patients has no particular significance. Von Graff argues that, since considerably more than half of the patients with stump cancers die, these losses should be taken into consideration when comparing the mortality rates of the total and subtotal operations.

Pathology

309 Experimental Chronic Peptic Ulcer from Caffeine Administration

H. HANKE (*Klin. Woch.*, July 7th, 1934, p. 978), experimenting on cats, was able to produce chronic gastric ulcer similar in all respects to that in man. Caffeine sodium salicylate 2 to 3 grams was injected subcutaneously daily. The cats were given a large meal at night, the remains of which were removed in the morning. The injection was given at noon, so that they fasted four hours prior to, and six hours after, each injection. Eight of the ten experimental cats died spontaneously, but in two characteristic ulcers were found at the end of two months: two control cats, fed in the same manner but not receiving injections, showed no signs of ulcer. Hanke believes that the ulcers were undoubtedly produced by the caffeine acting on an empty stomach and eroding the mucous membrane. The continual ingestion of large doses of caffeine has, he thinks, the same effect on human gastric membrane, producing a peptic gastritis, due to excessive production of gastric juice on the mucous membrane of the empty stomach, and leading to chronic peptic ulcer.

310 Spirochaetes of the Mouth

R. VINCENT and M. DUFRESNE (*C. R. Soc. de Biol.*, 1934, cxvi, 490) record briefly the results they have obtained in classifying the buccal spirochaetes. Working on the belief that a proper classification would be possible only when these organisms had been studied in pure culture, they proceeded to isolate spirochaetes from the mouths of patients with pyorrhea and stomatitis. Using a medium made up with serum, agar, and a fragment of tissue under

a seal of vaseline, they isolated eleven strains of spirochaetes. These strains have been provisionally classified into six groups, labelled A to G. Group A is not yet identified. It differs from B in the greater motility and suppleness of the organisms morphologically, and in the absence of a fetid odour in culture. Group B corresponds to *Sp. microdentium*, and is the easiest of all to cultivate. Group C corresponds morphologically to *Sp. skolidonti* (Hoffmann) and probably to *Sp. acuta* (Seguin). Group D is certainly identical with *Sp. trimerodonta* (Hoffmann) and *Lepto. buccalis* (Fontana), though it is not a true leptospira. Group E is a large group, and corresponds to *Sp. macrodentium* (Noguchi). Group G is also an important group, but so far only one member has been isolated, which apparently belongs to the species *Sp. buccalis* (Cohn). This organism, which under dark-ground illumination appears as a large spirochaete with a double contour, and which is abundant in Vincent's angina, has not yet been obtained in pure culture, though it has been cultivated for many months in association with other organisms. The detailed description of these various organisms will be given in a subsequent paper.

311 Apparatus for Detecting Free Gastric Acid

A method of testing for free acid successive samples of gastric contents withdrawn by controlled suction is described by H. NECHELES and L. SCHEMAN (*Journ. Amer. Med. Assoc.*, July 14th, 1934, p. 107), who point out that by ordinary methods of examination a small quantity of free hydrochloric acid escapes detection, having been neutralized by mucus after withdrawal. The apparatus consists of a glass T-tube, the vertical limb of which is wide enough to hold a stopper with a bore, through which is passed the lower end of a burette filled with Töpfer's reagent. One end of the T-piece is connected to a suction device, with a mercury manometer and needle valve, while the other is joined to the stomach tube. Small sealed glass tubes with various concentrations of hydrochloric acid and reagent may be attached along the horizontal part of the tube for comparison. As the suction begins to work and the stomach contents appear in the T-tube, drops of Töpfer's reagent are allowed to fall on them from time to time, and the colour reactions are noted. Mucus, bile, and pure stomach juice can thus be tested separately before admixture and consequent neutralization. In this way the authors have been able to demonstrate free acidity in eighteen out of twenty patients with subtotal gastrectomies, and to elucidate the problem presented by an apparently complete anacidity and a lack of response of the acid secretion of the stomach even to histamine in patients complaining of heartburn and the vomiting of sour material.

312 The Abortive Action of *Br. abortus*

I. L. KRITSCHESKI and E. P. HALPERIN (*Zeit. f. Immunol.*, July, 1934, p. 421) have attempted to find out why *Br. abortus* gives rise to abortion. Preliminary experiments in rabbits showed that this organism was incapable of giving rise to the Schwarzmänn phenomenon, and it therefore appeared as if this phenomenon was unlikely to be concerned in undue contractions of the sensitized uterus. The direct action of the endotoxin of the organism was then investigated on the virgin uterus of the guinea-pig. A so-called endotoxin was prepared by heating a thick saline suspension of *Br. abortus* to 60° C. for two to two and a half hours. The effect of this extract on contraction of the uterine muscle was tested by the Dale technique. A marked contraction was observed to follow the addition of 0.5 c.m. of a 1 in 50,000 solution of histamine. Control experiments made with the typhoid bacillus, Friedländer's bacillus, and *Staphylococcus aureus* showed that these organisms had little or no effect on uterine contraction. Further work, shortly to be published, by Kritschewski and Galonowa disclosed the interesting fact that the uterus of guinea-pigs that had been immunized against *Br. abortus* did not respond to the endotoxin. If this should be confirmed it would explain, as the authors point out, why living or dead vaccines of *abortus* should protect against actual abortion while being unable to destroy the organisms in the body.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

313 Public Health Measures in Epidemic Infantile Paralysis

K. HROLV (*Ugeskrift for Læger*, July 19th, 1934, p. 804) gives an account of an epidemic of this disease which broke out in the summer of 1932 in Greenland, and which he met with various public health measures. There were about 700 persons in the colony, and the total population of the area involved was about 2,500. Apart from abortive cases, there were eighty-three well-defined cases, twenty of which terminated fatally. There had been a serious epidemic in the same colony in 1914, and it was significant that none of the patients in the present epidemic was more than 17 years old. As soon as the author suspected an outbreak of infantile paralysis he secured the complete isolation from the rest of the colony of a children's sanatorium housing twenty scrofulous patients. This isolation was so rigorous that he even omitted his daily call, remaining in touch with the sanatorium only by telephone. The epidemic was over in five weeks, and neither at the time nor later did any of the children in the sanatorium develop acute anterior poliomyelitis. Other measures included closing of the schools and interdiction of meetings, dances, and church services. Burial services were permitted only in the open, and no more than six persons at a time were allowed to enter the local shop. The patients were isolated in hospital, their homes were disinfected, those who had lived in the same home were kept in quarantine at home for three weeks, and visits in hospitals were forbidden. A sanitary cordon was drawn between this and neighbouring colonies, and the crews of ships touching at the colony were forbidden all intercourse with its inhabitants. Presumably as a result of these measures, a neighbouring colony remained immune till half a year later. With this exception and that of the sanatorium already referred to, the measures described seemed to have no effect on the course of the epidemic.

314 Early Diagnosis of Exudative Tuberculosis

H. AHRINGSMANN (*Med. Welt*, July 14th, 1934, p. 982) deprecates that the exudative form of pulmonary tuberculosis is seldom diagnosed early in practice. If it is diagnosed and treated within the first four to eight weeks complete cure occurs in the majority of cases. The diagnosis is manifestly difficult, for in the early stages there is no rise in temperature, no cough or sputum, no malaise, and nothing to be found on percussion and auscultation. The history of the illness is of great importance. Gastric symptoms, especially feeling of discomfort in the epigastrium and loss of appetite, should raise suspicion of tuberculosis. If the x-rays show that there is no organic disease of the gastro-intestinal tract, an x-ray of the chest should be insisted upon. Screening of cases is not enough, and a film should be obtained. A blood sedimentation test shows an increased sedimentation in nearly all cases of progressive exudative pulmonary tuberculosis.

315 Post-influenzal Polyradiculitis

In 100 cases of post-influenzal polyradiculitis J. RUSSETSKI (*Ann. de Méd.*, July, 1934, p. 142) noted that this condition, consisting chiefly of intense pains, usually appeared on the fifth to the tenth day of the disease, rapidly reached its maximum, and lasted for periods varying from a few days to several months. Disorders of voluntary movement and of the reflexes were minimal, the sensory and sympathetic systems being primarily affected. The dorsal region was most frequently affected, the cervical and lumbar regions being rarely involved. As a rule, the radiculitis was unilateral; bilateral involvement occurred only when the disease extended to the lower

cervical region. At the onset, hyperaesthesia and a lowered local temperature were present; this was followed in three to ten days by an inverse state of hypo-aesthesia and hyperpyrexia. The neurotonic vasomotor reaction was therefore a type of sympathetic hyperactivity. During the painful period good results were obtained by intravenous injections of sodium salicylate and urotropine combined with physiotherapy; in refractory cases repeated lumbar or suboccipital punctures were made. During the regenerative period oral doses of an iodide solution, intravenous injections of sodium iodide, and applications of iodized ionization were employed.

316 Anaemia from Lice

A. FINKEL (*Wiss. Arch. f. innere Med.*, June 20th, 1934, p. 49) has followed the blood changes in laboratory attendants to whose arms daily applications of pediculi vestimentorum were made; culture of the vermin was required for preparation of antityphus vaccine. Small, repeated, daily blood losses of 5 to 10 grams led to increase both of red blood cells and of haemoglobin percentage. With larger blood losses of 10 to 25 grams daily a secondary anaemia, with erythrocytes descending to 3,000,000 and a colour index of approximately unity, occurred in a few months. It is inferred that inhabitants of vermin-infested houses may as a direct consequence suffer from chronic anaemia.

317 The Kidney in Diphtheria

M. A. M. GRENET (*Thèse de Paris*, 1934, No. 488), who records thirty-nine cases in patients aged from 2 to 13 years, states that involvement of the kidney is rare in mild and moderately severe attacks of diphtheria, and when it does occur is always slight. In malignant diphtheria, on the other hand, nephritis may be observed (a) at the onset, when it is rarely permanent; (b) in the course of the disease, as shown by the presence of casts, albuminuria, and moderate hyperazotaemia; (c) at a late stage—but such an occurrence is very rare. In any case it is quite exceptional for the nephritis to become chronic. The renal lesions seen in fatal cases are essentially parenchymatous. The lesions in the kidney produced experimentally in guinea-pigs by injection of diphtheria toxin are identical with those found clinically in man. Anatomical and clinical observation has shown that vaccination by anatoxin is absolutely harmless for the renal system. The hyperazotaemia is only in part due to the renal lesion, cellular disintegration being mainly responsible.

318 Trauma as a Cause of Diabetes

H. STURSBURG (*Deut. med. Woch.*, June 29th, 1934, p. 981) refuses to subscribe to the doctrine that traumatic diabetes is a figment of the imagination, and records the case of a policeman whose father had died of diabetes. About six months after his urine had been found normal, the policeman, aged 22, received a hard blow over the right side of the abdomen. During the next few hours he suffered from severe abdominal pain and repeated vomiting; thereafter he never felt well, but he kept at work for about half a year in spite of increasing discomfort and great thirst. He was then admitted to hospital, where the urine was found to contain much sugar. A few years later he was still excreting sugar in the urine, although he could keep his diabetes otherwise in check with insulin and dieting. The only other demonstrable physical change was a tender and palpable liver. Professor Stursburg considers it most probable that the injury provoked diabetes in this case, and that the hereditary factor was a predisposing influence. This patient might well have developed diabetes later without any traumatic provocation, and his case does not prove more than that trauma may play a certain part in the genesis of diabetes.

Surgery

Carbuncle of the Kidney

319 G. LAZARUS (*Amer. Journ. Surg.*, July, 1934, p. 155) describes carbuncle of the kidney as a metastatic renal involvement from a healed or active staphylococcus lesion, such as a carbuncle of the neck, a furunculosis, an osteomyelitis, or a simple paronychia. The carbuncle usually starts as a central abscess, which as it enlarges becomes flanked by a number of smaller abscesses. A fully mature renal carbuncle may remain localized as a single inflammatory tumour or it may suppurate, and the infection may extend through the cortex and break into of the kidney to give rise to a pyelocystitis, and rarely the abscess may extend centrally and into the calyces and pelvis, setting up a pyelocystitis, and finally heal spontaneously. In every one of eight cases reported pain was experienced, and there was costovertebral tenderness over the affected side, with bulging or tumefaction in the loin. Palpation of a tender mass in the lumbar region was possible in five cases. X-rays showed obliteration of the psoas margin in all cases, with enlargement of the renal silhouette of the affected kidney in four instances. A history of a pre-existing furuncle or carbuncle in some other part of the body was obtained in all but one case. Operative treatment consisted of incision and drainage, with excision or gentle curetting of the lesion in all the cases reported. Wound dakinization helped to shorten convalescence, and the patients all made a good recovery.

320 Limits of Operability in Cancer of the Breast

JEANNERNEY (*La Gynéc.*, June, 1934, p. 341) remarks that to extend the local limits of operability in cancer of the breast will not improve a surgeon's statistics, but will improve his patient's chances of survival. He himself regards as operable (if excisable) ulcerated carcinomata, those with supraclavicular gland-metastases which can be excised, and carcinomata adherent to the thorax. For primary growth adherent to the thorax he has done palliative curetting, excision, or diathermic coagulation in five cases, followed in three instances by radiotherapy. Survival for five years followed in two instances. Before attempting radical operation for primary cancer adherent to the thoracic cage, metastases in the contralateral axilla or supraclavicular fossa and the liver should be excluded, as well as—radiographically—those in the skeleton or lungs. The operation may include excision of ribs and opening of the pleura. Jeannerney's two best results in this class are survivals of eleven and sixteen months respectively, but Delbet and Mendaro had—together with eight deaths within two years—an unexpected survival of nearly twelve years. Even when faced with recurrences adherent to the thorax Jeannerney does not recoil—if other metastases, so far as can be ascertained, are absent—from excision by knife or diathermy; he can report three cures for one to three years. With these operations have been associated as a rule radiotherapeutic measures, and occasionally in premenopausal subjects a radiotherapeutic ovarian castration.

Mammary Tuberculosis

321 HAMANT and CHALNOT (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, June, 1934, p. 428) give short notes of cases of mammary tuberculosis. This condition may occur in either a diffuse or a localized form, with a single large cavity, it is usually accompanied by an extensive involvement of the axillary lymph nodes, an important diagnostic sign. In one of the recorded cases the lesion was localized in the axillary prolongation of the gland; in another, with an extensive localized lesion, a yellow discharge occurred from the nipple for some days. Treatment consists in excision of the breast and adjacent lymph glands. The axillary curetting need not, however, be as complete as in cases of cancer.

Therapeutics

Serum Treatment of Poliomyelitis

322 S. BAASTRUP (*Ugeskrift for Læger*, July 19th, 1934, p. 759) has observed 120 cases of acute anterior poliomyelitis in his hospital, and has given thirty-two of them serum. In ten of these cases Pettit's serum from the Pasteur Institute was used and found to be unsatisfactory. In the remaining twenty-two cases the serum of human convalescents, imported from Prague, was used. It gave encouraging results, the proportion of subsequent paralyses being approximately half that observed in the controls. But, in the author's opinion, serum treatment is useless after the onset of paralysis, and he recommends it only in the pre-paralytic stage, before the appearance of symptoms referable to the cells of the spinal cord (tremor, ataxia, etc.). The serum should, he states, be given in a single large dose by intravenous injection, never by the intraspinal route. It is conceivable that the dosage has hitherto been too timid, and until more exact information is forthcoming on the subject, it would be well to fix the minimum dose at 20 to 30 c.cm. for children a year old, the dosage being increased according to age and weight until 50 to 70 c.cm. are given to adults. If the serum of convalescents is not obtainable, the serum of healthy adults may be used; some of them, particularly if they are town dwellers, will doubtless have poliomyelitis antibodies in their blood.

Cheese in the Dyspeptic's Dietary

323 F. RAMOND, NICOLAS, and LEBLANC (*Presse Méd.*, July 18th, 1934, p. 1154) enumerate the dietetic advantages of cheese as opposed to milk. In a small volume it contains almost all the nutritive elements, except the lactose, of milk; 100 grams of cheese contain as much casein and fat as 1,000 grams of milk. The pressure and action of the organisms used in its preparation convert the casein into proteins and hydrolyse a certain amount of the fats. Cheese therefore possesses a greater digestibility than milk. Experiments have shown that cheese diminishes the free hydrochloric acid and increases the total acidity, total chlorine, and fermentative properties of the gastric juice, and, owing to its great content of proteins, causes a quicker opening of the pylorus and more rapid duodenal transit than is the case with meat. Clinical results have proved that addition of cheese to the diet causes marked improvement (absence of emaciation and anaemia and a regaining of vitality) in cases of dyspepsia and of gastro-duodenal ulcer, especially old ulcers complicated with chronic gastritis. It is also of benefit in cases of gastric cancer.

324 X-Ray Treatment of Acute Inflammations

MIRIAM LIBERSON (*Rev. d'Actinol. et de Physiothér.*, May-June, 1934, p. 185) reviews the literature and records the results of personal experiments relating to the mode of action of x rays on inflammatory conditions. Small radiation doses were found to be the most effective. The best results were obtained in superficial staphylococcal infections, gynaecological conditions, dental disorders, and diseases of glandular organs. Liberson discusses the various current hypotheses of the mechanism of the improvement, including the enhancing of the bactericidal power of the blood, the promotion of phagocytosis and the production of antibodies, stimulation of the reticulo-endothelial system, increased bactericidal activity and proteolysis, and modification of the local circulation. The often contradictory conclusions reported permit no very definite understanding as to how x-radiations operate, but the consensus of opinion is that they have a very certain therapeutic value in such local inflammations. If a commencing lesion is treated sufficiently early, it aborts, or requires a very mild subsequent operative intervention. Some have even found that local suppuration would often open spontaneously immediately after the

first radiation and then heal spontaneously. In thirty-five cases of tuberculous abscess of the axilla there were no bad sequels, and subsequent vaccine therapy seemed to have been definitely expedited. The fact that patients so treated can be dealt with as ambulant cases is cited as another reason for using x rays in this condition. The pain of anthrax lesions was relieved, and the inflammation was reduced. Facial furuncles were particularly benefited, a satisfactory result in view of the difficulty of treating them by surgical methods without resulting deformity. Various authors differ as to the benefit to be expected in affections of the nose, ears, and eyes, but periodontitis, dental periosteitis, and maxillary inflammations generally responded well, even in senile patients.

325

Treatment of Obesity

According to E. H. STOKES (*Med. Journ. of Australia*, June 23rd, 1934, p. 804) the common practice of using thyroid substance only in the treatment of obesity cannot be too strongly condemned. Patients whose basal metabolic rate is below normal will probably lose weight, but in others harm may be done. There is no characteristic change in the metabolism of the obese, and hyperthyroidism may be induced in some cases. It is remarked that patients with frank myxoedema often do not lose much weight; in some cases the weight actually rises after a preliminary fall. In a series of fifty cases of obesity the author used thyroid substance, when it appeared to be indicated, in conjunction with other measures. The initial dose was half a grain twice a day. If the patient proved tolerant the dose was doubled, and in some cases where myxoedema was present as much as 15 grains was given daily. Stokes remarks that exogenous obesity is frequently associated with endogenous obesity, particularly of thyroid origin. One of the series of patients benefited from the exhibition of pituitary whole gland extract in that retarded sexual development was simultaneously accelerated, but its employment in the case of adults was without any noticeable effect. A combination of thyroid substance and whole gland pituitary extract appeared also to be beneficial sometimes. Extracts of the genital glands gave no results. Stokes emphasizes the importance of careful dietetic regulation. He considers that a low fluid intake is neither necessary nor desirable, except in cases with cardiac complications. Admission to hospital, the careful calculation of the caloric value of the food intake, and the weighing of all articles of diet may be necessary in some cases.

Disease in Childhood

326 Magnesium Sulphate in Hirschsprung's Disease

B. E. BONAR (*Amer. Journ. Dis. Child.*, July, 1934, p. 123) finds the term "pelvi-rectal achalasia" useful in designating the type of Hirschsprung's disease which is apparently caused by failure of relaxation of the musculature at the pelvi-rectal flexure. He reports the case of a boy aged 3 with this dysfunction, who was treated by repeated intrarectal injections of a saturated solution of magnesium sulphate. In the course of two years more than 200 satisfactory bowel movements were obtained; the abdominal distension was reduced, and the nutrition and health were decidedly improved. When the injections were given at the time that mass peristalsis was occurring the evacuations were more copious. Bonar remarks that magnesium sulphate has been used for some time to relieve certain spastic states of the recto-sigmoid apparatus in adults, saturated solutions being injected into the rectum; but its use in the somewhat analogous condition of this form of Hirschsprung's disease seems to have been overlooked. The success which attended the present instance seems to warrant a trial of it in other cases of this form of megacolon. It acts apparently by local irritation of the neuromuscular elements of the intestinal wall. While it is admitted that sympathectomy is the operation of choice as a general rule, the age and the condition of the child often make preliminary medical treatment

necessary. The author adds that if his results receive confirmation by others this line of treatment would be of considerable value.

327

Intussusception in Nurslings

E. POULIGUEN (*Presse Méd.*, September 12th, 1934, p. 1421) emphasizes the importance of early diagnosis in infantile intestinal intussusception, and maintains that treatment should not be deferred until the pathognomonic bloody stool appears. Two early diagnostic signs are colicky pains, especially if intermittent, and repeated vomitings. The diagnosis can be confirmed by radiological examination after a barium enema. Two methods of treatment may be employed—operation or enema. Pouliguen favours the latter course, and administers an enema containing 20 grams of baryta to a litre of water. This amount is given under a pressure of 1.2 to 1.5 m., and under x -ray control; by the latter and by palpation it can be determined whether reduction has occurred. Should this measure fail immediate operation is indicated. A right lateral incision is advocated; the invagination should be reduced by manual manipulations, persisted in if necessary. In irreducible cases resection must be performed, though this is dangerous and death usually ensues. Post-operative care is of the utmost importance. Notes on three cases are given to illustrate the dangers of delayed treatment.

328 Powdered Apples in Diarrhoea of Childhood

P. FREUD (*Wien. med. Woch.*, September 8th, 1934, p. 1001) has treated nine cases of acute and two cases of chronic intestinal catarrh in a children's home in Vienna with pulverized apples sold by an Austrian firm under the name of "pomfarin." He was encouraged in this therapeutic essay by several recent publications in which praise of raw mashed apples in the treatment of diarrhoea was unanimous. The reaction of all the author's eleven patients, whose ages ranged from 9 months to 8 years, was prompt; the diarrhoea was completely arrested, at the latest within eighteen hours of the institution of this treatment. After there had been no stools for twenty-four to thirty hours, the first motion would be of the consistency of an ointment, or formed and no longer malodorous. Infants under 9 months are liable to lose weight too rapidly under this treatment to stand it well. Freshly prepared apple powder is preferable in many ways to the raw mashed apple. The dosage of the former can be regulated with greater accuracy, and it confers independence in the matter of the seasons of the year, the quality of different apples, etc. The powder is also easier to mix with water, and is better tolerated than the raw article. Children take the powder readily when given in sweetened water. The powder is soaked in warm water (not over 50° C.) for ten minutes and is given lukewarm or cold. A new lot of powder should be used for each feed. The weight of 100 grams of pomfarin corresponds to 100 grams of fresh whole apple, and a dose of about 30 grams on the first day may be raised to 50 to 60 grams on the second day. In refractory cases the same dose may be required on the third day. Only small quantities are given at a time. No other food is given, but thirst is relieved by tea sweetened with saccharine.

329

Sinusitis in Children

According to A. H. PERSKY (*Arch. of Pediat.*, September, 1934, p. 589) sinusitis is a very common condition in children, being the direct cause of many unexplained coughs and questionable bronchitis. The acute condition is always a sequel of an acute rhinitis, increases the severity of the symptoms, and delays their clearing up. After an infection there is always damage of the mucous membranes, and if this has not completely healed by the time the next attack occurs, the injured area is the first to become involved, and its healing is still longer delayed. Finally, permanent thickening results. Local nasal treatment alone will not clear up the condition. The nasal cavities should be cleared, and some astringent such as ephedrine or cocaine and antipyrine be applied. The

suction process can then be extended to the sinuses, which can be similarly cleared, and arrangements be made to ensure regular drainage and aeration of them. The author finds dietetic supervision useful, but does not commend vaccines for acute sinusitis; for chronic sequels, however, vaccine therapy has often proved useful. The quartz lamp and, in some cases, infra-red rays are also helpful. Persky considers that the best results may be expected from the combination of local treatment with general dietary and tonic measures.

Obstetrics and Gynaecology

330 Bispinous Diameter in Persistent Occipito-posterior Presentation

S. HANSON (*Surg., Gynecol. and Obstet.*, July, 1934, p. 102) discusses the influence exerted by an unduly narrow bispinous diameter on the mechanism of labour, particularly as regards the persistence of an occipito-posterior position. Observations were made on a series of 2,254 consecutive cases, of which 811 were primiparae, the bispinous diameter being measured with a specially devised pelvimeter. The average bispinous diameter was found to be 10.51 cm. Pelves with a diameter of 9.5 cm or less were rather arbitrarily classed as narrow; of these there were 143 instances among the primiparae. Hanson insists that in such investigations it is always essential to distinguish between primiparae and multiparae, since in the latter the relaxed perineum is a complicating factor. It was found that persistence of the posterior position, predisposing to the narrow in the primipara series the bispinous diameter was in the primipara series of thirty-eight (71 per cent.) narrow in twenty-seven out of thirty-eight (71 per cent.) of the cases of persistent occipito-posterior position. The measurement exceeded 10.5 cm. in only one of the thirty-eight cases. This finding was rendered even more significant by the discovery that such narrowing was only discernible in 17.67 per cent. of the whole series of cases examined. The average measurement for the group was only 9.46 cm., as compared with the normal of 10.51 cm. Conversely there was a very high incidence of the persistent posterior position among this group of pelvises—twenty-seven out of 143 cases (18.9 per cent.)—approximately thirteen times greater than the incidence of the persistent posterior position in the group of 668 primiparae with normal bispinous diameters. In these cases of narrow bispinous diameter the other pelvic measurements were usually about normal, except the bi-ischial diameter, which was narrow in most, but in only two instances to an extent where it would impede delivery. Among fifty-two cases of persistent occipito-posterior position in multiparae in the series investigated there were eighteen cases with a narrow bispinous diameter, an incidence of only 34.6 per cent. Hanson concludes that it is very necessary to differentiate early in labour by interspinous measurement between those cases in which anterior rotation will proceed normally and those in which there will be obstruction. Early intervention in the second class will eliminate a long and futile second stage, with its attendant difficulties and disastrous complications.

331 Pernicious Anaemia in Pregnancy

P. BARON (*Gynecol. et Obstet.*, July, 1934, p. 731) believes that pernicious anaemia is a specific disease of pregnancy, and gives the full history of a case. The patient presented, with the anaemia, the usual symptoms of pregnancy intoxication: intractable vomiting, marked albuminuria, and icterus, a rarer and in this case the initial symptom. All these symptoms, with the exception of the anaemia, which increased, disappeared after delivery. Two blood transfusions and administration of a prothable liver extract produced no improvement. A progressive amelioration with ultimate cure was obtained in six days by giving raw calves' liver (Whipple's method) in doses increasing from 50 to 200 grams.

Pathology

332 Human Influenza and Canine Distemper

A. EICHMORF and N. J. PYLE (*Journ. Amer. Med. Assoc.*, June 23rd, 1934, p. 2082) record experimental work which indicates that the virus of influenza in man may induce in ferrets an immunity against the distemper of dogs. Pigs were being tested in the United States for susceptibility to human influenza virus, the virulence of which was maintained by passage through ferrets. In testing canine distemper virus, ferrets were also employed and, not suspecting a possible relation between this virus and that of influenza, the authors used some of the ferrets which had recovered from the influenza infection for tests with canine distemper virus. Marked differences were noted in the ensuing reactions, as compared with other ferrets which had not been exposed to influenza virus. The usual period of incubation was lengthened from nine or ten days to thirteen or even seventeen days, and two of the ferrets proved apparently immune to distemper. In view of the authors' experience that the strain of distemper virus with which these experiments were made, and which had been studied in more than 800 ferrets, had never failed to kill the ferrets, and had always shown a uniform incubation period, these results clearly suggested that the animals which had recovered from the infection with influenza virus had acquired a resistance to the canine distemper virus. In a second series of experiments six out of eleven ferrets received only two instillations of influenza virus and the remaining five three nasal doses of canine distemper virus. Injections of lethal doses of canine distemper virus, in the first group one ferret remained well, and in the second group three were entirely unaffected by the distemper virus. All ferrets that died showed a marked delay of the distemper symptoms. The authors conclude that the influenza virus induces some immunological reaction in ferrets against the distemper virus. Limited cross-neutralization experiments and immunizing attempts with hyperimmune distemper serum against the influenza virus are now in progress. They think that some evidence is emerging in support of the long held theory that there is a close relation between the occurrence of human influenza and canine distemper.

333 Intestinal Mucosa in the Stomach and the Pathology of Gastric Ulcer

According to F. CLAR (*Brun's Beitr. z. Klin. Chir.*, August 8th, 1934, p. 145) the occurrence of islets of intestinal mucosa in the lining of the pathological stomach (gastritis, ulcer, carcinoma, achylia, and pernicious anaemia) has been known for seventy years, and is now usually regarded as a mark of imperfect regeneration in an inflamed area, except in a very occasional instance in which the areas have been present at birth. Clar believes that the areas of bowel mucosa are rarely a secondary formation and nearly always congenital. One or several such areas were found in all of fifteen foetuses of six or seven months, in one of three foetuses at term, but in none of twelve adults free from gastropathy or duodenal ulcer. Regression of the islets towards the end of foetal life appears, therefore, to be the general rule. In operation specimens from the pathological stomach Clar has found that the islets of intestinal mucosa resemble minutely those of the small gut, possessing a terminal membrane, goblet cells, Paneth cells, etc. Further, the demarcation zone where the intestinal joins the gastric mucosa is perfectly sharp-cut, resembling the pyloro-gastric or gastro-oesophageal mucous junctions. It is concluded that, although some islets are secondary to inflammation, the great majority are congenital, and that congenital islets, being digestible by the gastric juice, play an important part in causation of gastritis, erosions, and chronic ulcers. An analogy is drawn with the occurrence of peptic ulcer in Meckel's diverticula, in which islets of gastric mucosa are not very uncommon.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

334 Lymphogranulomatosis

E. ADLERCREUTZ (*Finska Läkarsällskapets Handlingar*, July, 1934, p. 587) publishes a study of the thirty histologically examined cases of lymphogranulomatosis observed in a hospital in Helsingfors in the period 1915-33. The fact that as many as twenty of them were concentrated within the last four years of the period under review was probably indicative of diagnostic improvements rather than of any increase in the true incidence of this disease. In contrast to observations made in other countries, the excess of male over female patients was only as seventeen to thirteen. The cases were fairly uniformly distributed between the ages of 10 and 60. The tendency to distinguish between localized and generalized forms of the disease, in conformity with its clinical manifestations, is, it is stated, unsound and arbitrary; the only type which the author recognizes as clinically definable from the rest is the mediastinal form of the disease, whose course as well as localization possesses distinctive features. Though none of the thirty patients was observed in the latent stage of the disease, there were as many as eleven who had already passed through such a stage, the duration of which had been from one month to three years. There were two cases which during the latent stage had presented only one symptom—obstinate pruritus. In some cases the transition from the latent to the active stage had been quite sudden. All but one of the thirty patients were given x-ray treatment, which seldom had any direct effect on the anaemia. But after every series of exposures there was a fall, often considerable, of the total number of the leucocytes, whose numerical relationship to each other was but slightly changed. When lymphopenia had already developed, it was progressive in spite of x-ray treatment. According to the author, it probably prolongs life in some cases, and its achievements would possibly be more impressive if it were given earlier in the disease. Adlercreutz's discussion of its aetiology, and the modern tendency to regard it as an infectious disease, draws attention to the lack of accurate information on this point.

335 The Heart in Diabetes

A. KLINGENBERG (*Norsk Mag. f. Laegevid.*, August, 1934, p. 940) has made a special cardiac study of the fifty-five unselected cases of diabetes treated in her hospital during the past two years. In only twelve were normal electrocardiograms obtained. In fourteen cases electrocardiograms changed from pathological to normal with the therapeutic regulation of the metabolism which, in six other cases, affected an appreciable improvement. This observation suggests that the best treatment of the diabetic heart is treatment of the diabetes itself. Only one patient was addicted to alcohol, and only one was syphilitic. Not one had taken digitalis, but there were as many as three whose cardiac condition might be traced to injudicious insulin medication. Four patients were excessively fat. The author concludes that the old clinical experience concerning the close association of diabetes with heart disease is to be interpreted in a certain proportion of cases as a more or less direct action of the diabetic state on the heart.

336 Radiology of the Aorta in the Aged

In a study of 178 cases (126 females and fifty-two males), of ages ranging from 80 to 100 years, P. BRODIN, H. DE BALSAC, and MME TÊDESCO (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, July 9th, 1934, p. 1132) noted important aortic changes on radiological examination; these are due to a lengthening by distension with thickening of its walls, which causes an increased flexibility with dilatation and change of colour. The most constant characteristic of the senile aorta was its "swan-neck" appearance, seen in the right anterior oblique position. Other changes were:

marked, limited opacities; especially at the origin of the vessel and the upper part of its pedicle; localized dilations, particularly at the commencement of the arch; and calcifications in the arch. When seen in younger subjects, these changes indicate premature senility. P. BRODIN and R. JOSEPH (*ibid.*, p. 1139) maintain that the state of the arterial tension provides earlier information as to the underlying condition, especially if a comparison of the tensions in the upper and lower limbs be made—the former is usually slightly higher and the latter lower than normal. An increase, but particularly a diminution, in the normal difference between these two tensions provides evidence of aortic lesions and of atheromatous areas, which are most marked at the bifurcation of the aorta and which may extend into the iliac arteries.

337 Recovery from Streptococcus Meningitis

J. FELSEN and A. G. OSOFSKY (*Journ. Amer. Med. Assoc.*, June 30th, 1934, p. 2170), who record a personal case, have collected fifty-seven examples of recovery from streptococcus meningitis. The onset in these cases usually followed an infection of the upper respiratory tract. The organisms that have been isolated include both the haemolytic and non-haemolytic type, and *S. viridans* was found in only four instances. Trauma was directly responsible for the meningeal infection in four cases, and of these one showed a haemolytic streptococcus and another *Streptococcus viridans*. The present case was that of a man, aged 22, who developed meningitis as the result of a lacerated wound of the scalp. Smears of the turbid cerebro-spinal fluid showed cocci and a Gram-positive bacillus suggestive of the anaerobic group. Anti-gangrene serum, 5 c.cm., was therefore given intrathecally, and the dose was repeated the same day. Much improvement occurred, and two more doses were given, with the result that rapid recovery took place. Further bacteriological examination showed *Streptococcus viridans* in pure culture.

338 Malarial Polyneuritis

DOAN-KHAL-THINH (*Thèse de Paris*, 1934, No. 41) reports the histories of eleven cases of malarial polyneuritis in patients aged from 21 to 58. The condition is frequent, but is often mistaken for beri-beri, from which it is distinguished: (a) clinically, by its association with attacks of malaria; (b) haematologically, by the presence of haematozoa; (c) therapeutically, by its yielding to quinine; and (d) geographically, by its occurrence in countries where beri-beri is unknown, such as Equatorial or Western Africa.

Surgery

339 Malignant Degeneration of Gastric Ulcer

H. FINSTERER (*Rev. de Chir.*, July, 1934, p. 511) describes malignant degeneration as one of the most serious complications of gastric ulcer, and one which can be avoided in many cases by early diagnosis and prophylactic treatment. Diagnosis of malignant degeneration is extremely difficult, as the onset is seldom recognized either clinically or during operation, since signs of malignancy in the ulcer cannot be detected by the naked eye. It is often only when invasion has taken place that symptoms of cancer of the stomach are manifested, and by that time it is too late for operation. When the patient no longer has hyperacidity, when the appetite fails and loss in weight takes place, malignant changes should be suspected and operation undertaken at once. Radiography at this stage does not show signs of malignancy round the edges of the ulcer, nor can it be recognized by the surgeon after resection. If operation is not carried out before radiography is able to demonstrate the irregular edges of the

ulcer, filling defects, or the peristaltic changes characteristic of cancer, there is no hope that operative treatment will bring about the radical cure of the patient. A prepyloric ulcer is very prone to malignant changes, and operation should therefore be undertaken immediately in the case of a patient with this type of ulcer who has a failing appetite. During operation it is difficult to make a definite diagnosis of malignancy, but if the lymphatic glands are hard and enlarged, malignant change must be suspected. In these cases a radical operation should be performed with removal of the great omentum. When the growth has penetrated to the floor of the ulcer and when it has formed characteristic nodes under the peritoneum, diagnosis is easy, but the prognosis is bad. In a series of eighty cases of simple gastrectomy for malignant ulcer there were only three deaths, but it is pointed out that in cases of primary cancer, or where the growth has penetrated the pancreas, the mortality is much higher.

340

Subphrenic Abscess

W. HAILES (*Aust. and New Zeal. Journ. Surg.*, July, 1934, p. 3) considers that subphrenic abscess may arise from an inflammatory condition, or perforation of a neighbouring viscus, or by the spread of infection from a distance. This happens in appendicitis when the infection travels along the outer side of the colon from an appendix situated extracoeccally or from a pelvic appendix. Subphrenic abscess may develop, particularly on the right side, as a complication of a general infection or soiling of the peritoneal cavity. When a patient, following operation for an upper abdominal or for an acute abdominal inflammatory or perforating lesion, has a raised temperature and pulse rate with sweating or rigors, a secondary abscess formation in the abdomen must be considered. In the case of a subphrenic abscess, pain is frequently present in the loin or over the upper portion of the rectus abdominis muscle, just beneath the ribs. Pleural pain and irritation may cause a slight cough and an increase in the respiratory rate. Diagnosis can only be confirmed by x rays, exploratory puncture, or laparotomy. Only abscesses posteriorly placed are suitable for puncture, and in cases where the patient is seriously ill a direct attack on a localized abscess with posterior drainage under local anaesthesia may give good results with less risk than is caused by an exploratory laparotomy. Transthoracic drainage has proved satisfactory, although infracostal incision is the approach of choice for those abscesses which are localized as low as the tenth or eleventh space. It is considered that the development of empyema might be minimized by first localizing the abscess and then tracing it downwards with fresh needle and syringe through successive intercostal spaces till its route of subpleural drainage is indicated. Ten cases are reported, of which eight recovered and two died. There were four cases of empyema in the series.

Therapeutics

341 Thoracoplastic Operations for Pulmonary Tuberculosis

E. KEY (*Hygiea*, July 31st, 1934, p. 481) has performed thoracoplastic operations in Sweden on 265 patients suffering from pulmonary tuberculosis between 1915 and the end of 1932. Follow-up investigations undertaken after 1932 showed that in 114 cases the patients were rendered fit for work and practically symptom-free, without tubercle bacilli in the sputum. Fitness for work was achieved in thirty other cases, but certain symptoms persisted, and several of the patients remained sputum-positive. In a third category sixteen patients were unfit for work and sputum-positive. Among the deaths were thirty-one within eight weeks of the operation, fifty-seven occurred later and were directly due to tuberculosis, and eleven more were due to some other disease. There

remained six patients who could not be traced. At first the author was doubtful as to the value of partial thoracoplastic operations on the upper part of the chest, and he was afraid of aspiration disasters, but he has gradually acquired a growing faith in these operations, which achieve their object even when large cavities exist. The partial, as distinct from the complete, thoracoplastic operation eliminates a minimum of functional lung tissue, and if enough has not been included in the field of operation it is possible to perform supplementary thoracoplastic operations. Of the total of 265 patients operated on up to the end of 1933, only 185 were subjected to a total thoracoplastic operation, the operations in the remaining 100 cases being incomplete or partial. It is most important, in the author's opinion, that the patient who has undergone a thoracoplastic operation should be under medical supervision for years, and that his medical adviser should know that when a thoracoplastic operation does not restore complete health because one or more cavities prevent the complete collapse of the lung, recovery may yet be effected by one or more supplementary operations.

342 Dietetic Treatment of Chronic Pyuria in Childhood

J. M. RECTOR and W. E. WHEELER (*New England Journ. Med.*, July 26th, 1934, p. 143) agree that most satisfactory results can be obtained from putting on a ketogenic diet children suffering from chronic cystitis and chronic or recurrent pyelonephritis in the absence of congenital anomalies of the urinary tract. Most children are thrown into ketosis easily by high-fat-low-carbohydrate diets, and if over the age of 2 years seem as a rule to tolerate them very well. On account of the difficulty in preventing children from eating small amounts of carbohydrates apart from their meals, ketosis may be difficult to maintain. The authors suggest that this difficulty can be partly met by raising the ratio of fat to carbohydrate in the diet. They aim at establishing intense ketosis as soon as possible, and to render the urine sterile before the beneficial effect has disappeared. To this end the child should be immediately placed on a ketogenic-anti-ketogenic diet ratio of 3:1, and there should be no hesitation in increasing this ratio to 4:1 or 5:1, or more, if the ketosis tends to decrease. By the term "ketogenic ratio of 3:1" is implied a ratio in the diet of 3 grams of fat to every gram of carbohydrate and protein combined. Good results cannot be expected in infections due to organisms other than those of the *B. coli* group, nor if there is anatomical deformity or advanced pyelonephritis with impaired renal function. The pH of the urine must be kept constantly less than 5.5, and acetone or diacetic acid should be present in large amounts. The diet should not be discontinued if the patient feels nauseated or vomits at the outset; a short period without food will probably relieve the symptoms. Normal diet should not be resumed until the urine cultures have remained bacteriologically negative for a week. Pus may continue to be present in the urine for several weeks after sterility has been established, even in cases which do not recur.

343 Serum Treatment of Cerebro-spinal Meningitis

J. QUÉRANGAL DES ESSARTS (*Arch. de Méd. et de Pharm. Napoléon*, April-May-June, 1934, p. 236) reviews the results of the serum treatment of cerebro-spinal meningitis in the naval hospital of Brest in the period 1900-32. Before the institution of this treatment hardly a quarter of the patients recovered, and when they did so it was at the cost of serious complications or permanent deformities. With the introduction of serum treatment in 1909 the proportion of recoveries rose to 70 per cent., at which level it remained till 1920, in spite of a serious epidemic during the war. Between 1920 and 1932 the proportion of recoveries has been 78 per cent. The complications and sequels have become rare, and the duration of the disease has been appreciably shortened. The author contrasts these observations with those in certain other countries where serum treatment has been discredited because it has not prevented mortalities ranging from 60 to 80 per

cent. They can, he believes, be largely explained away by civilian conditions, under which patients do not receive serum treatment till the fifth to the seventh day of the disease, or even later. Under military service in France most patients are given serum treatment within the first three days of the disease. Time is everything in serotherapy, and it is thanks to the application of this principle that in the French Navy recovery has been effected in 67.5 per cent. of 564 cases observed in the course of twenty years, and that the mortality has been reduced to 16.6 per cent. The author deals in detail with the dosage of the serum, the varieties of the disease, the influence of the patient's age on his reaction to the disease and on the treatment thereof, the duration of the disease, its complications and sequels, and the ultimate fate of the patient.

Laryngology and Otology

344 Therapeutic Dilatation of the Oesophagus after Poisoning by Caustics

H. SALZER (*Wien. med. Woch.*, June 30th, 1934, p. 736) contrasts the generally accepted principle of preventing strictures by early intervention with the hitherto common practice of waiting till a stricture has developed before dealing with it. For many years he has been cautiously shortening the interval between caustic soda poisoning in childhood and dilatation of the oesophagus with a sound. In 1920 he demonstrated the results of this treatment applied to thirteen cases, twelve of which terminated in recovery. Professor Salzer's present paper covers the period 1920-33, and deals with 180 cases of injury to the oesophagus in children who had swallowed caustic soda. All these cases were recent when treated; they did not include any child in whom a stricture of the oesophagus had already developed when first admitted to hospital. There were three deaths from sepsis, five from pneumonia, and one from diphtheria. None of these deaths had anything to do with the prompt institution of oesophageal dilatation with a sound. There were, however, three deaths associated with perforation; in the two cases of perforation of the stomach the post-mortem examination failed to link this accident up with the passage of a sound. The author leaves it in place on the first day for only a few minutes. On the second day it is left in place for five minutes, its sojourn being prolonged by the fourth day to thirty minutes once a day. This treatment is continued for a month, after which the sound is passed every other day, and later every third day. The number of free days is gradually increased to seven, and then to a fortnight, a month, two months, and three months. Finally, the child is re-examined at intervals of half a year. While this treatment is comparatively safe if instituted directly after the accident, it is more dangerous in the case of children thus injured half a dozen days earlier, for in the interval ulcers may have formed, and they may be perforated by a sound. It is never certain in the case of a child who has tasted caustic soda whether some of it has been swallowed or not; and it is wiser to extend this treatment to all doubtful cases than to omit it in one actually needing it. Fever provoked by this treatment should not be an indication for discontinuing it, as the rise of temperature may be no more serious than that which follows the change of dressings. The author quotes the statistics of hospitals other than his own to prove what an advance his treatment represents.

345 Radiography of the Maxillary Sinus

H. J. SEDWICK (*Amer. Journ. Roentgen.*, August, 1934, p. 154) records a study of the form, size, and position of the maxillary sinus at various ages by means of radiograms of the skull, with a view to establishing standards of normality. He found that this sinus varied greatly in shape, size, and position, not only in different individuals but also on the two sides of the same person.

The sinus appears to reach its maximum size during the third decade of life, and later there is a definite tendency towards the assumption of a triangular form. When the sinus is triangular the position of its base varies. The relation between the floor of the sinus and that of the nasal cavity is variable, and is not a sex characteristic. The sinus lies in close proximity with the sides of the nasal cavity, and the position of the walls of the latter influences its size. The only racial difference between the maxillary sinuses in skulls of the white and Indian peoples in those examined was that the vertical height was less in the latter, a fact which might be correlated with the shorter nose and broader cheeks of that race. The average measurements of the sinus, based upon 173 cases (346 sinuses examined), were as follows: height, 34 mm.; width, 25 mm.; antero-posterior length, 39 mm. The average maximum and minimum measurements were: height, maximum 46 mm. and minimum 22 mm.; width, maximum 35 mm. and minimum 17 mm.; antero-posterior length, maximum 51 mm. and minimum 29 mm. The average height for males was 35 mm. and for females 34 mm. The average width for males was 25 mm. and for females 24 mm. The average length for both sexes was 40 mm. Sedwick thinks that these figures should be of assistance in the radiological examination of the maxillary sinus for disease. The way in which the measurements were made is described.

346 Surgical Treatment of Fixation of the Vocal Cords

A. RÉTHI (*Rev. de Laryngol., d'Otol. et de Rhinol.*, July-August, 1934, p. 801) describes a surgical procedure he has devised for treating medial bilateral fixation of the vocal cords, whether this is due to paralysis of the recurrent nerve or to ankylosis of the crico-arytenoid joint. He opens the trachea in the mid-line, and resects, according to Hartmann's technique, a semicircular piece of the anterior tracheal wall. He cuts through the cricoid cartilage with Killian's scissors, and opens the larynx by extending the cut with a bistoury. He then extirpates the adductor muscles on one side, preferably on the left, which is the easier. In a simple operation for paralysis the laryngeal opening is allowed to close in a fortnight. At first the voice is very feeble, but it gradually grows stronger, thanks in part to hypertrophy of the stylopharyngeus. At first phonation is strident and monotonous, but a course of voice production soon brings suitable modulation, permitting the patient ultimately to engage in ordinary conversation or even to make a speech. The author remarks that ordinarily the stylopharyngeus does not function as a phonation muscle, but it comes into play in this respect when the ordinary muscles concerned in voice production are paralysed or their action is impeded by joint inflammation. Together with the ventricular bands and the aryteno-epiglottic muscle, which plays an important constrictor part, it restores the voice in a marked degree. Details illustrated by coloured diagrams are given of the steps in the operation and of the final state.

Obstetrics and Gynaecology

347 'Oedema of the Cervix during Labour

Presenting a study of cervical oedema during labour, V. CATHALA and S. SEYDEL (*Gynéc. et Obstét.*, July, 1934, p. 1) divide this condition into two forms—the soft (simple) and the hard (oedema with rigidity). The former rarely affects the entire intravaginal portion of the cervix, and is usually confined to the anterior lip; the latter, the less frequent form, is more extensive, occupying more than half of the cervix, occasionally its entirety. Both forms are extreme types of the same cervical alteration, and intermediate varieties occur, dependent on the degree and tension of the oedema, the intensity of the vascular congestion, etc. The authors do not believe that infection is an aetiological factor, but consider that the cause is

purely mechanical and that the oedema is due to circulatory troubles occasioned by compression of the cervix between the presenting foetal part and the pelvis. The soft variety occurs especially in flattened curved pelves, and the hard in retracted grooved ones.

348 Cervical Cancer during Pregnancy

R. KELLER (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, June, 1934, p. 433) records three cases of cancer of the cervix uteri which showed no, or very few, symptoms during pregnancy. Death occurred rapidly in two of these patients after delivery; the third still survives, following treatment with ultra-penetrating x rays. Despite the dangers of causing a haemorrhage or disseminating the infection, Keller maintains that a biopsy is absolutely necessary in all suspicious cases. The rapid growth of cervical cancer following delivery has been noted by several authorities. This is probably due to dissemination of the cancer cells by dilatation of the cervix, movements of the foetal head, changed vascularization, etc. These young cells possess a marked radiosensitivity, a fact influencing treatment. During the first half of pregnancy an extensive hysterectomy should be performed in operable cases, and radium applied in inoperable ones. During the second half of gestation radium should be employed till term, then a Caesarean section, followed by hysterectomy, be performed in operable cases, and in inoperable ones radium should be applied till delivery, when a subtotal hysterectomy should be done.

349 Treatment of Vaginitis due to Trichomonas

A. HOCHLOFF, writing from Ukraine (*Zentralbl. f. Gynäk.*, July 28th, 1934, p. 1775), reports having found *Trichomonas vaginalis* in sixty of 300 cases of vulvo-vaginitis. The parasites were destroyed by daily swabbing (after careful drying under guidance of the speculum) of the vagina with a saturated solution of lactic acid in sulphuric ether. In twenty-nine cases four or five treatments sufficed; ten cases required as many as eleven to fifteen. Disappearance of the flagellates was verified microscopically, and in fifty-five cases was proved to persist by re-examination three to five months later.

Pathology

350 Fibromyomata in the Newborn

R. BOURG (*Bruxelles-Médical*, July 29th, 1934, p. 1237) records a case of a fibromyoma of the upper lip occurring in a female infant. At first diagnosed as a chondroma, a tumour known to exist congenitally, the present growth, which was removed by a cuneiform resection of the lip, proved histologically to be a fibromyoma exactly similar to the uterine type. The case is reported owing to its rarity and the congenital nature of the tumour. Bourg, referring to the little-known pathogeny of uterine fibromyomata, suggests that in certain cases they may be congenital, and that their growth commences and is accelerated coincidentally with the establishment of the genital functions.

351 Neurotrophic Cellular Alterations and Tumour Formation

P. SUNDER-PLOSSMAN (*Bruns' Beitr. z. klin. Chir.*, July 11th, 1934, p. 75) refers to recent histological demonstrations by himself and others of fine fibrillary neural terminations which come into close contact with cells of vessels, muscles, glands, epithelium, and, indeed, all tissues. To this "synectium," derived from vegetative nerves, is ascribed a trophic activity. In naevi of the lip the terminations are specially abundant; in carcinoma of the lip they show marked degenerative changes. After section of the sinus nerve (which is purely parasympathetic) in rabbits the author has found duplication of the nuclei of the superior cervical ganglion. On these and

other grounds Sunder-Plassman agrees with those who assign to widespread changes in the vegetative nervous system an important part in the causation of malignant disease. He quotes, among others, the observations of Mühlmann, who found in the brain typical microscopical alterations in cancer patients; those of Matalimov, who noted degeneration in the neural network of the putamen and globus pallidus; and those of Shaw and Camille, who have suggested morbid alterations in sympathetic-hormonal balance as a causative factor in tumour formation.

352 Acute Meningitis due to Pfeiffer's Bacillus

E. BENHAMOU, HUCK, and JAHIER (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, July 23rd, 1934, p. 1264) believe that Pfeiffer's bacillus should be suspected as the possible causal factor, even in the absence of an influenzal epidemic, in an acute meningitis of abrupt onset with a high pleocytosis and polynucleosis in the cerebro-spinal fluid. A case (an infant aged 4 years) is reported in which these bacilli were isolated first from the cerebro-spinal fluid and later from the blood. The treatment of such cases consists of a subcutaneous and intraspinal bacteriotherapy with an autovaccine. In the present case, intraspinal injections were not given owing to the cachectic condition of the child, and four subcutaneous injections proved unavailing, possibly because of the late institution of the treatment. To avoid the delay in obtaining an autovaccine, experiments are being made, especially in America, to prepare a specific vaccine. Though some cures have been reported with such a vaccine, the results are not comparable with those obtained by anti-meningococcal sera in meningococcal meningitis.

353 Intradermal Tests for Hydatid Disease

OTERÍÑO NÚÑEZ and CALVELO LÓPEZ (*Anales de Medicina Interna*, July, 1934, p. 609) state that Casoni's intradermal test is not specific, inasmuch as it gives a positive reaction when there is no infection by *Taenia echinococcus*. It is, however, of great value as a test for the presence in the organism of some, if not all, of the Taeniadae. There are antigenic substances which are common to these helminths, and Casoni's reagent extracted from hydatid fluid is not superior to extracts from any of the others of the group. Employing an antigen derived from a fresh intestinal taenia treated by a method which is fully described, the writers found that the response was much more specific and accurate than that obtained from Casoni's reagent, and state that their experiments have been quite recently corroborated by L. Morenas, who used an antigen derived from cysts of *Taenia serrata* in the peritoneal cavity of the sheep.

354 Humoral Nature of Insulin Resistance

R. BOLLER, K. UIBERRAK, and W. FALTA (*Wien. Arch. f. innere Med.*, June 20th, 1934, pp. 1 and 25) have taken as a test for the presence of insulin in the blood the appearance of a reduction in the blood sugar of a diabetic, previously proved sensitive to insulin, in whom a transfusion of the blood in question was made. They find that after a carbohydrate meal: (1) a healthy person's blood contains insulin in very small amounts, not more than 1 to 2 units per 100 c.cm.; (2) the blood of insulin-sensitive patients with severe diabetes contains no insulin; and (3) that of insulin-resistant diabetics contains no insulin, and may indeed increase the blood sugar of the recipient. In a further series of experiments the writers tested for insulin the blood of persons who had received large doses of it subcutaneously. They found that insulin was present in the blood in these conditions, in healthy persons, and in diabetics who respond to insulin; it was absent in six cases of typical severe insulin-resistant diabetics. The disappearance of the effect of subcutaneously injected insulin in these six patients cannot, it is stated, be due to its excretion in the urine, as has been established by previous observations; the insulin must have been "fixed" or (more probably, it is suggested) destroyed by antagonistic substances present in the diabetics who are not responsive to insulin.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

355 Significance of Tuberculous Bacilluria

H. WILDBOLZ (*Münch. med. Woch.*, July 6th, 1934, p. 1012) controverts the opinion, recently revived, that a tuberculous bacilluria—denoting excretion without affection of the urinary or genital tracts—is common in those suffering from pulmonary or bone tuberculosis only. In most of the researches supporting such a view, he points out, the urogenital tract has been insufficiently investigated, or the specimen has not been taken by catheter, or has been subject to contamination from sputum or faeces. Confronted with detection of tubercle bacilli in the urine, the practitioner should seek signs of urogenital tuberculosis, of which, in the male, those most easily detected are infiltration of the vesiculae seminales or prostate, or nodules in the epididymis, and, in the female, an infiltration of one or other ureter in the anterior vaginal fornix. If these signs are absent and the result of an animal inoculation test is positive, special examinations of the urinary tract are called for—cystoscopy, ureteral catheterization and excretory pyelography. The vast majority of those excreting tubercle bacilli in the urine possess a caseous focus in a kidney; and cure is obtained after nephrectomy in 50 to 60 per cent. of cases of unilateral tuberculosis. Yet nephrectomy is not immediately justified by discovery of a unilateral excretion of bacilli: a very small percentage of early cases are curable by fresh air and other general treatment, provided there is little or no pyuria and the kidney function is good. In Wildbolz's experience of so-called early cases, the vast majority, when first seen, have the triad of symptoms—bacilluria, pyuria, and impaired function—which justifies nephrectomy when the morbid condition is one-sided. He has seen twenty-four cases only in which he has postponed nephrectomy, and in all but four of these removal of a kidney (now showing cavernous tuberculosis) has later been necessary. He concludes that a "tuberculous bacilluria" similar to the common *B. coli* bacilluria and a "tuberculous nephritis" are so rare as to be of no practical importance.

356 The Influence of Diet on the Gums and Teeth

A. LINDSTRÖM (*Hygiea*, August 15th, 1934, p. 529) has taken part in an extensive health survey in the North of Sweden. It was hoped that definite information would be obtained as to the influence of climate, diet, housing, and other factors on the health of the community. The author's contribution to this survey was a study of the teeth and gums of children and adults. The dietary was mainly lacto-cereal. The more it was supplemented by meat, the greater was the freedom of the gums from inflammatory changes. Perfectly healthy gums were rare, and advanced gingivitis was the rule rather than the exception among older persons, but only up to the age of 65. Those over this age had, as a class, fairly healthy gums, possibly because survival beyond this age implied a robust constitution. Twice as many girls as boys brushed their teeth, but the author failed to establish any convincing connexion between this practice and healthy teeth and gums. Indeed, in one area with an exceptionally low caries rate there were no tooth-brushing children. It is true that slight forms of gingivitis were less common among the devotees of the tooth-brush than among their more negligent neighbours, but where severe forms of gingivitis were concerned, particularly in elderly persons, the daily wielding of the tooth-brush appeared to have given no relief. No correlation could be established between addiction to coffee on the one hand and diseases of the mouth on the other; and as for the chewing of tobacco, it may even have checked the development of caries, however injurious it may have been to the gums.

Though in this respect the action of tobacco on the teeth and gums may have been respectively beneficial and harmful, the frequency with which the author found freedom from caries associated with healthy gums suggests that there may be a common factor in the development of both caries and gingivitis.

357 Spontaneous Recovery from Acquired Syphilis

J. VIEUCHANGE (*Thèse de Paris*, 1934, No. 675) has collected thirty cases showing that in some instances of acquired syphilis recovery may take place with little or no treatment. It is impossible to determine exactly the frequency of such cases, but the possibility of such an occurrence suggests that cases of syphilis may be classified in the following three groups—namely, those in which spontaneous recovery takes place, those in which a cure is due to treatment, and those which develop visceral complications in spite of treatment. The idea of a spontaneous recovery from syphilis indicates the importance of the individual constitution as the cause of the disease and the necessity of general treatment, in addition to specific medication.

358 Gonococcal Myositis

R. A. RUBI (*Semana Médica*, July 12th, 1934, p. 125) considers myositis to be an exceptional complication of urethritis, occurring either during the acute and primary stage or in an exacerbation, or after injudicious instrumentation. The severity of the urethritis has no bearing on the development of myositis. It is most frequent in adult males, and in the muscles most often in action. There are three forms—mild, acute phlegmonous, and suppurative. The mild form may develop into either of the more severe types, and is often followed by synovitis or arthritis, though it generally clears up with the urethral condition. The phlegmonous form is preceded by arthralgia and slight pyrexia, lymphangitis being often absent. One muscle is usually attacked, and this is hard, stiff, increased in volume, painful, and tender, with reddening of the overlying skin. The writer had ten cases of the suppurative type; of these, two were fatal. They began like cases of the mild type, but after the third day showed signs of deep suppuration in one or more muscles, with grave constitutional disturbance. Two cases with multiple foci died of pyaemia. Coexistence of a myositis with gonococcal urethritis, corroborated by blood culture and agglutination tests, will establish the diagnosis. Treatment, apart from that of the urethral and para-urethral areas, is purely symptomatic. The author recommends absolute rest, with counterirritation with iodine for the mild form, and continuous fomentations for phlegmonous cases, while in the suppurative variety opening of all abscesses early and free drainage. Specific vaccines, subcutaneously or focally, are of great value, and Bier's passive hyperaemia method is of use where the limbs are the seat of the disease. Once the acute stage is over, passive movements of the affected muscles and slight massage are imperative.

359 The Hypersthenic Syndrome and Gastric Cancer

Referring only to cases of rapid evolution, A. CADE and M. MILHAUD (*Journ. de Méd. de Lyon*, August 20th, 1934, p. 551) state that, as in ulcer, gastric cancer is evidenced by a hypersthenic syndrome. Short notes on thirteen such cases are appended. The clinical symptoms of this syndrome are: absence of the periodicity of painful crises; marked, repeated early vomitings; a less sedative and shorter effect of food and medicaments; rapid emaciation with anaemia, though the appetite is often conserved; and occult haemorrhages. This syndrome is of considerable importance, its presence, even in young subjects, being indicative of cancer.

Surgery

360

Abuse of Parathyroidectomy

J. SIMARRO (*Rev. Méd. de Barcelona*, July, 1934, p. 19) sounds a warning to those who would seek to cure by parathyroidectomy rheumatoid conditions attended by rarefaction of bone and hypercalcaemia, and who believe that the coexistence of these signs is sufficient proof of parathyroid over-action merely on the ground that Recklinghausen's fibro-cystic osteitis is connected with an adenomatous condition of the parathyroids. The majority of failures to effect a cure by parathyroidectomy go unpublished, and, what is worse, little mention is made of the resultant tetany, infralaryngeal nerve paralysis, and regional vasomotor disturbance. While far from decrying the operation in suitable cases of parathyroid adenoma and in certain conditions where the existence of hyperparathyroidism has been established both clinically and biochemically, it should, thinks the author, be reserved for these. Hypercalcaemia is not invariably due to parathyroid hyperaction, and frequently yields to treatment which has no direct influence upon the parathyroids. Though it may be reduced after the operation, the concomitant rheumatoid condition is frequently unchanged. There is a non-adenomatous hyperparathyroidism secondary to other endocrine derangements, and the connexion between the pituitary, thyroid, suprarenal, genital glands, liver (this last so often and so unjustly relegated to a second place by endocrinologists), should not be overlooked. Amorosi's work on the bile outside the digestive apparatus may, the author states, serve as a foundation for further research into the mechanism of the types of hypercalcaemia and decalcification.

361 Pre-operative Treatment of the Dilated Stomach

In pyloric obstruction due to ulcer or malignancy the stomach may show a marked degree of dilatation, and T. G. ORR and W. C. CURRIE (*Surg., Gynecol. and Obstet.*, July, 1934, p. 92) describe a method of reducing its size by continuous gastric lavage with suction. They point out that it is unwise to conduct extensive operations upon any acutely distended portion of the gastro-intestinal tract, since the tone of the stomach or intestinal wall has been lost, and the blood supply has been disturbed. They therefore pass an indwelling Levine tube into the stomach through the nose, and the patient is urged to drink as much water as possible, all fluid, secretions, and gas being promptly removed by continuous suction. After a few hours of such lavage, liquid will often begin to pass through a previously completely obstructed pyloric orifice. During the process, which may have to be continued for four to six days, careful attention must be given to maintaining the chemical, water, and metabolic balance—water, salt, and glucose being given intravenously or by hyperdermoeclysis. Since loss of the gastric juice reduces the body chlorides, a daily check of the blood chloride content is desirable. Radiographic illustrations are given of a stomach which was reduced to normal dimensions after ten days' treatment on these lines. A gastro-enterostomy was then performed, and recovery was free from complications. The simple apparatus used is a modification of methods recommended by R. Ward, and later by J. H. Wangensteen.

362 Excessive Shortening of the Lower Limb

According to C. P. VAN NES (*Le Scalpel*, August 4th, 1934, p. 1077), excessive shortening of a lower limb may be congenital, due to arrested development of the femur or leg or to congenital dislocation of the hip; other causes are poliomyelitis, hip disease, and, less frequently, osteomyelitis and malunited fractures of the femur. Orthopaedic correction of this deformity, necessitating the wearing of a heavy, ugly limb, is not advocated. Two surgical interventions are described—lengthening of the affected limb or shortening of the sound one. In the former, a Wladimiroff-Mikulicz resection, or osteotomy

of the femur (or of the tibia and fibula) with extension of the limb, is performed. In the second procedure, portions of these bones are resected, usually only of the femur, but should the shortening of the affected limb amount to 14 to 18 cm., all three bones must be resected. The latter method is preferred, as it gives an equal length to both limbs and obviates the disadvantages of the first method—namely, slow consolidation of the bony fragments, risk of future fracture, and undue extension of the nerves and vessels.

Therapeutics

363

Hypopituitarism and Blood Pressure

K. RUDSIT (*Wien. klin. Woch.*, July 13th, 1934, p. 878) examined the blood pressure of fifty-eight patients on standing, sitting, and lying. In Group I (twelve cases) the systolic pressure was higher in the vertical position than on sitting or lying, the diastolic pressure remained stationary or sank, the pulse pressure increased, and the pulse rate was increased. In Group II (twenty-eight cases) the systolic and diastolic pressures remained constant in all three positions, and the pulse rate increased on standing. In Group III (eighteen cases) the systolic pressure fell on standing, whereas the diastolic pressure remained stationary or rose; the pulse pressure was diminished. The latter group largely contained vasoneurotic patients who complained of faintness, dyspnoea, cardiac pain, sweating, paraesthesiae, and tachycardia, and who in bad cases were bed-ridden. According to Rudsit vasoneurosis is due to a dysfunction of the anterior lobe of pituitary, for the tone of the blood vessels depends on a nervous mechanism and the hormone of anterior pituitary. The author used the hormone of the anterior pituitary gland with success in five vasoneurotic patients whose history he describes in detail. He believes that the examination of the blood pressure in various body positions aids in the diagnosis of these cases and helps in the control of treatment by the anterior pituitary hormone.

364 Treatment of Venereal Lymphogranuloma

According to E. P. FARINAS (*Thèse de Paris*, 1934, No. 415) general treatment is the rule in all forms of this condition, and may be sufficient in recent cases in which suppurative adenitis has not yet developed. The best treatment consists in Lugol's solution associated with hyposulphite of soda, given by mouth and intravenously in progressive doses. When supuration takes place local treatment is necessary, the method of choice being electrocoagulation. Acute rectitis requires only medical treatment (local and general), and operation should be reserved for cases of fibrous stenosis. In such cases, however, general treatment should precede, accompany, and follow the surgical measures. In cases of obstinate adenitis with cellulitis, biological treatment in the form of a specific antigen or serum should be employed. The thesis contains the histories of twenty-three patients aged from 20 to 45. J. KLEINBERG (*ibid.*, No. 640), who records ten cases (nine of which were in men and one in a woman), states that intravenous injection of sodium salicylate in daily doses of 0.5 to 1 gram causes a considerable diminution in the inguinal adenitis without giving rise to any general reaction or discomfort. The drug may also be given by mouth, provided the patient be kept in bed on a milk diet. It chiefly acts on the acute process, and prevents extension of the inflammation, but has very little effect on the fibroid lesions of the rectum and genital regions. P. SÉGAL (*ibid.*, No. 657), who records thirteen cases in men aged from 24 to 40, recommends a combination of local treatment, consisting of injections of pure glycerin and glycerin iodoform, with the administration of sodium salicylate by mouth or intravenously. Partial excision, as well as radiotherapy, may also be needed. Treatment should be commenced early before the stage of softening or formation of fistulae. F. VELASQUEZ (*ibid.*, No. 659) records fifty-five cases, fifty-two of which occurred in men

and three in women. The following treatment was used: intravenous injection of sodium-antimony tartrate in nineteen, chrysotherapy (thiopropional and chrysalybine) in two, ammoniacal copper sulphate in one, emetine in three, glycerin in eight, Lugol's solution in three, sodium sulphate in eight, vaccine therapy in six, ultra-violet rays in one, and electro-coagulation in four.

365 Suprarenal Cortex Therapy in Graves's Disease

I. BRAM (*Med. Record*, July 18th, 1934, p. 67) gives an account of the results of treating twelve cases of exophthalmic goitre with the glycerinated extract of suprarenal cortex in the form of ten-grain pills, given in doses of three or four by the mouth three times a day. Smaller doses were found to be inadequate. Another dozen patients were used as controls, and did not receive the extract. Both groups were kept under a broad medical programme, which included moderate rest, an ample dietary, and psychotherapy, any necessary sedatives or other indicated medications being given. It was found that the addition of the suprarenal extract resulted in comparatively prompt relief from tachycardia, the heightened basal metabolic rate, nervousness, and fatigability. This relief occurred approximately eight weeks sooner than in the control patients. The average duration of the cortex treatment was ten weeks. A paradoxical fall in blood pressure was noted, due evidently to the restoration of the heart rate to normal. Bram points out that there are many types of Graves's disease, requiring different forms of medical treatment. Failure to recognize this fact has been the cause of disappointment in the past. Suprarenal cortex therapy is said to be harmless in all varieties, and of definite assistance in many. The author considers that psychotherapy is necessary in all cases of Graves's disease.

366 Hypertonic Solutions in Epilepsy

G. VILLEY-DESMERERS and J. FR. BUVAT (*Paris Méd.*, August 4th, 1934, p. 109) present a preliminary report concerning the use of hypertonic solutions in epilepsy, and record three cases illustrative of the good results obtained by this method. These consisted in a rapid diminution in frequency and intensity of the epileptic crises and a progressive improvement of the condition. Intravenously, either sodium chloride 2 grams or sodium bromide 2 grams and sodium chloride 1 gram in 20 c.c.m. of sterile distilled water were given at each injection. These should be systematically given thrice weekly for a prolonged period. Drop rectal instillations of magnesium sulphate, 15 grams to 150 c.c.m. of boiled water, may be used as adjuvants or substitutes; they are, however, less efficacious. Gardenal in daily doses of 25 to 40 cg. according to the case should be combined with the hypertonic treatment.

Ophthalmology

367 Uniformity in Field-taking

A. H. THOMASSON (*Arch. of Ophthalmol.*, July, 1934, p. 21) detects the beginning of a scotoma by using the smallest normally perceptible object for the particular part of the field under examination. He uses a $\frac{1}{2}$ mm. object at 1 metre up to 20 degrees from the centre, a 1 mm. object up to 25 degrees, and one of 5 mm. beyond. Any scotoma which can be detected with a coloured object can be equally well observed with a sufficiently small white object. A white object is equivalent to a coloured object ten times its diameter. Many errors, such as colour-blindness, and the difficulty of obtaining uniform colour tint, occur with the use of coloured objects, which should only be used for differential diagnosis or toxic amblyopias. A tangent screen should be used for defects within 25 degrees, and a perimeter for observations outside that circle. Variation in illumination of more than three foot-candles causes little effect upon the field, and daylight between 9 a.m. and 3 p.m. is preferable because the lighting is a natural one. If artificial, the

illumination should be "daylight" of seven foot-candles. Nebulae or lens opacities cause irregularities of the fields. Presbyopes should be examined with correcting glasses. The confrontation method is very valuable as a preliminary. Any defect found should then be further examined by the perimeter or screen. It is best to work from a blind to a seeing area and investigate the regions above and below. The blind spot in glaucoma should be mapped out with a $\frac{1}{2}$ mm. white object at 1, 2, or 3 metres. Poor visual acuity necessitates the use of larger test objects, and care should be taken that the patient is not unduly fatigued.

368 Gonorrhoeal Ophthalmia

J. I. FARRELL (*Amer. Journ. Ophthalmol.*, July, 1934, p. 591) examines the records of 189 patients over 6 months of age, suffering from the above condition, to determine the effect upon the prognosis of a concurrent genital infection. The conclusion is that the prognosis is not affected. Several interesting statistical findings emerge from this inquiry. Thus, the average stay in hospital was 28.4 days, slightly more in the presence of genital gonorrhoea, and less in its absence. Corneal invasion prolonged hospital treatment to 33.8 days. Foreign protein therapy (diphtheria antitoxin, typhoid vaccine, and milk) gave results which were not encouraging. Of the total number of cases 8.5 per cent. lost an eye, while 61.4 per cent. were discharged with normal, 7.9 per cent. with good, 4.8 per cent. with fair, 2.6 per cent. with poor, and 13.2 per cent. with very poor vision. The treatment in the majority of cases was: irrigation with lot. ac. bor. (3 per cent.) followed by the instillation of argyrol (20 per cent.) and ung. ac. bor. This was carried out half-hourly or less frequently, according to the amount of discharge. A Saemisch section or conjunctival flap was necessary in many cases.

369 Syphilitic Retrobulbar Neuritis

B. H. HARRY (*Canadian Med. Assoc. Journ.*, June, 1934, p. 632) points out the necessity of "looking beyond the sphenoid-ethmoid area and disseminated sclerosis" for the aetiology of retrobulbar neuritis, and records an illustrative case. A man, aged 30, while at work noticed that his vision was rapidly failing, until within the next twenty-four hours it had diminished to almost complete blindness. Syphilitic signs were manifest. A series of fourteen intramuscular injections of 3 grains of thio-bismol brought about some mental, physical, and ophthalmic improvement. He was then given malarial treatment, and after two months' interval a second series of thio-bismol injections with tryparsamide. Good recovery ensued. At the time of his admission to hospital the ophthalmoscopic picture was negative, except for a small amount of hyperaemia of the left disk. The recovery of central vision under treatment was not accompanied by a corresponding enlargement of the peripheral field, perimeter charts revealing an appreciable amount of peripheral atrophy.

370 Ophthalmological Effects of Pilocarpine

J. A. VAN HEUVEN (*Brit. Journ. Ophthalmol.*, September, 1934, p. 511) points out that occasionally the instillation of pilocarpine in chronic glaucoma produces bad or diminished vision for one to one and a half hours after instillation. This occurs in people over 50, but never in a young person. It is unrelated to the presence of opacities in the lens. The same effect may occur with eserine. Hess, after experiments on himself, considers it to be due to a spasm of the capillaries, or an opacity in the retina. There is, in some cases, a temporary enlargement of the blind spot, and diminution in the field. Though the writer thinks that the condition is due to a spasm of the vessels, he is unable to confirm this in animal experiments. Using a Scheerer entoptoscope, an initial slowing down of the blood current near the macula is followed by an enlargement of the area where no vessels are to be seen (Maxwell's spot). This is

coincident with the onset and duration of reduced vision. The effect may be neutralized or overcome by small doses of nitroglycerin by mouth, or by the addition of cocaine to the pilocarpine. Van Heuven has found that 2 per cent. pilocarpine is equivalent to 1 per cent. pilocarpine + 0.3 per cent. eserine + 0.5 per cent. cocaine. With this solution no diminution of vision is observed though the reduction in tension is preserved.

Obstetrics and Gynaecology

371 Intravenous Urography in Urogenital Fistula

According to W. DOERANIECKI and W. GRABOWSKI (*Gynecol. et Obstet.*, June, 1934, p. 326) almost one-half of women having vesico-vaginal, uretero-vaginal, or other urinary fistulae following obstetric trauma have consequential and serious affection of the uretero-renal apparatus due to perivesical, perivaginal, and periauricular scar formation. Excretory urography, as after intravenous injection of uroselectan or tenebryl, is an invaluable preliminary to operation. It furnishes, far more than instrumental urography, reliable information regarding morbid anatomical and functional changes. It may serve to prevent—at operation—discovery of pyonephrosis of pyoureter at the moment of implantation of the urter into the colon, or occlusion of a healthy urter in repair sutures per vaginam while the other is obstructed, causing renal atrophy; both these accidents have occurred in fistula operations. In order to demonstrate effectively the pelvic and vesical positions of the urter, it is often necessary, in fistulous subjects, to occlude the urine in the bladder by inflation of a bag placed in the vagina. Among the illustrative cases recorded is that of a woman in whom almost the whole of the vagina was cicatricial, and a uretero-vesical ostium, probably the left, was detected in the prolapsed mucosa of the bladder, but could not be catheterized; a recto-vaginal fistula was also present. The operation planned was repair of the fistula, followed by colonic implantation of the ureters. After injection of uroselectan, however, the right urter was found to be dilated and inactive, the right renal pelvis distended, and the right kidney the site of hydronephrosis. Accordingly, the first step undertaken was implantation of the right urter, followed later by that of the left and finally by repair of the recto-vaginal fistula.

372 Radium Therapy of Cervical Cancer

H. HOFMANN (*Zentralbl. f. Gynäk.*, August 11th, 1934, p. 1886) would reserve radiotherapy of carcinoma of the cervix during pregnancy for the exceptional cases in which the mother, ardently desiring a living child, declines operation. His reasons are threefold. First, cancer of the cervix in pregnancy includes a high proportion of operable cases (80 to 100 per cent.), and operation gives a low primary mortality (4.2 per cent. according to Weibel) and a fair rate of five years' survival (42 per cent. in Pankow's collected statistics). Secondly, injury to the child by irradiation is not infrequent; it occurred in seven of thirty-five cases collected by Hofmann, and two instances of microcephalic idiocy were included. Thirdly, the proportion of cures after radiotherapy is not greater than 27 per cent. Hofmann describes the case of a two-para, aged 29, who during the fifth month of pregnancy was found to have carcinoma of the cervix, but, having rejected operation, was given a vaginal application of 2,040 mg.-hours of radium—a comparatively small dose—in two sittings. Birth, at term, was precipitate, and the child was and has remained healthy. Eight months later a recurrence on the cervix was found to coexist with a two months' pregnancy. Vaginal extirpation of the uterus and a small coil of vagina was done, the lower being left behind. After three months there is no sign of recurrence. The malignancy of both the cervical cancers was proved most capably.

Pathology

373

The Zoster Virus

S. A. GLAUBERSON and G. S. BARG (*Acta Med. Scand.*, lxxxii, V-VI, 1934, p. 579) remark that the prevailing uncertainties concerning the relations of the viruses of herpes zoster, symptomatic herpes, and varicella are largely due to their being practically incommunicable to lower animals, although the possibility of transference from man to man by injection has recently been proved. They point out the scientific and practical desirability of culture of the virus, and give the results of their endeavours to do so in tissue cultures—rabbit plasma containing an equal amount of tyrode solution and fragments of embryonic chicken heart. The content of the vesicles in herpes zoster, sterile in ordinary bacteriological tests, preserves its activity after four days' incubation at 37° C. and two further days at room temperature, in tissue cultures: injected into two children it was found to produce locally typical vesicles and crusts, which were absent in control children injected with cultures to which tissue fragments had not been added. The incubation periods were nine and sixteen days respectively. In one child, shortly afterwards exposed to chicken-pox infection, a typical varicella rash occurred, so that the zoster virus had not protected against chicken-pox. On the other hand, neither of the vaccinated children caused infection with varicella in their numerous contacts. The zoster virus, in 40 per cent. glycerin, appears to retain its activity for at least four days in the ice chamber.

374 Experimental Pre-Anaesthetic Medication

L. LENDLE (*Schmerz Narkose-Anaesthesie*, July, 1934, p. 20) reports the results of a study of the duration of anaesthesia, the lethal dose, and the time of survival (1) in rats after preliminary administration of ephedone, cardiazol, or caffeine, and (2) in cats after that of digitoxin or strophanthin. The anaesthetic was avertin, given subcutaneously in 2.5 per cent. solution in rats, orally in doses of 0.25 to 0.36 gram per kilogram of body weight in cats. In the first series of experiments no shortening of anaesthesia was noted, and the tolerance as estimated by the lethal dose was either not increased or diminished. It would therefore appear that if indications for administration of ephedone, cardiazol, or caffeine occur during anaesthesia the response to injections given then is more effective than that to premedication. From the second series it appeared that pre-operative digitalization, so far from diminishing the danger of an overdose of avertin, increased its toxicity: possibly digitalis and strophanthus interfere with the mechanism of carbohydrate metabolism by which avertin is detoxicated.

375

Jerusalem Artichoke in Diabetes

With a view to determining whether the carbohydrate in Jerusalem artichokes was more available for the nutrition of patients with severe diabetes than equal quantities of other carbohydrates, L. K. CAMPBELL (*Arch. Int. Med.*, July, 1934, p. 82) undertook feeding experiments with two such patients and a completely phloridized dog. A large part of the reducing substances in the artichoke was found to be laevulose, but the hydrolysate always gave a strong reaction for ketoses. In the dog the extra dextrose obtained by feeding it with artichoke was 64.6 per cent. of the theoretically available dextrose, a result comparable with that obtained when pure dextrose was administered. In the case of the diabetic patients a method was developed for studying the production and utilization of dextrose in food substances. In one patient the increase in the amount of dextrose in the urine from ingested Jerusalem artichoke was greater than that from an equivalent quantity of oatmeal, but in the other patient it was less. Campbell concludes, therefore, that there is no striking difference in the utilization of Jerusalem artichokes in diabetes from that of an equivalent amount of oatmeal.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

376

Causes of Sudden Death

J. V. DUHIG (*Med. Journ. of Australia*, July 28th, 1934, p. 112) reviews the findings at 500 consecutive necropsies, with a view to indicating the causes to be looked for first in cases of sudden death or unexpected serious illnesses. He finds that the large majority of sudden deaths are due to diseased coronary arteries, atheroma being the commonest condition. He states, as a practical point in performing a necropsy, that the degree of atheroma and of calcification of the arteries generally runs exactly parallel with the degree of calcification of the costal cartilages and that the degree of senility in a physiological rather than in a purely temporal sense can be accurately determined by this costal manifestation. Duhig adds that arteriosclerosis is extremely rare as the cause of such sudden death. Atheroma is very capricious in its distribution: the best place to observe it is in the aorta at its bifurcation and the common iliac arteries. It is surprisingly rare in syphilitic patients, just as syphilis is hardly ever found as the cause of coronary artery disease. In thirty-four deaths due to cessation of the brain function—representing the unexpectedly small percentage of 7 of all the deaths—cerebral haemorrhage was concerned in thirty-two. Other comparable percentages in this series were: cardiac disease, 38; suicide, 28; accident, 17; pulmonary, 2.6; and anaesthesia, 2. The males in this series of sudden deaths outnumbered the women by three to one. The figures indicated that men commit suicide three times more frequently than women; nearly six times as many men are accidentally killed as women; and three and a half times as many men drop dead or are found dead of heart failure as women.

377 Ultimate Fate of Sanatorium-treated Cases of Pleurisy

O. HELMS (*Hospitalstidende*, July 24th, 1934, p. 31) has investigated the subsequent fate of 150 patients who underwent sanatorium treatment in Denmark for pleurisy. The period covered was eight years, and the diagnosis was confirmed by the stethoscope, x rays, exploratory puncture, and the clinical course of the disease. No doubtful cases were included in this material, nor were those in which tuberculosis other than of the pleurae was demonstrable on admission to the sanatorium. The average duration of the sanatorium treatment, which included sun and light baths, was four months. When information was sought two years after discharge three patients could not be traced, and two had died. Five had been readmitted to the sanatorium and three were unfit for work. The remaining 137 were fit for work. It would thus seem that a maximum of only 7 per cent. of these patients had developed definite tuberculosis after discharge. This ratio could be reduced to only 5 per cent. if the study were limited to the eighty-four patients admitted to the sanatorium in the first five years of the period under review and kept under observation five years after discharge. Four could not be traced, three were dead, one was readmitted, and seventy-six were still fit for work. Comparing these results with those of earlier writers, who have found from 40 to 100 per cent. of their pleurisy patients subsequently developing other forms of tuberculosis, the author suggests that his relatively good results may partly be traced to the advances made in x-ray diagnosis, which provided him with patients in a comparatively early stage of disease. Several of the patients of earlier writers were doubtless already suffer-

ing from pulmonary tuberculosis when first treated for pleurisy. Again, the patient with pleurisy is now taken much more seriously than he used to be, thanks in large part to the ominous character of the older statistics. The author is not in favour of such radical treatment as sanocrysin and artificial pneumothorax for uncomplicated pleurisy, and he expresses disapproval of the indiscriminate admission to sanatorium of all light cases of pleurisy.

378

Aetiology of Pellagra

R. FLINKER (*Wien. med. Woch.*, August 18th, 25th, and September 1st, 1934, pp. 900, 930, and 960) has investigated 403 cases of pellagra treated in his hospital in the Bukovina between January 1st, 1922, and December 31st, 1932. Although its population is made up of Rumanians, Ukrainians, Germans, Jews, Poles, and a few Hungarians, it is only the two first-named nationalities which are subject to pellagra, its incidence being sixty times greater among them than among the other component nationalities of the country. The author sees in this racial distribution of the disease a refutation of the theory of an infectious aetiology. He also considers as untenable the theory which at present is most in favour—that pellagra is really an avitaminosis—for pellagra often breaks out on a well-mixed dietary, and clears up spontaneously, even when no change has been made in the composition of the food. There is also the observation, disconcerting to the avitaminosis theory, that persons who have remained free from pellagra for decades develop it without having changed their dietary. As the aetiology of this disease is still obscure, the author suggests that progress may be made by correlating its manifestations with those of conceivably allied diseases, and he picks out pernicious anaemia for this purpose. Both diseases are characterized by remissions which may last for years and recur four times and even oftener. Common to both diseases are glossitis, anorexia, vomiting, and, above all, achylia. Diarrhoea is common in pellagra and an important symptom in pernicious anaemia. The similarity of the spinal manifestations is most striking, and psychic disturbances, common in pellagra, are apt to be associated with pernicious anaemia. In both diseases oedema occurs in the later stages, and women are more liable than men to both. There is also the favourable response of both to arsenic. Returning to the gastro-intestinal tract, the author refers to nineteen cases of pellagra in which a special study was made of the gastric functions. In almost every case a complete absence of free hydrochloric acid was demonstrable. Indeed, it is probable that every case of pellagra is associated with digestive disturbances, and is very likely caused by them, a contributory factor in some cases being alcoholism.

379 Syphilitic Meningitis Affecting the Pituitary

According to F. WINKLER (*Med. Klinik*, July 20th, 1934, p. 967) it is probable that the great majority of cases of syphilitic meningitis of the region near the sella turcica are first diagnosed post mortem, yet early recognition is imperative if blindness is to be avoided. The case is recorded of a syphilitic woman, aged 38, who had homonymous left hemianopsia, bilateral papilloedema, and slight left hemiparesis without morbid pyramidal signs. That the right optic tract was subject to compression from the pituitary region was indicated by: (1) a galactorrhoea and frontal chloasma which had persisted for two years since parturition, and (2) a recent alteration of the menses to a two weeks' type. Antiluetic treatment cured the visual and motor symptoms and restored the menstrual rhythm, but did not diminish the secretion of milk.

Surgery

380 Retroperitoneal Perirenal Lymphangioma

H. KRETSCHMER and W. HIEBS (*Arch. of Surg.*, July, 1934, p. 112) state that the retroperitoneal tissues above and below the kidney may be the seat of benign or malignant, cystic or solid, tumours. Of these, benign and solid tumours are more common than the malignant or the cystic type. Only four cases of true retroperitoneal lymphangioma have previously been reported, but particulars are given of a further case in which the tumour by its growth caused pressure atrophy of the lower pole of the kidney and was attached to the kidney. Retroperitoneal lymphangiomas do not as a rule cause any particular symptoms until they have reached a considerable size. Dyspnoea and ureteral pressure may then occur, or abdominal pain and distension. The chief aids in diagnosis are cystoscopy, ureteral catheterization, and pyelography. When the tumour occurs low in the abdomen it may be confused with lesions of the uterus or ovaries, and may even simulate pregnancy. Treatment, which must be surgical, frequently necessitates the removal of the kidney when this has been engulfed by the tumour. The chief difficulty in the removal of retroperitoneal growths lies in the dissection of the adhesions of the tumour to the mesentery and intestines, which may cause injury to the mesenteric vessels and necessitate resection of portions of the intestine. Although removal is the ideal treatment for cystic lymphangioma of the retroperitoneal regions, drainage with tamponade and suture of the edges of the cyst to the peritoneum may be carried out when the tumour is unilocular. Radium may also be used when the tumour cannot be extirpated.

381 Percaine Anaesthesia in Urology

N. MONO (*Zentralbl. f. Chir.*, August 11th, 1934, p. 1865) in 3,000 cases in which the urethra or bladder was anaesthetized by applications of percaine solution (0.1 per cent. with 5 drops of adrenaline in 100 c.cm. of solution) saw no toxic effect. Care was taken not to inject the solution under pressure: when an instrument has been recently passed a tear of the mucosa may be present, and pressure may force the anaesthetic substance into a vein. For the anterior urethra 3 to 4 c.cm. are left in for ten to fifteen minutes, voided, and replaced by the same amount for ten minutes. In cystoscopy in the male 8 to 10 c.cm. are placed in the anterior urethra, and a further injection is given ten to fifteen minutes later; sometimes a gauze strand moistened with percaine must be left in. In urethral stricture percaine facilitates instrumentation by abolishing spasm. In anaesthesia of the female urethra, if percaine applied in solution on gauze or in bougies is ineffective, a psychogenous cause of the symptoms should be strongly suspected. For bladder anaesthesia percaine has been found superior to other anaesthetics; according to Lichtenstern's technique 30 to 50 c.cm. are instilled for thirty minutes, withdrawn, and replaced by a like amount for the same time.

382 Abdominal Distension in Retroperitoneal Haemorrhage

Recording three cases of retroperitoneal haemorrhage following trauma, CH. LENORMANT and G. CORDIER (*Presse Méd.*, August 8th, 1934, p. 1257) state that an intestinal reaction, evidenced by distension, is frequently noted during sub- and retro-peritoneal haemorrhages without involvement of the serosa or of an intra-abdominal organ. Blood is an important factor in peritoneal irritation. If this acts on the very sensitive anterior peritoneum contracture will readily occur, as observed in the intra-peritoneal haemorrhages of splenic rupture. If a less sensitive zone such as the posterior, pre-renal, and pelvic peritoneum is irritated, intestinal irritation with abdominal distension will result. If the haemorrhage is arrested irritation ceases, and the tympanites disappears, if it

persists, and especially if a continuous irritative factor such as a clot is superadded, paralytic ileus or a parietal response of defence ensues. The authors believe that tympanites is merely evidence of irritation of the parietal serosa, and not necessarily an indication for operation. In cases of abdominal distension following lumbar or pelvic trauma, pelvic fracture, extraperitoneal vesical laceration, and renal injury must be considered. Expectant treatment is advocated and not surgical intervention, for in most cases the distension yields to medical measures.

Therapeutics

383 Treatment of Generalized Osteitis Fibrosa Cystica

M. CUTLER and S. E. OWEN (*Surg., Gynecol. and Obstet.*, July, 1934, p. 81) record a case of generalized osteitis fibrosa cystica associated with hypercalcaemia in which marked clinical improvement followed treatment by x-radiation of the parathyroid glands. They commend this method in cases in which a surgical operation is contra-indicated, or in which parathyroidectomy has failed to bring about cure. Radiation of each parathyroid area separately is suggested as a possible aid in determining the site of the adenoma before operation, a procedure which may render the operation less difficult. In the case recorded there was a more pronounced lowering of the serum calcium figure when the left parathyroid area was irradiated, as compared with the right. Radiographic illustrations are given of the striking bone changes which followed treatment.

384 Suboccipital Puncture in Cerebro-spinal Fever

R. TRAUT (*Thèse de Paris*, 1934, No. 637), who records thirteen illustrative cases in children aged from 5 months to 14 years, maintains that a fall in the temperature and improvement in the clinical signs and character of the cerebro-spinal fluid are the result of suboccipital puncture in cerebro-spinal fever. The method should not be confined to cases in which blocking has taken place, but should be used as a routine measure and at an early stage, not only in infants, but at all ages—at least in children. It should be used alternately with lumbar puncture, which should not be discarded, but the use of alternate injections by the suboccipital and lumbar route respectively seems to be indispensable.

385 Bromide Therapy and Mental Deterioration

H. A. PASKIND (*Journ. Amer. Med. Assoc.*, July 14th, 1934, p. 100) denies that the bromides in rather full therapeutic doses tend to cause mental deterioration in epileptic patients. He bases this conclusion on the records of fifty-four such patients who had been treated with bromides for a year or longer. Five of these had been treated for one year, nine for two years, five for three, three for four, seven for five, five for six, four for seven, three for eight, one for nine, one for ten, three for eleven, two for twelve, three for thirteen, two for sixteen, and one for seventeen. Of these only three (5 per cent.) were found to be mentally deteriorated. The rest showed no sign of any behaviour disorder, and performed their usual tasks, sometimes very responsible ones, with the same efficiency as persons in good mental health. He believes that one of the reasons why bromides have acquired a bad reputation in this respect is failure to adjust the dosage, for doses which will produce salutary effects in one patient will induce bromism in another, with symptoms of blunting of the intellectual faculties, impairment of memory, and the assumption of a dull apathetic state. Such intoxication is very different from true mental deterioration, and quickly disappears when the drug is suitably diminished. Moreover, bromides have been given to patients who have already deteriorated mentally because of epilepsy, a sequel often associated with the family history and environment. Another argument against their exhibition has arisen from their asso-

ciation with the chance occurrence of behaviour disturbances in insane or neurotic epileptic patients who had received bromides, and in whom such behaviour disorders occur without bromides. As they are used frequently in institutions for advanced cases, the medical practitioners concerned are thought by the author to have developed a biased outlook in this respect, not having realized that there are large numbers of epileptic patients who do not undergo mental changes, and are never placed in institutions.

386 Amniotin in Gonorrhoeal Vaginitis of Children

J. HUBERMAN and H. H. ISRAELOFF (*Journ. Amer. Med. Assoc.*, July 7th, 1934, p. 18) have had encouraging results from the prescribing of amniotin in gonorrhoeal vaginitis in children, and believe that this preparation offers a simple method of treatment which may eradicate the disease. It seems to have no cumulative action, being freely discharged in the urine. The authors believe, however, that the renal threshold varies in different cases, but the amount of oestrogenic substance in the urine, as determined by the Kurzkrook method, is directly proportionate to the intensity of the treatment. Although there is produced an increase in the number of epithelial layers of the vaginal mucous membrane during its exhibition, this is not the sole factor responsible for the eradication of the disease. The most important aid it confers in combating gonorrhoeal vaginitis is the formation of the cornified layer of epithelial cells, which acts as a barrier against reinfection. The method of treatment was found to be safe, and there was a definite involution of the vaginal structures after its cessation. Another advantage of the method is that it does not necessitate the confinement of the patient to hospital.

Radiology

387 Congenital Stenosis of the Aorta

ELIZABETH F. TAYLOR (*Brit. Journ. Radiol.*, August, 1934, p. 452) records five cases of aortic coarctation, and discusses the aetiology and radiography of this condition. Its diagnosis is often easy, but in more obscure cases radiology is essential. Great hypertrophy of the left ventricle is revealed, and often dilatation of the first part of the aortic arch, with atheromatous changes. Sudden death may follow rupture of this part of the aorta, as occurred in one of the author's cases, although no radiographic evidence of aneurysm emerged in an anteroposterior examination. The normal shadow or knuckle representing the third part of the arch was missing in the five cases, but no defect or break in the continuity of the aortic outline was visible, even in the oblique position, nor could the bifurcation of the trachea be demonstrated as a pencilled outline because of the absence of the aortic shadow. Erosions of the under surfaces of the ribs due to the development of the collateral circulation were easily seen in all cases—a valuable diagnostic criterion.

388 Appendicular Stasis

L. BABALANTZ and S. KADRKA (*Journ. de Radiol. et d'Electrol.*, June, 1934, p. 290) discuss the diagnostic value of stasis of the appendix, and record a series of sixty-one cases occurring in a total of 1,288 patients submitted to complete examination of the alimentary canal. They define true stasis of the appendix as a retention of the opaque substance after evacuation of the caecum has occurred. The mechanism of such stasis is considered to be an arrest, functional or pathological, of the neuromuscular system of this organ, or to be conditioned by certain abnormalities of the mucosa consequent upon loss of tenicity, increased length of the appendix, caecal stasis, neuromatosis, and chronic appendicitis. Such an appendix, they find, is usually exceptionally long and of wide bore. The duration of the stasis is variable, but may extend over a week or more. In forty of the sixty-one cases the radiological diagnosis of chronic appendicitis

accorded with the clinical findings. In 50 per cent. of these the condition was proved to be as thought, and the presence of the usual lesions of this disease was determined as a rule. In the remaining twenty-one cases of stasis, observed in the course of various abdominal syndromes, the lesions of chronic appendicitis could not be excluded, notably in the cases of right-sided peritonitis, gastroduodenal ulcerations, visceroptosis with pain in the iliac fossa, and cholecystitis. The authors conclude that appendicular stasis indicates that chronic appendicitis is present, at any rate in most cases, and they deduce a causal connexion; they are not prepared, however, to state which is the cause and which the effect. Without attributing pathognomonic significance to appendicular stasis, they believe that the appearance of this phenomenon should always lead to a suspicion of appendicitis.

389 Short-wave Treatment of G.P.I. and Schizophrenia

L. HORN, O. KAUDERS, and P. LIEBESNY (*Wien. klin. Woch.*, July 27th, 1934, p. 936) give a further report concerning general paretics, and add records of ten schizophrenic patients (in all stages) treated by application to the brain of short electrical waves. Lapse of time has shown the improvement in general paralysis to be even less significant and less common than was first reported, and to be quite temporary. Of ten schizophrenic subjects also, thirty applications for twenty minutes of 15-metre waves were followed by fleeting remissions in two only. With regard to the biological effect of short waves on the brain the writers report from animal experiment an elective action on the meninges with intense hyperaemia and vascular ruptures; and from necropsy in general paretics who have had the treatment eight or ten months previously intense leptomeningitis, some tendency to softening in the superficial layers of the cortex, but subcortical exaggeration of the morbid changes associated with general paresis of the insane. It would appear that the increased protein content of the liquor after short-wave therapy in paretics is due not to increased meningeal permeability (as was hoped) but to direct immigration of blood from small areas of rupture. The writers point out, however, that these clinical and pathological results have followed short-wave treatment in which the technique, adapted from that of deep-seated viscera, is unsuitable for application to the brain. For future trial they recommend less frequent applications, in which the condenser plates shall be distant not 1 to 2 but at least 6 to 10 cm. from the skull.

390 Radiological Appearances of Terminal Oedema of the Lung

According to C. ROUBIER and M. PLAUCHU (*Arch. Méd.-Chir. de l'Appareil Respir.*, March 3rd, 1934, p. 189), pulmonary oedema in cardiac or cardio-renal disease seldom reveals any very special radiological signs. In four cases, however, in which the terminal oedema occurred in cardio-renal disease in comparatively young subjects with marked azotaemia, characteristic x-ray signs were noted. These consisted of either (1) a diffuse shadowy appearance, showing under the hand lens fine granite-like mottling of the whole of both lungs, with the exception of the apices and extreme bases, or (2) a parahilar dappling, affecting chiefly or exclusively the right lung, limited externally by a vertical line, and leaving the upper part of the lung clear. In these cases the pulmonary oedema was clinically subacute and progressive, with much dyspnoea but not much expectoration; post mortem the oedema was the sole morbid condition found in the lung.

391 Diathermy of the Female Pelvic Organs

A. BESSEMANS and L. VANHOUTEGHEM (*Bruxelles-Médical*, September 23rd, 1934, p. 1497) cite clinical results illustrating, in diathermy of the female pelvic organs, the influence of the technique adopted upon the focal temperature produced. If two cutaneous electrodes, even of large size, are employed a rise of only 1° to 1.5° C.

temperature is obtained, and less if small electrodes are used. If the active electrode is placed intravaginally and the indifferent one (of large dimensions) over the gluteal or the hypogastric region, a temperature of 40° to 42° C. or higher is immediately produced, and is of longer duration. The latter technique should be employed to obtain therapeutic effects.

Obstetrics and Gynaecology

392 Indications for Electrotherapy in Gynaecology

L. DELHERM and Mme FAINSILBER (*Journ. de Radiol. et d'Electrol.*, July, 1934, p. 376) compare the older methods of gynaecological electrotherapy with the more modern ones in order to point out that some of the earlier procedures have been inadvisedly neglected. They commend electrolysis with silver or platinum for haemorrhages in the virgin, uterine congestion, subinvolution, fibromatosis, endometritis, and cervicitis, in view of its freedom from complications as well as its efficiency. In cases of bleeding fibroids the association of galvanization with radiotherapy shortens the time in which haemostasis can be effected. They consider intrauterine galvanization superior to intracervical diathermy because its action is more extensive as well as more intense. For the pain of chronic salpingitis, metritis, and perimetritis, tension faradization and undulant and sinusoidal currents are applicable for the same cases as are benefited by diathermy or infrared and short-wave radiation. Indeed, the galvanic current will advantageously replace diathermy when the latter is not well tolerated. In primary vaginismus the faradic current is still better than high-frequency currents and diathermy; in other forms of this disease it can well be associated with other varieties of treatment, and will hasten recovery. The authors plead for further practical consideration of these older electrical procedures, either by themselves, in suitable cases, or associated with more modern methods. They add that they are often well introduced after a course of diathermy, for its repetition is sometimes disappointing.

393 Pregnancy in Tuberculosis

G. T. PALMER (*Amer. Journ. Obstet. and Gynecol.*, August, 1934, p. 173) suggests that tuberculosis may be the causative agent of thyroid dysfunction. He finds ischio-rectal abscess almost as suggestive of tuberculosis as pleurisy. Sanatorium routine is in itself curative of gynaecological ailments, while surgical intervention is to be avoided to the utmost. Pregnancy in cases of tuberculosis constitutes a tragedy. Metzger's beliefs are quoted as reasonable. Of incipient cases pregnancy will light up tuberculosis in 3 per cent.; of healed cases, about 50 per cent. will stand one pregnancy well. Pregnancy should never be contemplated in less than two years after complete cure, as shown by repeated tests, the most valuable being Cutler's sedimentation test—anything above ten implies doubt. The first three months of pregnancy and the six months after confinement are the dangerous periods. Sanatorium treatment is therefore necessary for the beginning of a pregnancy, the patient's response being carefully watched. Improvement shown after three months will be maintained. Deterioration points to therapeutic abortion; but the operation is unwarrantable in an advanced case, and more damaging than useful to a mild one, so that the intermediate cases only are likely to benefit. Preparation for evacuation of the uterus must include artificial pneumothorax or resection of the phrenic nerve (preferred by the author). Labour should always be shortened. Children should be removed at once from a tuberculous mother. According to Forner's recent figures, only 6 per cent. of children isolated developed tuberculosis by three years of age. Eighty-two per cent. were well, whereas of those kept with the mother 45 per cent. had developed tuberculosis and 182 per cent. were well.

Pathology

394 Identification of Aconitine

PEREZ VILLAMIL (*Crónica Médica*, July 15th, 1934, p. 510) claims to have discovered a test which will reveal the presence of as little as 0.1 mg. of aconitine, while differentiating it from the other members of its group. Having dissolved the alkaloid in one or two drops of chlorine water or dilute hydrochloric acid, he adds a drop or two of sulphuric acid solution saturated with potassium bichromate. A copious flocculent yellow precipitate is formed, which when heated in a water-bath (*bain-marie*) is redissolved, leaving a strongly acid emerald-green solution that becomes violet on neutralization with ammonia. A somewhat similar reaction is produced when chromium sulphate, acidified with sulphuric acid, is rendered alkaline with ammonia, but it differs from the above as it forms a copious flocculent precipitate of dirty greyish-violet colour. The author tabulates the results obtained by similar treatment of strychnine, quinine, brucine, veratrine, emetine hydrochlorate, atropine, and cocaine, all of which are readily differentiated from aconitine.

395 Inclusion Technique with Pathological Fluids

J. J. VIRON and two others (*Semana Médica*, July 26th, 1934, p. 234) write in terms of great approval of the method devised by Morin of Quebec for the examination in section of sputa, gastric contents, urinary sediments, pleural, peritoneal, and ascitic fluids, embedded in paraffin and stained by the usual colouring agents. An hour after it has been centrifuged the material is fixed for three or four hours in formol, absolute alcohol, or Bouin's fluid. It is then dehydrated in three alcohol baths, each lasting two hours, and in four baths of toluene, each of a duration of an hour and a half. It is then embedded in paraffin for a whole night, after which sections are cut. The advantages of the method are rapidity, better fixation and preservation of the cytological elements, and the possibility of the employment of ordinary staining agents. The writers illustrate their success by details of several cases, and by excellent microphotographs. They believe that the value of the method is assured by the rapidity with which it shows neoplasms and mycotic affections which require early surgical intervention.

396 Gynaecomastia in Lepers

R. S. BARRETO (*Anales de Medicina Interna*, August, 1934, p. 693) claims to be the first to attract attention to the frequent occurrence of true gynaecomastia in the leprosy, having found the condition present in a substantial percentage of 200 males examined in the leper colony of El Rincon, Cuba. The communication is profusely illustrated with photographs, and the writer comments on the frequency of previous testicular inflammation, whether due to the *Mycobacterium leprae* or to venereal or other disease. The writer classifies his cases under six different headings, carefully setting aside all those in which the hypertrophy was a pseudo-gynaecomastia or of the type called by German writers "Fett mamma."

397 Diagnosis of Glandular Fever

J. E. MEKINSHOFF (*Nederl. Tijdschr. v. Geneesk.*, August 11th, 1934, p. 3656) records his observations on the heterologous antibody reaction of Paul and Bunnell in cases of glandular fever, in normal controls, in different animals, in human beings after injection of horse serum, and in patients with various other diseases. He found that the reaction was rarely positive in normal persons in a dilution of more than 1 in 32, whereas a positive agglutination in a dilution above 1 in 64 was probably specific of glandular fever.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

398 Massive Atelectasis in Pulmonary Tuberculosis

According to P. NAVEAU and M. PESQUE (*Arch. Méd.-Chir. de l'Appareil Respir.*, ix, 3, 1934, p. 239) massive atelectasis differs anatomically from massive collapse simply in the non-permeability of the bronchial system in the former: clinically and radiologically the conditions are identical, and even lipiodol injection does not always penetrate the bronchi in massive collapse. In pulmonary tuberculosis massive atelectasis is not uncommon, and its effect is different according to its occurrence in a lobe which contains cavities or in a different lobe of that lung. In the former case bronchial obliteration and massive atelectasis favour cicatricial cure: in the latter the exaggeration of negative pleural pressure may cause extension and aggravation of cavities lying in the upper lobe when the lower is collapsed. Most commonly in phthisical patients atelectasis follows hæmoptysis and is transitory, but chronic forms occur, of which the following example is related. A woman, aged 26, with a six years' sputum-positive history, was found to show, as well as recent acute distress, clinical and radiological signs suggesting massive pleural effusion. Puncture, however, showed the absence of fluid and an increased negativity of the intrapleural pressure (-10 , -20 mm.). Pneumothorax was instituted at once, and the opacity was absent in the photograph now taken. Treatment by repeated pneumothorax is the best for such cases, and the outlook is then not unfavourable.

399 Subphrenic Abscess Simulating Massive Pleural Effusion

H. HARTUNG (*Zentralbl. f. Chir.*, July 28th, 1934, p. 1750) describes a case in which a left-sided extraperitoneal subphrenic abscess simulated an empyema, filling the left pleura. A woman aged 48, as a sequel of paraneuritic abscess following tuberculosis of the left kidney, had an effusion of pus extending from the lower limit of the thorax to the left clavicle, and displacing the heart and vessels to the right. In the radiogram the shadow of the left half of the diaphragm was invisible, but the fact that the upper subclavicular margin of dullness was convex upwards, corresponding with the left cupola, pointed to subphrenic abscess. The thoracic shadow disappeared after drainage of the abscess through another phlegmonous swelling in the groin; the diaphragm then resumed its normal position. No perforation was seen during inspection of the diaphragm at the attempted operation which followed: the neighbouring granulations were histologically tuberculous.

400 The Tongue in the Production of Asphyxia

According to C. JACKSON and C. L. JACKSON (*New York State Journ. Med.*, August 1st, 1934, p. 681) the greatest menace to the patient in danger of death from asphyxia is the falling back of the tongue, which thus brings into operation a "lingual check valve," allowing fluids and gases to pass only one way, and preventing the ingress of air. If artificial respiration is tried without ensuring that the tongue is not occluding the larynx the pressure on the chest walls will force air out of the lungs, but there will be no inspiration effect, thus causing bilateral pulmonary atelectasis and instant death. The authors define two classes of cases in which this death zone has to be remembered. The first comprises those in which the primary obstruction causing the asphyxia is located in the death zone—for example, cases of tumour, foreign body, or suicidal hanging. It also occurs in the course of administration of an anæsthetic. The second group includes those cases in which there is apnoea from the

effect of gases, electric shock, and other general causes, the death zone coming in as a secondary factor. Many of the deaths attributed to cardiac failure in alcoholism are, they state, really due to lingual asphyxia. The authors consider the best way of eliminating the lingual check valve is by direct laryngoscopy, a bronchoscope being subsequently introduced in order to administer oxygen and release the secretions. They add that, in addition to gravity, suction is a factor in the retention of the tongue in the fallen-back position, and that the "death rattle" is often the final flapping of the lingual check valve. They urge the importance of devoting more attention to obviating this risk in the course of ambulance training.

401 Tobacco and the Peripheral Vascular System

I. S. WRIGHT and D. MOFFAT (*Journ. Amer. Med. Assoc.*, August 4th, 1934, p. 318), as the result of experiments on confirmed smokers in an average state of health, came to the following conclusions. (1) A marked drop in temperature occurs at the tips of the fingers and toes. The average drop was 5.3° F. and the maximum 15.5° F. Surface temperature at the forehead and waist did not show a similar change. Slowing and stoppage of the blood flow in the capillaries of the nail-fold were frequently observed during these tests. Very slight, if any, difference could be noted between the effects of standard denicotinized and mentholated brands of cigarettes. No direct relation between the degree of drop of peripheral surface temperature and the skin tests for tobacco and nicotine could be established. The lack of symptoms in experienced smokers was probably due not to the development of immunity to the toxins of tobacco smoke, but to conscious or subconscious control of the rate and depth of inhalation, which keeps the toxic effects at a submanifest level. The evidence seemed to indicate that nicotine is at least one of the toxic factors and that carbon monoxide and the products of the cigarette papers can be eliminated.

402 Nervous Complications and Sequelae of Enteric Fever

From a study of the enteric epidemic in Lyons during 1928-9, A. DUFOUR and R. FROMENT (*Presse Méd.*, August 1st, 1934, p. 1225) conclude that the nervous are the most important sequelae of this disease, and rank in frequency next to the hepatobiliary complications. In the 3,000 cases of the epidemic nervous sequelae occurred in fifty-two (1.7 per cent.). In thirty-six cases (1.2 per cent.) psychic phenomena, such as dementia, diminution of the memory and intellectual faculties, nervousness, and neurasthenia, were noted. Neuritic sequelae—namely, neuralgias and sensorimotor troubles localized in one or several nerves—occurred in ten cases (0.3 per cent.). Other nervous sequelae, such as chorea, hemiplegia, and aphasia, and especially epilepsy, were observed in six cases (0.2 per cent.). In a certain number of cases these sequelae, particularly the neuritic, were temporary, and disappeared in from a few weeks to a few years. The psychic variety, in particular epilepsy, were more definite and of longer duration. All these conditions occurred most frequently in young subjects.

403 The Electrocardiogram in Cases of Apparent Death

O. BRAUNS (*Munch. med. Woch.*, August 10th, 1934, p. 1225) observes that the usual clinical methods for determining whether death has occurred are inadequate. This is shown by the number of authentic cases in which patients have "come to life" many hours after apparent cessation of the heart-beat. The electrocardiogram is, he states, the only method of diagnosing with certainty whether life is extinct, and by its means the author was able to observe that the heart continued beating long

after cessation of the pulse and heart sounds. It is therefore urged that in all cases requiring artificial respiration this be carried on till rigor mortis sets in. Electrocardiographic control of the apparently dead has made it possible to observe the gradual cessation of the heart's activity and to estimate the value of various methods of artificial respiration. It has shown that purely mechanical or chemical stimulation of the skin or mucous membranes when the corneal reflexes are absent is valueless; further, that the classical methods of Silvester, Howard, and Schafer are valuable as means of producing "endomassage" of the heart by the to-and-fro movement of the blood within it, but that they must be combined with energetic massage of the heart when it has ceased to beat. Any method of artificial respiration which does not allow of massage of the heart by knocking, shaking, or pressure 70 to 100 times a minute is to be condemned. Bruns has proved experimentally that actual cessation of the heart as shown by the electrocardiograph is permanent, and injection of adrenaline into the heart muscle, carotid, or jugular vein, combined with artificial respiration and massage, is of no avail. Reported cases of brilliant results achieved when clinically the heart had stopped beating may be explained by the fact that an electrocardiogram would certainly have shown evidence of the heart's action.

Surgery

404 Acute Suppurative Parotitis

H. TALBOR (*Amer. Journ. Surg.*, August, 1934, p. 267) states that acute suppurative parotitis is generally a secondary condition which may occur as part of a post-operative complex, after an infected wound, in the course of an acute infectious disease, in any markedly aesthenic state, and as part of a terminal condition. In many cases pneumonia is present, whilst in 10 per cent. of cases reported there was a history of a preceding cold or sore throat. It has been demonstrated that the *Staphylococcus aureus* is the infecting organism in the majority of cases, and it can generally be grown in pure culture from pus expressed through the meatus of Stenson's duct when acute suppurative parotitis is present. In most instances the infection must reach the gland through the blood stream or by ascending through Stenson's duct from the mouth. The majority of cases show clear evidence of infection of Stenson's duct, pus being present at its orifice. Small abscesses may appear in different parts of the parotid gland with areas of healthy tissue between, but usually the whole gland is indurated. Sloughing, and more rarely gangrene, may occur. Other complications which may be seen in cases of suppurative parotitis are: a spreading cellulitis, involvement of the external ear, phlebitis, and thrombosis. Extension of the infection to the mastoid process and to the breast has been known to occur. The onset of the disease is usually sudden, with fever and pain and swelling over the gland. Motion of the lower jaw is painful and difficult, and there may be spasm of the masseter muscle. In fatal cases the course is rapid and death may occur within two days. Prophylactic treatment should consist of careful attention to the hygiene of the mouth, and the maintenance of a free flow of saliva. In the more virulent cases surgical intervention is necessary as soon as there is evidence of localized pus. In a case reported it was possible to evacuate a large quantity of pus under local anaesthesia, and the patient made a good recovery.

405 Autoplastic Bone Grafts in Surgical Tuberculosis

ROBERTSON LAWELL, professor of surgical pathology in the University of Buenos Aires (*Soc. Med. Arg.*, August 2nd, 1934, p. 517), after careful and prolonged observation of the methods of defence of bony tissue invaded by Koch's bacillus, and having noted the favourable prognosis in such cases of what he calls "hypertrophic and not infective tuberculosis," states that, after dealing with

the affected parts in the usual classical surgical procedure, he inserts into some of the foci small grafts of bone taken from the patient. The action of these not only expedites cicatrization and healing of the parts so treated, but frequently produces a disappearance of the tuberculous process in other organs, and complete restoration to health of patients with active tuberculosis of the lungs. The article is profusely illustrated with radiograms and microphotographs, and in corroboration of his claims the writer mentions the names of colleagues who have assisted him and upon whose cases he had operated.

Therapeutics

406 Snake Venom as an Analgesic in Cancer

J. KÖRBLER (*Klin. Woch.*, August 18th, 1934, p. 1185) states that snake venom has long been used by homeopaths in the treatment of cancer. Cases have been reported in which patients suffering from leprosy and cancer have had relief of pain after having been accidentally bitten by snakes. In some cases snake venom has caused a retrogression of the tumour, but this is rare. The author believes that the analgesic action of snake venom is due to paralysis of sensory nerves and to a specific metabolic effect on cancer tissue. He describes two cases treated with cobra venom. In the first, a lymphosarcoma, the result was excellent, pain being completely relieved after the third injection. In the second, a cancer of the breast with metastases, no relief was obtained. There were no untoward results. In a further series of twenty-six cases the venom of *Vipera ammodytes* was used. The dose was 5 to 10 mouse units—one mouse unit, based on a mouse weighing 15 grams, contains 0.00002 gram of the venom. The injections, which were painless, were given subcutaneously in the arm or thigh of the diseased side every second day. In a few cases there was tenderness at the site of injection and oedema. In all cases analgesia was obtained. In most of them there was complete freedom from pain lasting for forty-eight hours after injection. Analgesia was present even when radium applications were in progress, which does not occur with cobra venom. In a few cases the venom appeared to cause a retrogression of the tumour. In two cases of severe neuralgia and arthritis deformans analgesia was obtained by injection of snake venom.

407 X-Ray Treatment of the Tonsils

K. HUNDEMER (*Med. Klinik*, July 27th, 1934, p. 994) has tried to ascertain by means of follow-up investigations what, if any, are the benefits of x-ray treatment of chronically inflamed and hypertrophied tonsils in childhood. His material consists of the eighty-two children between the ages of 3 and 14 years given x-ray treatment in a hospital in Würzburg during 1931 and the first half of 1932. The follow-up investigations were conducted in 1933. Information was obtained in seventy-eight cases, in about half of which written reports were received, while in the remaining half the children were re-examined. An attempt was made to classify this material according to the nature of the morbid changes, but it was found difficult to draw hard-and-fast lines between "soft" and "hard" tonsils. Broadly speaking, however, tonsils whose hypertrophy was of the soft lymphatic type responded better to this treatment than the hard and densely fibrous tonsils. In about two-thirds of the cases characterized by recurrent attacks of sore throat, with various sequelae such as fever, the x-ray treatment was followed by the cessation of these manifestations. In many other cases the frequency and severity of the recurrent attacks of sore throat were appreciably reduced, and the cases showing no improvement represented a very small minority. Only in five of the seventy-eight cases had operative treatment been subsequently carried out. So it may be claimed that most of the remaining twenty-three patients had been cured by the x-rays from an operation. In many cases considerable enlargement of

the glands of the neck and behind the angle of the jaw yielded promptly and completely to the x rays, and did not recur in those cases in which repeated infections of the throat ceased after x-ray treatment. A case of poly-arthritis and another of haemorrhagic nephritis cleared up under this treatment, which is perfectly safe. A note on the technique employed is appended.

408

Artificial Respiration

HÉDERER (*Bruxelles-Médical*, August 26th, 1934, p. 1362) states that the manipulations employed in artificial respiration act chiefly on the cardio-respiratory centres, thus stimulating respiratory movements and cardiac contractions; their action on the pulmonary gaseous interchange is much less marked. From a physiological standpoint the manual methods of Silvester, Howard, and Schäfer are thus placed in the order of their efficacy; in practice the method adopted varies with the case. In the "blue" drowned Schäfer's method is recommended; in "blue" subjects asphyxiated by non-caustic gases Silvester's is the best method; and in pale syncopal cases the latter method combined with rhythmical tractions on the tongue is advocated. Mechanical compression apparatuses have proved more efficacious than manual methods; the best of these is stated to be Héderer's "palmiventilator," which has been adopted by the French Department of Marine.

409 Prevention of Lumbar Puncture Headache

SHELPE (*Amer. Journ. Med. Sci.*, August, 1934, p. 247) states that post-puncture headache may be attributed to leakage of fluid. He bases his conclusion on the fact that after a cisternal injection of lamblack into a cat Ayer found this substance in the cervical muscles at necropsy, and that Nelson found the cerebro-spinal fluid pressure much lower during post-puncture headaches than at the conclusion of the original punctures. The author confirmed the findings of Heldt and Maloney that there is a negative pressure in the epidural space of from 1 to 18 mm. of mercury. He has often seen a drop of fluid sucked into the needle as the latter was pulled out of the dura. He is unable to explain the negative pressure satisfactorily, and suggests several possible factors in causation. Ever since he has used a fine 22-gauge needle and has allowed it to aspirate air into the epidural space for thirty seconds before withdrawing it, he has only had three slight headaches in his last 100 punctures on ambulant patients, as compared with 10 per cent. of headaches previously.

Anaesthetics

410

Evipan Anaesthesia

A. WESTERBORN (*Nord. Med. Tidsskrift*, August 4th, 1934, p. 997) has performed 500 operations, mostly major, under sodium evipan anaesthesia in the course of about a year in a Swedish hospital, and is profoundly impressed by the many and substantial merits of such anaesthesia by intravenous injection. When he began with this anaesthetic in the spring of 1933, he used it only early in an operation, preferring to complete his work under ether or ethyl chloride. He now finishes the operation under sodium evipan, the dosage of which, he states, is the most serious of the problems to which it gives rise. The differences in the reactions to this drug are so great that for the same sex, age, and duration of operation one patient may need 4 c.cm. and another 15 c.cm. Instead, therefore, of establishing a scale of dosage based on sex, age, weight, and general condition, it is preferable to let the dose required to induce loss of consciousness be the deciding factor in each case. From a half to an equal quantity of this dose is given as soon as consciousness is lost, and this is sufficient to induce deep sleep for five to fifteen minutes. The biggest total dose hitherto given by the author is 27 c.cm. By the administration of only 1 to

2 c.cm. at a time during the operation, whenever the patient shows signs of returning consciousness it cannot be said in reproach of such intravenous anaesthesia that it is irrevocable. Young patients often needed twice as much sodium evipan as patients between 60 and 80, and anaemic or otherwise debilitated patients needed much less than those who were comparatively robust. Among the 450 patients undergoing 500 operations were twenty who were restless and excited on regaining consciousness, and four or five of them were so violent that they had to be forcibly restrained. There was not a single anaesthetic death in this series. The four chief merits of sodium evipan are that it (1) spares the patient much mental anguish, (2) provokes little or no post-narcotic discomfort, (3) greatly facilitates abdominal operations by the abolition of reflexes, and (4) is associated with a very low post-operative risk of lung and heart complications.

411

Pre-operative Medication

M. L. AXELSON (*Current Researches Anesth. and Analg.*, July August, 1934, p. 164) has investigated the effects of combining opiates and barbiturates in pre-operative medication. Throughout his study the aim has been to produce a tranquil state of mind in the patient, to lessen as far as possible the amount of supplementary anaesthetic needed, and to diminish the danger of anoxaemia caused by too great a dose of barbiturate alone. He believes that by combining small doses of opiates and barbiturates a better effect is produced than by giving a larger dose of one or the other. The barbiturate which he used was "alurate." After trying this method on more than 300 cases he had reached the following conclusions. A combined dose of opiate and barbiturate definitely reduces the amount of supplementary anaesthetic needed. It permits of an increased percentage of oxygen when gas oxygen anaesthesia is given. It permits of a reduced dose of each drug with better clinical results. Omnipon has a great advantage over morphine when used with barbiturates. Blood pressure is not materially affected. The combination of codeine with barbiturates and of scopolamine with barbiturates did not seem to be efficient in producing a tranquil state of mind in the patients. Morphine tends to depress the respiration more than omnipon when used with barbiturates. It is an advantage to give the barbiturate in divided doses, 3 grains being given on the night before the operation, and a second dose of 3 or 6 grains about two hours before the operation.

412 A Complication of Percaine Spinal Anaesthesia

J. CONTIMPER (*Le Scalpel*, June 16th, 1934, p. 859) mentions a complication which he noted during the past two years in seven of 375 cases of percaine spinal anaesthesia. On the day following the anaesthesia a diffuse redness, which developed into a more or less extensive gangrene, appeared on the sacral region; this always formed rapidly, in less than forty-eight hours, both on and below the surface. Infectious complications never occurred, though cicatrization was necessary in two cases. Neurological and cerebro-spinal fluid examinations were always negative. This complication appeared in young subjects with a vitality unimpaired by the disease. Contempre believes that this gangrene could not be due solely to vascular compression, but primarily to an alteration of the nervous system, vascular compression only subsequently favouring gangrene formation.

413

Post-anaesthetic Vomiting

G. F. RAWDON SMITH (*Brit. Journ. of Anaesth.*, July, 1934, p. 132) has been studying the factors which may play a part in the causation of post-anaesthetic vomiting. He first used several brands of ether, and found that there was little difference in the after-effects provided that pure ether from a reliable firm was used. The use of ethyl chloride during induction did not appear to make any difference to after-sickness in abdominal cases, and in minor operations actually reduced it, contrary to popular ideas on the subject. With regard to premedication he

found that an injection of morphine and atropine seemed to give the best results. Chlorotone by mouth was of value in quieting the patients, but increased the sickness in major cases. The use of CO₂ at the end of the operation to de-etherize the patients was found to be unsatisfactory. On the whole, the patients had more vomiting, and the treatment was most unpopular with the nursing staff. The administration of oxygen during the anaesthetic had a slight beneficial effect, chiefly in minor operations. By far the most satisfactory results were obtained by the careful use of glucose and insulin. Two ounces of glucose were given by mouth three hours before operation, and five units of insulin were injected half an hour before. On returning to the ward the dose of insulin was repeated, and four or five hours later 4 oz. of glucose were given per rectum. By this means post-anaesthetic vomiting was reduced to less than 50 per cent. in major cases and to about 25 per cent. in minor cases.

Obstetrics and Gynaecology

414 Radiological Exploration of the Uterus

MM. HAMANT, CHALNOT, and THOMAS (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, July, 1934, p. 458) obtain a picture of the uterine cavity in relief—that is, an impression instead of a mould—by an adaptation of the method of "thin" exposure in radiography. The patient being in the lithotomy position, two cut portions of a ureteral catheter No. 16 are passed, without preliminary dilatation, into the cervix. The longer is carefully pushed up to the fundus, the other just within the internal os. A few c.cm. of distilled water are injected through the longer catheter to ensure that the return flow by the other is established. Then 3 to 4 c.cm. of opaque fluid are injected, and flow out. A skiagram is now taken. Oily fluids are unsatisfactory—a 25 per cent. suspension of oxide of thorium is employed by the authors. No accidents have occurred. The films, though not always easy to interpret, show characteristic outlines of polypi, new growths, reduced cavity, etc., as verified by subsequent exploration. Pregnancy and profuse haemorrhage are the only contraindications.

415 Tincture of Iodine in Treatment of Septic Abortion

F. A. WAHL (*Zentralbl. f. Gynäk.*, September 8th, 1934, p. 2121) states that at Marburg treatments of septic abortions (1) along conservative lines, (2) by curetting, (3) by intervention, provided haemolytic streptococci are not found, (4) by deferring curetting till the third to the seventh apyrexial day, have all been found inferior to the method introduced by Kehrer, in which, immediately after operative emptying of the uterus, an interior application of diluted tincture of iodine is made. If an abortion is incomplete and uncomplicated by extrauterine extension, the cavity after careful dilatation of the cervix is washed out with several litres of 0.05 per cent. potassium permanganate solution at 50° C., and is emptied by the finger and/or a sharp curette. After a second similar lavage two strips of gauze dipped in a 10 per cent. solution of tincture of iodine are successively placed for five minutes in the cavity uteri. Quinine and pituitary extract are also given. During the past eight years 145 cases thus treated gave a mortality of 1.4 per cent. only, and showed a notable shortening of the average stay in hospital to eight days. This treatment, like other active measures, is contraindicated by complications such as parametritis, adnexal inflammation, or vulvo-vaginal ulceration. Its efficacy is ascribed in some degree to bactericidal activity of iodine, but also to stimulation by alcohol, induction of uterine contractions, and the occurrence of local immunizing reactions in the necroses which occur after the application.

Pathology

416 Haemolytic Streptococcus of Scarlet Fever

C. SABETAY (*Thèse de Paris*, 1934, No. 548) examined the pharyngeal mucus of eighty-six persons for the presence of haemolytic streptococci. This group included sixty-two cases of scarlet fever in various stages, nineteen non-scarlatinal cases, most of whom had acute infections of the nasopharynx, and five children with scarlatiniform eruptions, doubtful desquamation, or nephritis following tonsillitis in which a diagnosis of abortive scarlet fever had been made. Haemolytic streptococci were found in only 80 per cent. of the scarlet fever cases. This relatively low figure was attributed partly to the method employed (investigation of haemolysin in a liquid medium), and partly to the fact that several of the negative results were obtained after the twentieth day of disease. Positive results occurred in all the five cases of abortive scarlet fever. The number of positive results obtained in the case of non-scarlatinal pharyngitis (eleven out of nineteen), though lower than in the case of scarlet fever, was still fairly considerable. The haemolytic power of the streptococci isolated from the scarlet fever throats, as measured by the titration method of Cesari, Cotoni, and Lavalle, appeared, however, to be more intense than that of the haemolytic streptococci isolated from the pharynx of non-scarlatinal cases. Moreover, the haemolysis of the streptococci from the non-scarlatinal cases appeared to be fragile and of short duration, while that of the scarlatinal streptococci seemed to have more resistance and was still present after five months.

417 Blood Phosphatases in Osseous Affections

Affirming that estimations of the blood calcium and phosphates may occasionally fail to elucidate the diagnosis in osseous diseases, G. CORYN (*Le Scalpel*, September 22nd, 1934, p. 1301) recommends a determination of the blood phosphatases as of great diagnostic value. These ferments, which are capable of hydrolysing the organic compounds of phosphorus and of liberating the inorganic phosphates, are present in the tissues and act on the glycerophosphates and other substances, splitting the former into calcium phosphates and glycerol; their action may be reversed in the presence of an excess of the latter substances, and a synthesis of calcium glycerophosphates may occur. Their estimation by Roberts's method is described. The amount of blood phosphatases is normal in myelomatosis, essential cysts, arthritis, rhizomelic spondylitis, and senile osteoporosis; it is slightly raised in osteomalacia, pregnancy, and osseous metastases, and markedly increased in rickets and Recklinghausen's and Paget's diseases. In fractures and osseous grafts the blood phosphatases are at first slightly increased, but rapidly return to normal.

418 Pathological Significance of "Paracoli" Bacilli

From observations made chiefly in cases of alimentary disturbance in in-patient infants and young children, K. HASSMAN (*Wien. klin. Woch.*, July 20th, 1934, p. 904) is satisfied that bacilli of the "paracoli" group (giving white colonies on endo-agar and blue on Drigalski plates) are of pathological importance in enteritis and alimentary toxicosis, as well as in certain cases of pyuria and simple icterus. By repeated culturing, mutation of "paracoli" into ordinary *B. coli* strains, and vice versa, could be induced. Strains of parabacilli from clinically severe alimentary disturbances were particularly stable to repeated culturing, and particularly virulent on animal injection of the culture filtrate. Some 10 per cent. of children, having no morbid intestinal symptoms, were "paracoli carriers." The parabacilli from these, filtered, were without action on perfused rabbits' intestine, which, however, was first stimulated and later paralysed by filtrate from paracolic strains derived from cases of acute enteritis.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

419 Herpes Zoster and Trauma

M. RAUATÉ (*Thèse de Paris*, 1934, No. 656), who records numerous illustrative cases in patients aged from 39 to 91, maintains that in some instances there is an undoubted connexion between trauma and herpes zoster, and that such cases have both a scientific and a medico-legal interest. From the scientific aspect the trauma appears to give rise to zoster either (1) by directly affecting the nerve centres, spinal cord, spinal root, or peripheral nerves, in which it reduces or destroys the trophic influence; or (2) by affecting the skin, in which it diminishes or destroys the local immunity. From the medico-legal aspect a relation of cause and effect may be established between the trauma and the zoster under the following conditions: (1) when the zoster develops in the region to which the trauma has been applied; (2) when the skin only has been affected the zoster should develop *in situ*; (3) though the incubation period may vary it must not exceed four weeks—if it is longer the zoster may be a mere coincidence.

420 Agranulocytosis Fatalities from Amidopyrine and other Drugs

P. PLUM (*Ugeskrift for Læger*, August 23rd, 1934, p. 916) attaches such sinister importance to amidopyrine that he believes it is responsible for more deaths than any other drug if cases of overdosage and suicide are excluded. Since May, 1933, eighty-five cases of agranulocytosis have been recorded as a sequel to therapeutic doses of amidopyrine, and as many as sixty-one of these cases have terminated fatally. In Denmark alone forty-one cases have been recorded during the past year, and thirty-seven of them have proved fatal. The author publishes details of a case showing how even a very small dose of amidopyrine (approximately the amount contained in a single tablet of cibalgin) may, in a susceptible person, have a profound effect on the leucocytes. A classification of the cases of agranulocytosis, according to the patients' ages, shows that most of the women were between 40 and 50, and most of the men between 60 and 70. It would therefore seem that susceptibility to amidopyrine may be connected with disordered functions of the endocrine glands. As, however, cases have occurred at other ages in adults the danger of amidopyrine poisoning cannot be wholly averted by such a simple expedient as withholding it from persons of the above susceptible ages. It is also not feasible to examine the blood of a prospective recipient of a dose of amidopyrine and to note how the leucocytes react to a minute quantity, for at present little is known of the duration and variations from time to time of anyone's susceptibility to the drug. Thus there appears, at the moment, to be no alternative to a general ban on amidopyrine for all adults. Its free sale should also be forbidden. It is present in the following drugs: afanal, allonal, asciatine, barbipyrene, barbipropyrene, butapyrene, causyth, cibalgin, compal, diallypyrene, dianalgin, dolorin, gardan, geamin, lealgin, leumon, klimaxid, prokliman, propyrene, pyralyl, sedallyl, trigemin, vepydol, veramon, and veropyrin.

421 J. GROEN and C. J. GELDERMAN (*Nederl. Tijdschr. v. Geneesk.*, July 28th, 1934, p. 3444) record their observations on thirteen cases of agranulocytosis in patients aged from 27 to 77, admitted to the Wilhelmina Hospital, Amsterdam, during the last three years. In two cases neosalvarsan, and in six pyramidon, had been used in combination with other drugs. In one case pyramidon had been used alone, and in two antipyrine alone. In another there was a history of aspirin having been taken,

and in one of aspirin and quinine sulphate. Eight of the cases were fatal. Of the two cases treated with neosalvarsan one died, and of the six pyramidon cases five were fatal. The patient who had had pyramidon alone recovered after the drug had been discontinued. Of the two antipyrine patients one died, as did also the patient treated with quinine sulphate and aspirin. The writers' conclusions are as follows: Agranulocytosis may follow the use of certain drugs, especially antipyrine and pyramidon. The possibility of a similar result from the use of other drugs, especially the barbiturates, must be borne in mind. The risk, however, of agranulocytosis following the use of certain drugs is probably confined to allergic individuals. A constant study of the leucocyte count is imperative during the administration of antipyrine or pyramidon.

422 Mistaken Diagnosis in Headache

G. VOSS (*Deut. med. Woch.*, August 25th, 1934, p. 1278) considers that idiopathic neuralgia of the first branch of the trigeminal is so rare that it should never be diagnosed until all other possibilities have been eliminated. He has known patients suffering from diseases of the frontal sinuses or ethmoid cells to be treated with all the standard remedies for trigeminal neuralgia, including injections of alcohol, on the assumption that the symptoms were due to supraorbital neuralgia. It should be noted that although the supraorbital nerves are tender on pressure in one as well as in the other condition, this tenderness is limited to the nerves themselves in neuralgia, whereas it often extends to their neighbourhood when the symptoms are due to disease of the sinuses or of the neighbouring bones. As for the headache following accidents, it is the rule, in this automobile age, for the subjects of head injuries and concussion to consider themselves privileged and almost under an obligation to suffer henceforth from headache, even for years. There is nothing so difficult as the distinction between fictitious and real headaches in this class; but it is very suggestive of a real post-traumatic headache when the patient, on being asked to look upwards, does so with an expression of pain on his face. There is another kind of headache which seems to have become comparatively frequent of late. It is the sequel of acute or subacute serous meningitis in the posterior cranial fossa. After a feverish onset, due to a sore throat or influenza, the patient complains of rather sudden attacks of severe pain in the back of the head and the nape of the neck. There are few positive clinical findings; slight stiffness of the neck and tenderness over the occipital region and of the muscles of the neck are apt to give the mistaken impression of muscular rheumatism. Other signs may be moderately contracted pupils and nystagmus. The symptoms include pain, giddiness, and an inclination to vomit. Under treatment, which includes the exhibition of quinine and salicylates, the symptoms begin to clear up in eight to ten days.

423 Malaria in Drug Addicts

J. A. BRADLEY (*Journ. Trop. Med. and Hyg.*, August 15th, 1934, p. 241) records six cases of malaria in drug addicts, and points out that the infection is very liable to be transmitted by the use of contaminated intravenous syringe outfits. Treatment must be immediate and energetic, for coma follows swiftly on the onset. Intravenous quinine therapy should be continued until the danger period has passed, and glucose injections be begun at once if no glucose is present in the urine. In some cases blood transfusion is imperative. Bradley considers that all cases of malarial infection in drug addicts should be regarded as potential cerebral malaria. He attributes the spread of the disease in some cases to pedlars of narcotics travelling through anopheles-infested areas, and cites evidence in support of this view.

Surgery

424

Cancer of the Stomach

P. BULL (*Norsk Mag. f. Lægevid.*, September, 1934, p. 1035) has succeeded in tracing all but five of the 289 patients treated for cancer of the stomach in a surgical hospital in Oslo in the fifteen-year period 1913-27. They were classed according as they were (I) not operated on, (II) explored by laparotomy, (III) treated by gastro-enterostomy, with or without other palliative operations, or (IV) treated by resection. The male patients were in the majority, in the ratio of 206 to 83—a ratio which corresponds approximately to that of the deaths from cancer of the stomach in Norway in 1923, when 70.7 per cent. of them were in males. The average age of the patients was 44.9, and that of the men alone 55.5 years. A study of the duration of the symptoms before the patients were admitted to hospital brought out the impressive fact that in 21.2 per cent. of the inoperable cases the symptoms had lasted only from one to three months. On the other hand, in 8.4 per cent. of the resection cases, the symptoms had already lasted for three to four years. Paradoxically enough, the average duration of the symptoms before admission to hospital was longer, for the resection cases than for the others. It is clear, therefore, that operability or inoperability does not depend exclusively on the duration of the symptoms. The average duration of life after operation or discharge from hospital of the patients in the first three groups (109, 49, and 58 respectively) was almost identical, being between five and six months. The average duration of life of the seventy-three patients undergoing resection was five to six times longer. A few of the patients in Group I were found to be still alive—an observation suggesting a mistaken diagnosis in the first place. There were no survivors in Groups II and III, and there were only two patients in Group II who lived for more than a year after the exploratory laparotomy. There were also only two gastro-enterostomy patients who survived this operation by a year. The operation mortality was higher for the gastro-enterostomies (21 per cent.) than for the resections (19.2 per cent.). Of the fifty-nine patients who survived resection, as many as twenty were still alive, but nine of them had been operated on within the last three years.

425 Ligature of the Angular Vein in Furuncles of the Upper Lip and Nose

H. SCHÄER (*Zentralbl. f. Chir.*, August 18th, 1934, p. 1907) alludes to the not inconsiderable mortality, from thrombosis of the superior ophthalmic vein extending to the cavernous sinus and from basal meningitis, in pustules of the upper lip and nose. As a preventive measure he recommends, describing three illustrative cases, ligature under local anaesthesia of the angular vein, which communicates with the cavernous sinus. He prefers an incision of 1 cm. internal to the inner canthus—that is, considerably higher than that recommended by American writers: the vein may be superficial or embedded in the quadratus labii superioris muscle. In certain cases ligature of the anterior facial vein and/or the internal jugular veins is called for in addition. The ligature is best done before the appearance of rigors. In one of Schäer's cases thrombosis of the anterior facial vein was palpable after a peritonsillar abscess: it was divided with the cautery at the same time as a section of the angular vein was ligatured and excised.

426 Cranial Fractures involving the Frontal Sinus

Discussing meningo-encephalitis following cranial fractures involving the frontal sinus, P. BÜRZER and A. ELBRIS (*Presse Méd.*, September 19th, 1934, p. 1463) emphasize that infection may be carried from the nasal fossae as well as the external wound. Most of the endocranial complications of inflammation of the sinuses result from a frontal sinusitis. The infecting organism is commonly a pneumo-

coccus, and these cases are as frequent as streptococcal ones. Both forms differ but little clinically. The onset is marked by intense headache, agitation, and fever. The condition usually results in a state of great excitation (delirium, etc.); states of depression are rare; death supervenes from the third to the eighth day. Localizing symptoms may be absent if the area of exudation does not lie in the psychomotor zone. In frontal fractures involving the posterior sinus wall or the nasal fossae, drainage of the sinus is imperative after operation. Surgical intervention is essentially preventive: once the meningo-encephalitis is established all measures are unavailing. Three cases are recorded: two succumbed, despite administration of specific sera; the third survived after operation with subsequent extensive drainage.

Therapeutics

427

Treatment of Chancroid

R. J. ROELOFS (*Nederl. Tijdschr. v. Geneesk.*, September 15th, 1934, p. 4176) records sixteen cases showing that soft chancre can rapidly be cured by a small quantity of hard x rays. As a rule considerable improvement was seen in from three to five days, and in almost every case the sores were completely healed within three weeks after the first application. The irradiation was not sufficiently strong to justify the conclusion that the causal organisms were destroyed by the rays: Necrosis was not produced in the cells of the surrounding skin, but healing was probably caused by stimulation of their activity.

428 Cod-liver Oil in Treatment of Wounds

W. LÖHR (*Zentralbl. f. Chir.*, July 21st, 1934, p. 1686, and August 4th, 1934, p. 1815) describes and illustrates remarkable results which he has achieved in his three years' experience of treating suitable wounds with applications of cod-liver oil. Recent accidental wounds, in which there is reason to assume a severe infection to be absent; burns, including those made by x-radiation or the electric current; compound fractures; amputation wounds; bed-sores; and chronic wounds following acute osteomyelitis are indications. Löhr excludes from immediate cod-liver oil treatment acute infective wounds—for example, whitlow or acute osteomyelitis—and those in which contamination by soil or by grossly infected substances makes a stormy convalescence probable. His treatment aims at accelerating mesenchymal and epithelial repair, and securing formation of a supple cutaneous scar, well supported by adequate superficial fascia. Among the cases described are those of (1) compound fracture of the elbow-joint with loss of skin of the forearm, healed with very slight limitation of flexion and extension after four months; (2) compound tibial fracture, with extensive loss of the soft parts, healed in eleven weeks; (3) third-degree burn from sacrum to neck; (4) frostbite affecting five toes in a patient aged 65; and (5) amputation of thumb in a patient aged 88. In no case since introduction of the cod-liver oil treatment has skin-grafting been found necessary in chronic wounds, however extensive. In many cases Löhr applies over the dressing of cod-liver oil a plaster-of-Paris unfenestrated case; this has been done without ill effect in accidents to fingers, burns of the limbs, extensive fracture wounds, and osteomyelitis after removal of sequestra. In other cases the dressing is changed as infrequently as possible, and then the contact of the wound with the inner portion of the dressing is left undisturbed. It follows that whether plaster has been applied or not, the dressings of a wound due to burn or following sequestromy are painless. The sole disadvantage of the treatment (W. ZUELZER, *ibid.*, July 21st, 1934, p. 1695) is the unpleasant smell which comes from the mixture of laudable pus and stale oil. The efficacy of Löhr's method is ascribed chiefly to the direct action

* See *Epitome*, para. 464, June 9th, 1934.

of the vitamins A and D on the tissues of the wound. Bacteria speedily disappear from the discharge—whether as a result of the bactericidal action of the oil, which has been demonstrated (LÖHR and TREUSCH, *ibid.*, August, 4th, 1934, p. 1807) or of stimulated tissue resistances, or of both, does not seem clear. Löhr uses fresh cod-liver oil, unheated and kept from admixture with chemicals: to increase its viscosity it is mixed with an indifferent oily medium until the consistence of a paste is reached.

429 Intrathecal Alcohol as an Analgesic in Cancer

SALTSTEIN (*Journ. Amer. Med. Assoc.*, July 28th, 1934, p. 242) describes the use of intrathecal absolute alcohol in eight cases of cancer of the cervix, two cases of spinal metastases from breast cancer, and one of cancer of the prostate. He states that it is a very much safer and easier method than chordotomy, removal of the pre-aclral nerve, or sacral nerve block by alcohol. He does a lumbar puncture between the first and second lumbar vertebrae, with the patient lying on the side opposite to that affected. Up to 1 c.c.m. of absolute alcohol is injected drop by drop. After twenty minutes the patient rolls over on to the back and remains there for two hours. There is usually burning for a few seconds, and there may be motor weakness of the legs for a few hours or days. Pain is relieved within two weeks in a successful case, and the relief lasts for six months. Ten of the eleven cases were much relieved. One case had a slight sphincter disturbance following the injection.

430 Ergotamine Tartrate in Migraine

BROCK, O'SULLIVAN, and YOUNG (*Amer. Journ. Med. Sci.*, August, 1934, p. 253) have investigated the effects of hypodermic adrenaline, ephedrine, ergotamine tartrate, mecholol, insulin, amyl nitrite inhalation, histamine, follutein, amniotin, etc., on twenty-five patients with typical long-standing, severe, and intractable migraine. Vagal stimulation has been shown to produce bilateral cerebral vaso-dilatation, and cervical sympathetic stimulation to cause ipsilateral pial vaso-constriction. This research was undertaken to study the effect of sympathetic, parasympathetic, and other organic drugs in causing or relieving migraine attacks. Histamine, follutein, and amniotin were the only ones which initiated attacks in an appreciable percentage of cases. Mecholin relieved four out of eight cases, but the headache tended to return in half an hour. Ergotamine tartrate 0.5 mg. (trade name, "gynergen"), which paralyses the sympathetic nerve endings, relieved fourteen patients in thirty-four attacks within one to three hours. It failed to relieve four patients. It was more effective subcutaneously than when given by mouth.

Dermatology

431 Pemphigus Foliaceus

G. PETGES, A. PETGES, and J. DUBARRY (*Ann. de Derm. et de Syph.*, June, 1934, p. 559) record the case, in an agricultural labourer, of pemphigus foliaceus, which progressed rapidly to a fatal termination, was of infectious aetiology, and probably led to septicaemia. A necropsy could not be obtained. While many of the signs and symptoms were the usual ones, the authors remark that this case raises the question whether pemphigus foliaceus is essentially a primary disease or may be secondary to such a seasonal dermatosis as had affected this patient annually in May, June, and the end of July for fourteen years before the onset of the pemphigus. These seasonal outbreaks coincided with harvest and threshing. The pemphigus started in July, 1933, and the patient died in the following December after pyrexia, wasting, and the recovery on repeated occasions of a staphylococcus and an enterococcus from the blood. The authors think that the eczematous lesions of the preceding years may have

operated in the direction of weakening the general resistance rather than of preparing the skin for the pemphigus. The onset of the latter condition was sudden, and the cutaneous signs reached their maximum in two days, contrasting thus with the more slowly evolving course of pemphigus foliaceus generally. The blood cultures were taken with most strict asepsis, and it is thought unlikely that the organisms repeatedly recovered were due to contamination. The rapid muscular wasting in this case is attributed to the rapidly advancing cachexia, which also prohibited the exhibition of such reputed remedies as arsenobenzene, and even of arsenic by the mouth.

432 Combined Arsenic-Gold Therapy in Lupus Erythematosus

K. STILNER (*Wien. klin. Woch.*, August 17th, 1934, p. 1018) succeeded in curing, within two or three months, fourteen out of nineteen patients with lupus erythematosus by a combination of arsenic followed by gold treatment. The great majority had proved refractory to other modes of therapy. Cases of the disseminated type and patients showing marked sensitiveness to arsenic made the best responses. Fowler's solution was first given in doses increasing from three to fifteen minims thrice daily until mild toxic symptoms (erythematous eruption, pruritus, dry throat, burning feeling in the eyes) occurred. The gold was now given as oily solganol B, in intragluteal injections increasing from 0.032 to 0.06 gram in about twelve to fifteen injections, with a total dosage not exceeding 0.5 gram and intervals of five to seven days. Slight recurrences were noted in two cases of the series.

433 Xeroderma Pigmentosum and Sensitivity to Light

F. W. LYNCH (*Arch. Derm. and Syph.*, June, 1934, p. 858) reviews the cutaneous conditions brought about by sensitivity to light, with special reference to the mechanism involved. He finds that urticarial reactions can apparently be evoked by either ultra-violet or visible radiation. Patients with prurigo aestivus have generally been shown to be sensitive to visible radiation. Most investigators have demonstrated sensitivity to ultra-violet rays in hydroa aestivale and vacciniforme. This contrasts with experimental haematoporphyrin sensitization in which the sensitivity may be in the field of visible light. In xeroderma pigmentosum there is sensitivity only to radiations shorter than visible light, in most cases including sensitivity to x rays and similar radiation. Lynch conducted experiments on a child patient with this disease, using glass filters which transmitted groups of radiations of various wave-lengths. This patient responded with erythema and pigmentation on previously unexposed parts to doses which would evoke vesiculation on normal skin; on first exposure to sunlight in infancy this patient had responded with marked erythema. Microscopical examination of the skin twenty-four hours after irradiation sufficient to produce erythema revealed none of the changes in the cells of the stratum spinosum usually observed in normal persons, but a heavy layer of parakeratosis was discernible, which was not seen in the normal child tested. The child with xeroderma was demonstrated to be most sensitive to radiations between 280 and 310 millimicrons. Since few radiations shorter than 297 millimicrons reach the surface of the earth, it is the sensitivity to radiations of from 297 to 319 millimicrons which is of prognostic importance to the patient, and from which the patient must be protected. The reaction of the child with xeroderma pigmentosum was greater with filtered than with unfiltered radiations, while in the normal child the greater reaction followed unfiltered radiation. This less rapid response in the xeroderma child to unfiltered radiations is held to be due to a less rapid response to the shorter rays. The author points out that similar studies must be made on a greater number of patients, and in a more detailed and exact manner. If simultaneous investigations are made along biochemical and genetic lines, greater knowledge should be obtained of the mechanism of the diseases due to sensitivity to radiation.

Obstetrics and Gynaecology

434 Radium Therapy in Gynaecological Bleedings

H. NAUJOKS and H. HOFFMANN (*Zentralbl. f. Gynäk.*, August 18th, 1934, p. 1922) report that at the Marburg Universitäts-Frauenklinik radium treatment plays an increasing part in the therapy of metrorrhagia due to benign disease, and in this connexion has almost completely replaced x-radiation. The great majority of cases of "non-malignant bleeding" which are treated by radium are those of women over 40 who have menorrhagia or metrorrhagia in the absence of any important morbid physical findings on bimanual examination: pathologically they fall in the groups of chronic induration, myomatosis, metropathia haemorrhagica, or glandulo-cystic hyperplasia. Together with 252 cases of this description, radium treatment was given for "benign bleedings" in twenty-five cases of myoma (including six of submucous myoma), two of blood disease with severe metrorrhagia, two of severe bleedings of puberty, and two of therapeutic sterilization. At Marburg operative treatment of myoma is the rule, radium therapy being reserved for occasional cases of very small myomata, or as a life-saving measure (because of the very prompt stoppage of the bleeding) in exceptionally blanched patients with large myomata. In bleeding at puberty radium is required—very, very rarely—as an alternative to hysterectomy in critical cases: in both the patients treated by radium the menses returned after a few months. The application of the radium, within the uterus, in a single dose of 50 mg. applied for twenty-four to forty-eight hours, is preceded immediately by curetting, and is never undertaken unless careful clinical examination has shown signs of inflammation, such as pyrexia, and abnormal erythrocyte sedimentation time to be absent. In seven instances of 285 the histological examination of the curettings showed a carcinoma of the corpus uteri: a second radium application was given a few days later and followed by x-radiation, and cure appeared to be attained in all. In the very great majority of cases of "non-malignant bleeding" the radium treatment had a prompt and satisfactory result, three-quarters ceasing to bleed after the radiation and nearly a quarter having only one more haemorrhage. One lethal case (from embolus), one abscess in the pouch of Douglas, and one femoral thrombosis were the total morbidity findings after 285 applications of radium. Menopausal symptoms were not severe. The mode of action of radium in these "non-malignant bleedings" is not clear. While not denying the possibility of ovarian affection, especially with large doses, Naujoks and Hoffmann are inclined, from the results of tests for folliculin and antuitrin in the blood, to look on the treatment as affecting chiefly the uterus, of which the lining is known to become structureless and necrotic without the cavity being obliterated.

435 Cancer of the Ovaries

CLAES VON NUMERS (*Finska Läkaresällskapet Handlingar*, August, 1934, p. 720) has found that among the 17,239 patients treated in a gynaecological hospital in Helsingfors in the fifteen-year period 1919-33 there were 151 suffering from cancer of the ovaries—an incidence of 0.88 per cent. The average age was 49 years, the youngest patient being 10, the oldest 77 years. The ages at which the cases were most frequent were between 45 and 50. The disease was bilateral in as many as sixty-two. Of eighty-eight cases verified by operation thirty-five were bilateral. Although it has commonly been taught that cancer of the ovaries is comparatively common among the unmarried and nulliparae, the author's material does not clearly endorse this teaching; and he notes in passing that a statistical study for the year 1930 has shown that 16.8 per cent. of the marriages which had lasted at least three years in Finland were childless. With regard to the symptoms, there were as many as twenty-eight patients who had no pain. Seventy-five complained of diffuse

abdominal pain, and forty-four of pain referred to one side or other of the abdomen. The subsequent operation showed in several of these cases that the pain had been referred to the wrong side, or that the disease was bilateral. There were forty patients referring their pain to the small of the back, and ten to the hip and thighs. Four patients complained of pain in the shoulders. The first symptom noticed was pain in sixty-seven cases and abnormal haemorrhage in twenty-five. The frequency with which various other symptoms were the first to appear proved to be comparatively low, and there were only four cases in which disturbances of micturition were the first symptom. The recovery rate for the operable cases after an observation period of five years was 30.8 per cent. This rate would be raised to 38.1 per cent. if the metastatic cases were excluded. The operation mortality was 7.3 per cent. (six deaths).

Pathology

436 Cholesterolaemia and Tuberculosis

L. LLOPIS LLORENTE (*Crónica Médica*, August, 1934, p. 54), investigating nearly forty cases of different types of tuberculosis, finds that there is a normal percentage of cholesterol in the blood of all, and that there is not the slightest relation between it and the form of tuberculosis from which any of those examined are suffering. He further states that there is no connexion between cholesterolaemia and arterial tension; neither is there parallelism between the amount of blood cholesterol and the sedimentation rates of the erythrocytes, nor their numbers, nor that of the leucocytes and monocytes. The writer believes that estimation of blood cholesterol is entirely devoid of prognostic value in pulmonary tuberculosis, and that treatment of tuberculous subjects by choline salts with an idea of increasing the blood cholesterol is based upon a misconception.

437 Foods and Bacterial Invasion

L. ARNOLD (*Amer. Journ. Pub. Health*, August, 1934, p. 854) records an investigation of certain foods (desiccated fruits and vegetables) to determine whether they have any influence on the defensive mechanism of the body against orally ingested bacteria. Rats were placed on standard basal diets, with variations in the carbohydrate components, and were fed with *B. enteritidis*. It was found that those given banana powder showed a physiological adaptation to the bacteria, and apple and prune diets acted similarly; corn starch and tomato diets did not prove to be protective. This difference did not seem to be attributable to interference with the self-disinfecting mechanism (Arnold) or to any change in the permeability of the intestinal wall. The intra-enteric and organ distribution of *B. enteritidis* was found to be the same whether the rats had received banana powder or corn starch. No resistance was discernible in the banana-fed rats three to six weeks after the bacterial injection, and the distribution of the organisms in the liver and spleen was identical; thus the theory of Wasserman and Citron of a fortification of the endothelial system following such a method of vaccinating, and a consequent increase in physiological response resulting in the destruction of bacteria *in situ*, was shown to be inapplicable. The author thinks that the explanation is to be sought along the line of considerations of viability, bacteria changing in the stomach from viable to non-viable, and back again in the lower segment of the small intestine and the large intestine. In his experiments so far, when these non-viable forms penetrated the wall of the intestine, and were cultivated from the internal organs, they showed certain biochemical and antigenic alterations from the original strain. Further study is proceeding of this aspect of the protective action of foods against pathogenic enteric bacteria in laboratory animals.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

438 Pulmonary Heart Disease in Pneumoconiosis

J. M. DYSON (*Amer. Heart Journ.*, August, 1934, p. 761) draws attention to the occurrence of pulmonary heart disease resulting from pneumoconiosis in anthracite-coal miners. Of 213 men with this lung disease the pulmonary circulation was interfered with in 127, and of these eighteen showed the typical radiographic change of pulmonary heart disease—namely, a prominence of the pulmonary arc and census of the right ventricle on the left border of the cardiac shadow. In none of these eighteen was there clinical evidence of mitral stenosis, syphilis, or high blood pressure. Definite right axis deviation was present in the electrocardiogram in fifteen of the eighteen cases. Two had auricular fibrillation, and four inversion of the T wave in lead I or lead II; in two the P waves were abnormally enlarged. A post-mortem was held on one of the only two patients who died: this showed enlargement of the right heart, hypertrophy of the right ventricle, and considerable increase in the circumferences of the pulmonary artery and its valve. Why pulmonary heart disease should occur in some cases of pneumoconiosis and not in others of equal severity the author does not claim to explain.

439 The Future of Epileptic Children

C. CLEMMESSEN and M. L. MOLTKE (*Ugeskrift for Læger*, September 6th, 1934, p. 969) have conducted follow-up investigations of the 100 children treated for epilepsy in a hospital in Copenhagen in the period 1917-27. Fifty-eight of them were boys and forty-two were girls. Twenty-four cases could not be traced. Of the remainder twenty-five could be considered as cured. There had been no fit for more than two years, there was no marked psychic defect, and these ex-patients were able to work. There were thirty-four who were not cured and seventeen who had died. The age at which the fits had begun did not, in this material, seem to affect the prognosis appreciably, but it was worst when the fits were most severe. The duration of the epilepsy before treatment was instituted was longer on the average among the incurables than the children who had recovered, although there were cases which had ended in recovery in spite of treatment having been deferred for years. This study suggests that epilepsy in childhood ends either ill or well; the mental condition becomes worse, and some patients die, or, on the other hand, a practically complete recovery is effected. An intermediate state of affairs is exceptional. This study also establishes the value of early and efficient treatment of convulsions in childhood.

440 Facial Hemiatrophy

According to KNUD FABER (*Acta Med. Scand.*, lxxvii, V-VI, 1934, p. 419), facial hemiatrophy commences in the great majority of cases in the first or (less frequently) the second decade, with no evidence of local disturbance. Lately it has been attributed to disease of the cerebral centres of the autonomic nervous system. In seven cases Mankowski and Chasanow have noted its occurrence after a typical attack of epidemic encephalitis; a crossed distribution (one side of the face and contralateral limbs) has several times been reported; and a series of thirty-five cases has been described by Marinesco, Kreindler, and Façon, in twenty-nine of which signs of sympathetic nerve disease, such as Horner's syndrome, mydriasis, heterochromia, exophthalmos, naevi, vitiligo, morphoea, or scleroderma, were present. Faber describes a case in which a female patient had in succession (1) facial hemi-

atrophy at the age of 10; (2) vitiligo appearing at 23 and spreading so as to cover the whole body, except on the atrophic side of the face; and (3) myxoedema after the age of 46. The patient was a congenital syphilitic, and her father died insane: she herself underwent several acute psychic disturbances. Faber inclines to the view that syphilis affected the mesencephalic trophic centres as a disturbing factor, and that the determining causes of the three diseases were acute psychic influences.

441 Fluoroscopy v. the X-Ray Film in Diagnosis of Pulmonary Tuberculosis

RIM (*Amer. Journ. Med. Sci.*, August, 1934, p. 178) compares the method of fluoroscopy with the ordinary x-ray picture in detecting tuberculosis among the applicants for employment of a big insurance company. The advantages of fluoroscopy are its cheapness and quick working. Of 1,035 supposedly healthy persons who were first screened and then filmed, two minimal cases of tuberculosis were missed on fluoroscopy. Since adopting fluoroscopy for routine examination in 1928, and only filming cases suspicious on clinical grounds, the incidence of new cases of tuberculosis per annum among 13,000 employees has fallen from 0.92 per cent. to 0.43 per cent. Approximately 90 per cent. of tuberculous applicants were detected solely by fluoroscopy. Of their sanatorium admissions in 1928, 47 per cent. were minimal cases. In 1932 76 per cent. were minimal. Fluoroscopy has been compulsory at the University of Munich since 1930. The author quotes Dr. Kattentidt, who is in charge of student health in Munich, as saying: "The clinical examination detected only a small portion of the tuberculosis cases which were found on fluoroscopy. Dr. V. Romborg proved that 95 per cent. of all the cases detected by the Röntgen-ray picture can also be diagnosed by fluoroscopy."

442 Invariable Association of Gastric Achylia with Pernicious Anaemia

E. MEULENGRACHT (*Nord. Med. Tidsskrift*, July 14th, 1934, p. 925) discusses the various signs indicative of pernicious anaemia, devoting special attention to gastric achylia. Its demonstration is a most important link in the diagnostic chain; in the absence of helminthiasis, it is unwarrantable to diagnose pernicious anaemia when there is no gastric achylia. It is true that, apart from the combination of helminthiasis with pernicious anaemia without gastric achylia, cases have from time to time been recorded in which this condition was absent and yet pernicious anaemia was diagnosed. But in his experience of hundreds of cases of pernicious anaemia the author has not once failed to find gastric achylia, and he suggests that if the records of the alleged exceptions to this rule be scrutinized, certain clinical and haematological lacunae will be found which raise justifiable doubts as to the validity of the diagnosis of pernicious anaemia. It is significant in this connexion that since liver and stomach treatment was introduced, and its specific action on genuine pernicious anaemia has become of diagnostic importance, the reports of cases of this disease, unassociated with gastric achylia, have begun to dwindle in numbers. It is probable that in most of these alleged cases of pernicious anaemia, without gastric achylia, the real condition was an aleukaemic leucosis, or an aplastic anaemia in which the erythrocytes present a megalocytic character reminiscent of that of genuine pernicious anaemia. It is not only often diagnosed wrongly; it is also often overlooked, even when the anaemia is profound, and about half of all the cases of pernicious anaemia admitted to the author's hospital in Copenhagen had been sent there with some other diagnosis.

Surgery

443 Treatment of Caverosus Haemangioma of the Tongue

N. PETROV (*Zentralbl. f. Chir.*, September 22nd, 1934, p. 2194) in five cases of cavernous haemangioma of the tongue has had satisfactory results, without bleeding, from the following operation. After ligature, in local anaesthesia, of the external carotid and lingual arteries of the affected side, the tongue is infiltrated with novocaine-adrenaline solution, and in the transverse direction seven or eight parallel strong silk ligatures are passed through the tongue around the tumour, and tied tightly at the outer border. A reduction in volume of the angioma is at once attained, and thrombosis followed by necrosis leads to piecemeal sloughing of the tumour at the end of the first week. A healthy granulating surface is noted a week later and healing at the end of the sixth week leaves a somewhat atrophic but well-formed and mobile half-tongue. In one of Petrov's patients, a man aged 41, the tumour had existed fifteen years, had caused much bleeding, and was large enough to produce considerable bulging in the submaxillary region when the lips were closed. In one patient (a child) the tumour persisted, albeit in considerably diminished volume.

444 Perforation of Jejunal Ulcer

H. SINGER and K. MEYER (*Arch. of Surg.*, August, 1934, p. 248) consider that jejunal ulcers of peptic origin are of a serious nature owing to the tendency of the lesion to extend rapidly beyond the wall of the intestine. This is due to the thinness of this part of the digestive tract. The complications of jejunal ulcer when this develops beyond the serous coat of the jejunum are of two principal types—penetrative and perforative. Penetration occurs when an adjacent structure becomes attached to the base of the ulcer before rupture takes place; sometimes a granulomatous mass develops and simulates a neoplasm. Perforation generally occurs into the free peritoneal cavity or into an adjacent hollow viscus, which is usually the colon. Sometimes the entire thickness of the ventral abdominal wall is perforated and a jejunal fistula is established. It has been noticed that there is increased disposition to perforation elsewhere after jejunal perforation, and it has also been seen that a fair percentage of cases of gastro-duodenal rupture treated by gastro-enterostomy have suffered from a subsequent jejunal perforation. This tendency to rupture is also seen in numerous cases of recurrent jejunal rupture. The chief differences between the benign and classic forms of rupture are observed in the post-perforative stage. In the classic rupture the acute pain of onset is followed by death, of progressive peritonitis, which may end with death, whilst in the benign or subacute type the diffuse peritonitis of onset rapidly recedes, and spontaneous recovery ensues. Four cases are reported, the first of which was of the classic variety and was treated by operative closure with recovery of the patient. The remaining three showed evidence of spontaneous closure; in two of these an abscess was drained with recovery, but in the other case death occurred from diffuse peritonitis.

445 Acute Infections of the Hand

S. KOEN (*Surg., Gynecol. and Obstet.*, September, 1934, p. 277) reports thirty-two cases of acute, rapidly spreading infection, following trivial injuries of the hand, dividing them into four groups. There were two cases in which the infection gradually subsided and cleared up without local destruction of tissue or abscess formation. In five cases the symptoms at the site of injury disappeared quickly, but marked axillary lymphadenitis developed with subsequent abscess formation in the axillary region. In eleven cases the abscesses and inflammatory reaction advanced rapidly at

first and then gradually receded, with localization and abscess formation and frequently extensive destruction of tissue. In the remaining ten cases the infection advanced rapidly and continued, in spite of treatment, to a fatal termination. Of the twenty-two patients who recovered all were treated conservatively with rest in bed, massive warm, wet, sterile dressings over the entire upper extremity, and forced administration of fluids. It was found that surgical procedure should be limited to the minimum, and in no case was the inflammatory process incised until there was absolute evidence of localization and abscess formation. A simple incision was then made without retraction or stretching of the wound edges, and without digital exploration of the abscess cavity. Of twenty cases in which bacteriological findings were available, a varying type of streptococcal infection was found in all but one case.

Therapeutics

446 Vaccine Therapy in Whooping-cough

K. KUNDRATITZ (*Med. Klinik*, August 10th, 1934, p. 1060) states that his favourable impression of the therapeutic value of pertussis vaccine is in accordance with that of most authors. Treatment must be early to ensure good results. He gives five injections at intervals of one to two days, commencing with 3,000 million bacteria and going up to 8,000 million. He analyses forty-eight cases in his private practice. In seven the treatment was commenced in the early stages of the disease. None of the children developed a whoop. In eight out of ten of these a blood count showed a leucocytosis of 12,000 to 21,000 and a lymphocyte count of 50 to 77 per cent. In two to three weeks the blood count was normal. In twenty-five cases treatment was commenced in the late stages; according to the history in seven the whoop was obtained in fourteen, the number of whoops diminishing after two to three injections, and ceasing completely eight to fourteen days after injection. The rationale of vaccine treatment in pertussis is that it increases the resistance to *B. pertussis*; it lessens the toxicity, as shown by the return to normal of the blood picture; it prevents the essential lesions of the bronchial mucous membranes and lung tissue; and if used prophylactically produces an immunity reaction. Failure to obtain good results may be explained on the grounds of low initial resistance, inability to form antibodies, treatment being instituted too late, or the use of inefficient vaccine. It has been shown that when old strains and low doses are used the good results amount to only 48 per cent., whereas when fresh vaccine and large doses are employed they are represented by the figure 81 per cent.

447 Treatment of Paroxysmal Tachycardia

According to G. SCHILDER (*Mösch. med. Woch.*, August 24th, 1934, p. 1297) an attack of paroxysmal tachycardia may sometimes be cut short by pressure on the vagal fibres in the carotid sinus; not all patients may succeed in the same patient the device may succeed in one attack and fail in another. Quinine is very often effective, especially after intravenous injection; such injection is suitable for hospital inpatients, but even then may be followed by effects which cause distress to the patient and anxiety to the physician. Learning some years ago from a pregnant patient that her paroxysmal tachycardia ceased immediately after pregnancy vomiting, Schilder was led to prescribe emetics, and he has not known them to fail in any of the ninety-eight attacks in which he has seen them taken. Other writers have also reported good results. Schilder gives every five minutes a tablespoonful of 1 per cent copper sulphate solution until violent emesis is induced. Habituation to

copper sulphate may be acquired, and then recourse is had to subcutaneous injection of 1 c.cm. of 1 per cent. apomorphine solution. Ipecacuanha has proved successful, but zinc sulphate does not induce a vomiting which is sufficiently forcible to be effective in stopping the tachycardia. The therapeutic effect is ascribed to an irritation of the vagal nucleus near the vomiting centre. In the prophylaxis of paroxysmal tachycardia oral administration of quinine is sometimes of great value, but very high doses may be required.

443 Renal Extracts in Arterial Hypertension

D. M. GOMEZ (*Presse Méd.*, September 1st, 1934, p. 1371) records the results obtained in forty hypertensive cases by the administration of renal cortical extracts prepared by Pons and himself (*C. R. Soc. de Biol.*, June 23rd, 1934). These were given in daily hypodermic doses of 5 c.cm. for six to eight days. The chief result noted was a slow but progressive lowering of the arterial tension, commencing usually on the third or fourth day; this was accompanied by a diminution of the blood urea. Subjective symptoms (headache, dyspnoea, nocturnal frequency of micturition, and insomnia) showed marked improvement. Amelioration in the physical signs (*bruit de galop* and other cardiac rhythmical disorders, especially the extrasystoles) was not so evident; the cardiac volume and aortic diameter showed no modification. Subsequent treatments were equally beneficial. Results were best in cases of renal insufficiency, and were less favourable in sclerous and so-called solitary hypertension, and in that of the menopause. Cardiac insufficiency, even though advanced, is not a contraindication to this treatment. Two illustrative cases are recorded.

449 Prophylaxis in Sea-sickness

T. G. MAITLAND (*Practitioner*, August, 1934, p. 146) states that the only form of sea-sickness which requires medical attention is the profound depression which goes with a severe vagal response, and that susceptibility as well as temperament has to be considered. For cases of moderate susceptibility atropine medication is advisable for the twenty-four hours prior to sailing; the ship surgeon will probably continue this. Patients with extreme suggestibility may be benefited by similar preliminary sedative medication with drugs of the barbitone or chlorotone groups. Such may be unnecessary if the patient is convalescing from a severe or exhausting illness, when he passes from the sympathetic to the vagal type. If prophylaxis is desired in such a case owing to great susceptibility to sea-sickness, it is strongly advisable that atropine or hyoscyamus should be given. It is important to distinguish beforehand between the vagal types, which will suffer severely unless treated for the vagotonia, and the sympathetic types, which will escape unless intensely susceptible and thereby prone to vagal reactions. Continued repression of the outward and physical manifestation of the emotions in the sympathetic type not infrequently results in vomiting.

450 Rapid Immunization against Diphtheria

A. E. KELLER and W. S. LEATHERS (*Journ. Amer. Med. Assoc.*, August 18th, 1934, p. 478) record the results obtained from prophylactic injection of a single dose of 1 c.cm. of alum-precipitated diphtheric toxoid. In one group of twenty-three Schick-positive children 60 per cent. became negative in fourteen days, 95.6 per cent. in twenty-eight days, and 100 per cent. in forty-two days after injection. In another group of fifty-three children 92.4 per cent. became negative twenty-two days after one injection, 94.3 per cent. in sixty days, and 96.2 per cent. in ninety days. The results following immunization with a single dose of alum-precipitated diphtheric toxoid thus compared favourably with those obtained from two doses of toxoid without alum or toxoid with alum, and were much better than those reported following one dose of toxoid without alum or with alum, or three injections of standard toxin or antitoxin mixture.

Neurology and Psychology

451 Pyrotherapy in Treatment and Prevention of Neurosyphilis

A. KRAL (*Med. Klinik*, July 6th, 1934, p. 898), surveying personal and other statistics concerning pyrotherapy in general paresis, notes that reports have become less optimistic with the progress of years. His figures agree with those of Jossmann, who found that complete remission of symptoms (restoration of working capacity, mental normality, normality of the serum and liquor in biological tests) follows in only one case in five. Other observers have reported good results in less and even negligible proportions. Mortality attributable to malariotherapy is as high as 10 per cent. Not denying that Wagner and Jauregg's treatment is the most beneficial, Kral believes that its earlier application is of great importance, but presents difficulty owing to the presence of advanced morbid cerebral lesions at a comparatively early stage, in which clinical symptoms are inconspicuous. Turning to the prophylactic use of malariotherapy for prevention of neurosyphilis, Kral agrees with Keri and others that in most patients having a positive Wassermann reaction in the cerebro-spinal fluid four to six years after infection, a malaria cure followed by salvarsan and bismuth therapy leads to negative biological findings and non-appearance of cerebral neurosyphilis within the customary limits of time. Such treatment is contraindicated by severe coexistent visceral disease. Reports concerning the value of pyrotherapy, combined with specific treatment given in early syphilis as a preventive of later development of general paresis, are conflicting. Morbid conditions of the liquor, even with a negative blood Wassermann reaction, are common in the earliest stages, and usually disappear in four to five years, spontaneously or after ordinary treatment, in which case neurosyphilitic syndromes do not develop later.

452 Epilepsy and the Cerebral Circulation

F. A. GIBBS, W. G. LENNOX, and E. L. GIBBS (*Arch. Neurol. and Psychiatry*, August, 1934, p. 257) cite evidence against the validity of the current theory that widespread anaemia of the brain is an immediate cause of epileptic fits. By means of a thermo-electric blood-flow recorder inserted through a hollow needle into the internal jugular vein of epileptic patients, changes in the blood flow through the brain with reference to *grand mal* and *petit mal* seizures were recorded. In none of the ten patients thus studied was any evidence obtained of a significant reduction in blood flow immediately preceding the onset of the seizures. During severe convulsions there was a great increase in the flow. The changes which accompanied the seizures seemed to be the result rather than the cause of them. It was unfortunately impossible to obtain simultaneous records of the blood pressure during the fits, owing to the violent muscular movements, but the authors are convinced that the pressure is raised during apnoea and the convulsions. This would be a sufficient explanation of the rise in pressure, but it appears probable also that the accumulation of carbon dioxide in the blood as the result of the apnoea tonic period would cause dilatation of the cerebral vessels and an increased blood flow. The hyperpnoea of the post-convulsive stage would act in the opposite direction, causing a restoration of the blood flow to its normal rate. Answering the objection that the instrument used might not have been fast enough to indicate a sudden decrease in blood flow preceding a convulsion, and that the decrease in flow after the seizure might really have occurred before it, the authors mention that the instrument faithfully recorded within a fraction of a second changes in the blood flow produced by compressing either the homolateral or the contralateral jugular vein. Syncope associated with a decrease in the cerebral blood flow did not occur until the instrument had given ample indications of such a decrease. It thus seems certain to the authors that no widespread ischaemia of the

brain preceded the observed seizures, and that there was no chronic stasis of blood flow through the brain for minutes or hours preceding the fit. They add that there remains the possibility that the convulsions were preceded by a spasm in a single vessel, or in a small area of the cerebro-vascular bed. They argue, however, that if anaemia of a small area produces seizures, these would be commonly associated with cerebral arteriosclerosis, which usually gives rise to localized anaemic areas in the brain. It is true that the incidence of seizures is relatively high in the age group in which arteriosclerosis is common, and in persons dying of cerebral arterial disease, yet the actual incidence in these groups is so low that arteriosclerosis cannot be of decisive or exclusive importance in the induction of fits.

453 Psychological Basis of Migraine

GRACE A. TOURAINE and G. DRAPER (*Journ. Nerv. and Ment. Dis.*, July, 1934, p. 1, and August, 1934, p. 183) describe a characteristic constitutional type for the migrainous person, in which the skull conformation shows acromegalic trends, the intelligence is outstanding, and the emotions appear to be retarded in development. The headache attack presents individual characteristics also, for each patient repeats the same pattern, and the attack recurs in similar circumstances. Situations involving the loss of home protection, a necessity for the person to stand alone or grow up, and the advent of personal adult responsibility mark the moment in life when the headaches first appear. This is true whether or no the patients have suffered in early childhood from attacks of acidosis. The authors find that there is an evident familial predisposition to migraine headaches, and the character of the attack is often similar in the several afflicted members of a family group. The factor of unwitting imitation of the migrainous ancestor appears to be an important aspect of the genetic interpretation. Satisfactory adjustments in the sexual sphere are absent, and there appears to be an arrest at some point in the psycho-sexual development. A conflict between the desire to escape from the mother's influence and a compulsion not to leave her results in an attempt to remain emotionally dependent upon her, and part of the individual personality is dissociated, being caught in the maternal attachment. Retardation ensues in the advance to complete individualization. The attack is like a recapitulation of the birth experience, and may consequently be precipitated by the continued oppression of the mother which forces the person to try to escape, or by any implication that a separation is about to take place. These threats may develop on either the unconscious or the conscious level. The migraine attack appears thus as a syndrome comparable to any other neurosis, its form being determined through the operation of a psychological mechanism in a person of a special constitutional type. This conception explains why migraine has for so long proved resistant to treatment, and the authors conclude that the psychological approach to the problem offers promising openings for further investigation and therapy.

Obstetrics and Gynaecology

454 Narcotic Treatment of Hyperemesis Gravidarum

E. SCHEHL (*Schmerz-Narkose-Anaesthetie*, July, 1934, p. 16) states that at Gauss's clinic rectal administration of narcotics plays the chief part in treatment of cases of pernicious vomiting of pregnancy in which isolation, suggestion, and other customary modes of treatment have been proved ineffective. Three preparations are used—namely, (1) suppositories containing 0.4 gram of the sodium salt of secondary butyl-3-bromallol barbituric acid, or the equivalent of 4 c.cm. of pernocton; (2) suppositories containing the same amount of "rectidon," the corresponding compound in which an amyl replaces the butyl group; and (3) a 20 per cent. solution of sodium bromide in yeast extract. The last-named is first tried: if it fails

recourse is had to rectidon, which gives a more profound partial narcosis, and is administered at first at the rate of three suppositories daily, diminished after a few days to two or one. Preliminary trial of this method in thirteen severe cases has been strikingly successful.

455 Chemical Extirpation of the Uterus

G. GAMBAROW (*Zentralbl. f. Gynäk.*, August 25th, 1934, p. 2015) describes three cases in which, in aged and debilitated subjects in whom operation was contraindicated, he tried the device described by Driessen in 1927. This consists in placing in the uterus a stick, some 8 to 10 mm. thick and 7 to 13 cm. long, of zinc chloride 40 parts, zinc oxide 10, excipient 30: the caustic action extends outwards, but is limited by the peritoneum, and a sequestrum of the shape and size of the uterus is expelled later. Gambarow's patients had cancer of the corpus uteri. One patient, aged 76, remained well for seven years afterwards, and another for one year at least; the third, in whom the disease was locally inoperable, died from recurrence eighteen months later. It is concluded that in a limited number of cases of carcinoma of the uterine body extirpation by caustic may be justified by contraindications to operation, and may be combined with radiotherapy.

Pathology

456 Chemistry of Corpus Luteum Hormones

E. FELS, K. H. SLOTTA, and H. RUSCHIG (*Klin. Woch.*, August 25th, 1934, p. 1207) have isolated from the yellow bodies of swine ovaries, and in much less concentration from the placenta (apparently the human placenta), two complex ketones which biological tests (induction of hyperaemia and the pseudo-pregnancy changes in the mucosa of the rabbit uterus) prove to be the hormones of the corpus luteum. This contains four ketones, of which "luteosterones" A and B are biologically inactive, but luteosterones C and D induce respectively (1) pronounced hyperaemia without muscular enlargement, and (2) the characteristic endometrial transformation in the test organ. Luteosterones C and D are isomers, of the formula $C_{27}H_{46}O_2$, and contain three complete benzene rings.

457 Sedimentation Rate in Pregnancy and Puerperium

L. S. PETERSEN (*Norsk Mag. f. Laegevid.*, September, 1934, p. 1048) studied the sedimentation rate of the red corpuscles in 400 cases of pregnancy, parturition, and the puerperium, 700 reactions being carried out with the following results. There was a gradual increase of the rate during the earliest months of pregnancy, though normal values were very often found in the third or fourth month. In many cases the rate reached its height in the last four to six weeks, without being delayed till the end of pregnancy, as stated by many authors. The variations in the rate in normal pregnancy were considerable, ranging from 100 mm. to the low degree found in non-pregnant women. Petersen emphasizes the fact, which has not previously been pointed out, that a pregnant woman may have a normal rate immediately before parturition. The hypothesis that a low rate indicated a low fibrinogen content of the blood and heralded post-partum haemorrhage was not confirmed. The age of the woman, the number of previous pregnancies, the sex of the child, and the toxæmia of pregnancy had no influence on the rate, but in the case of twins the increase in the rate was greater than in women with only one child. During the first twenty-four hours of the puerperium no change in the rate took place, but on the third or fourth day it was often increased. On the tenth day the rate was normally either of the same height or lower than at the time of delivery. When there was much post-partum haemorrhage the rate increased on the tenth day. In cases of puerperal infection the rate was more or less increased.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

453 Influence of Statics and Function on Venous Thrombosis

According to K. W. FISCHER (*Munch. med. Woch.*, September 7th, 1934, p. 1378) phlebitis and thrombosis occur most commonly in the lower extremity because of hydrostatic pressure and the long distance of the veins from the heart: in many cases the valves of the veins are too few or badly formed. Increased intravenous pressure may be produced by pregnancy, constipation, and pelvic tumours. The factors normally preventing thrombosis are the pumping action of the heart, the protection of the venous walls by tissues, muscles, fascia, and skin, and by muscular action during exercise, which, by pressure on the walls, empties the veins. A sedentary life, with increased intravenous pressure and atrophy of supporting tissues, leads to a compensatory thickening of the veins. This thickening of the veins is almost always accompanied by thickening of certain muscle fibres in the legs. This condition is termed "myogelosis," and when found is indicative of threatening phlebitis. It does not clear up with rest, but is often followed by myositis. The reason for this is that in the resting body the heart beats more slowly and the blood stream flows less quickly, resulting in asphyxia of the tissues, an increase of inflammation in veins and muscles, and an increased need of blood. Rest in bed further brings about a damming-up of blood containing an increase of metabolic toxins. The circulation is helped by the application of a good-fitting bandage and by muscular action, and an acute phlebitis can be cured in one to two weeks by this treatment. Prophylactically a physiological carriage and gait, combined with exercise—walking and running—prevents thrombosis and phlebitis.

459 "Infection Index" in Patients with Carcinoma

P. ENGEL (*Wien. klin. Woch.*, September 14th, 1934, p. 1118) defines the "infection index" of a patient as the number of infectious diseases he has had. He notes that patients with cancer have a low "infection index," and that they state that this is the first illness they have ever had. Engel examined 300 patients with carcinoma and 300 others in the carcinomatous age period suffering from various complaints. Infectious diseases which patients had had several times were recorded as one. In 300 cancer patients 113 had never been ill before; he noted 197 infectious diseases in childhood and 148 in adult life. In 300 patients suffering from other conditions only sixteen had never been ill before; he noted, however, 500 infectious diseases in childhood and 420 in adult life. The author gives three reasons for the low "infection index" in cancer patients: (1) the disposition to cancer gives the patient a high-grade immunity to infections; (2) a patient's constitution is so changed by infectious diseases that the disposition to cancer becomes minute; and (3) each patient has from the beginning a disposition to cancer or infectious diseases. Engel further points out that a low "infection index" was found more commonly in cancer of the intestine than in cancer of the stomach or breast, and that a high "infection index" was found in a small series of young patients suffering from cancer.

460 Basal Metabolism and Specific Dynamic Action in Heart Failure and Hyperthyroidism

A. BERLAND, T. DOUSKOWA, M. CHANDLER, and M. GOUBERGRIITZ (*Arch. des Mal. du Cœur*, August, 1934, p. 494) state that there are diverse views on the basal metabolic rate in heart failure. Their own observations, made on thirty-one patients, mostly with congestive failure, gave figures varying from -22 per cent. to +38 per cent., but in about half the cases the metabolism was more than +15 per cent., which is taken as the upper limit of normal. Diminished metabolic rates were found particularly in patients with considerable oedema, and the

authors point out the fallacy of figures based on a body weight increased by oedema. In the normal individual the effect of ingested protein is to increase metabolism considerably, but in cardiac patients the effect was in most cases found to be reversed. Half to one hour after giving 150 grams of meat an initially raised metabolism was found to be lowered, or one initially low was still further reduced. Employing the same method in cases of hyperthyroidism, the results of protein administration were found to be the same as in normal people, except where the disease was accompanied by gross heart failure, when the reversed action observed in failure from other causes was found. It is suggested that the method may be of value in distinguishing cardiac disturbances (short of gross failure) due to thyroid disease from those of other origin.

461 Diagnostic Signs of Slight Ascites

C. LIAN and V. ODINET (*Presse Méd.*, August 25th, 1934, p. 1337) state that in normal subjects a bruit can be heard on auscultation during abdominal percussion. In ascitic cases this is followed by a second bruit, longer and more intense, which is due to displacement of the ascitic fluid by the percussion. This bruit is best heard over one iliac fossa while percussing the other. As it may be absent in the dorsal decubitus, the patient should always be placed in the erect position, in which the bruit is constantly present. In this position another diagnostic sign is also obtained—namely, a zone of dullness limited at its upper part by a horizontal line. These two signs are always present in, and diagnostic of, even the smallest ascitic effusions. Illustrative notes on four cases are given.

462 The Tonsils and Photochemical Reactions of the Skin

S. PELLER and B. RUBINSTEIN (*Klin. Woch.*, August 25th, 1934, p. 1216), in support of the theory put forward by the former that the tonsils favour pigmentation of the skin in reaction to light, adduce the following statistical and experimental evidence. Among a large series of girls, aged 14 to 16, some 13.4 per cent. of the blondes but only 7.6 per cent. of the brunettes were found to have undergone tonsillectomy. Both in dark and in fair, but more noticeably in the former, those with hypertrophied, ordinary, or operatively removed tonsils respectively reacted to ultra-violet irradiations of the skin of the arm by a well-marked, moderate, or slight degree of erythema in the corresponding groups. The tonsils are therefore said to favour the defensive reactions of the skin to light, and their enlargement is regarded as an instance of work-hypertrophy.

463 Allergic Reaction of Bathers to Aquatic Vegetation

TEUSCHER (*Deut. med. Woch.*, September 7th, 1934, p. 1351) has observed several cases of urticaria and asthma among bathers. One of them was an asthmatic whose disease was aggravated when he lay on the grass by the shore while his skin was wet. Some of the bathers developed severe urticaria on entering the water. Other reactions consisted of violent sneezing, bronchial catarrh, and very troublesome asthma, which in some cases induced the persons concerned to give up bathing by the shore. The asthmatic reaction in the case of one woman was so severe while swimming that she nearly drowned. Suspecting aquatic plants as the cause of the trouble, the author concentrated his attention on two varieties—a member of the Potamogeton family and *Myriophyllum spicatum*—of which there were great quantities in the neighbourhood. He applied them to abrasions of his own skin and obtained an urticarial vesicle in response to the *myriophyllum*. Extracts were made of the two plants in question and used in skin tests, which invariably yielded a violent reaction to *myriophyllum* in the patients examined, whereas there was only a feeble or negative reaction to the extract of potamogeton. Further proof

of the part played by myriophyllum was found by the success with which even the most susceptible persons were desensitized in ten to fourteen days by carefully increased doses of myriophyllum extract. It transpired that the peccant plant had recently been introduced from abroad at great cost with the object of improving the fishing.

464 Typhoid Fever and Appendicitis

H. NICOLAS (*Thèse de Paris*, 1934, No. 703) records eight illustrative cases, in patients aged from 8 to 26, in which typhoid (seven cases) or paratyphoid fever B (one case) was complicated by appendicitis. The appendix was removed in seven, with one death, and one died without operation in twenty-four hours from the onset. Nicolas comes to the conclusion that the condition of typhoid appendicitis does definitely exist, especially as typhoid bacilli have been found in the appendix of typhoid fever patients suffering from appendicitis.

Surgery

465 Unrecognized Dislocations of Shoulder and Hip

According to F. REISCHAUER (*Zentralbl. f. Chir.*, September 1st, 1934, p. 2019), non-recognition of dislocations of the shoulder or hip in adults is due to a deceptive clinical history, to wrong interpretations of x-ray pictures, or to both. It must be remembered that dislocations have been reported in many cases (especially in the shoulder-joint) in which there is no history of accident. Examples are: shoulder dislocation during the night after retirement in a drunken condition; dislocation during a fit of coughing; unilateral or even bilateral dislocation of the shoulder in the disturbed muscular synergism of an epileptic fit; dislocation from muscle spasm due to contact with an electric current. It follows that in any acute limitation of joint movement, even if antecedent trauma is denied, elimination of a possible dislocation is the first step to be taken: the bony changes secondary to unrecognized dislocations have been taken to indicate (and so published, with radiograms, in recent literature) primary arthropathy. Confusion with fractures near the joint is also common. In the interpretation of radiograms measurement is useful; if, in the absence of lateral displacement, the sockets of the two sides are of the same size but the condyle of the paretic side is smaller or larger than that of the control side, a posterior or an anterior dislocation respectively is indicated. If an antero-posterior radiogram conceals a dislocation, it will be brought out readily by one taken with the rays directed from the side of the body to the centre of the joint.

466 Prognosis in Perthes's Disease

W. SCHMIDT (*Brans' Beitr. z. Klin. Chir.*, September 5th, 1934, p. 247) describes the experience of the Göttingen clinic in thirty-two cases originally diagnosed as Perthes's disease (juvenile osteochondritis of the hip) with special reference to the prognosis. Re-examination was made five to ten years after commencement of treatment, and led to exclusion of eleven cases in which the diagnosis had certainly or probably been wrong—six of tuberculous coxitis and five of coxa valga or growing pains in which the symptoms had speedily disappeared. In all these the radiological as well as the clinical findings had been taken to justify a certain or very probable diagnosis of Perthes's disease. Of the remaining twenty-one cases seven showed no residual impairment of joint function, but in three of these radiological signs of coxa valga luxans, or mushroom shape of the head of the femur, could be seen. Nine had some degree of limp and limitation of movement, together with radiological signs. In no fewer than five were to be noted limp, shortening, muscular atrophy, and considerable limitation of movement; the tracer line was above Nikitin's line in three, but in none was severe pain reported. Radiologically the five patients showed irregular bony structure, with

alternating rarefied and sclerotic zones and deformity of the joint cavity. The end-results were satisfactory in the various cases in proportion as the early treatment had been systematic; perfunctory treatment led to poor results. The inference is drawn that the prognosis of Perthes's disease, although good on the whole, is less certainly favourable than has been supposed, and is definitely improved by early treatment by rest with extension, followed by plaster support.

Therapeutics

467 Treatment of Ulcerative Stomatitis

Dealing only with the usual forms of ulcerative stomatitis, Mme. PAPILLON-LEAGE (*Paris Méd.*, September 1st, 1934, p. 171) states that the aetiology of these should first be determined. The two most frequent causes are drug intoxications and eruption of lower wisdom teeth. The condition often occurs with carious teeth, during infections, cirrhotic, diabetic, and renal diseases, and in latent blood infections (agranulocytosis and leukaemia). Treatment consists of daily careful disinfection of the ulcerations, mouth cleansing every three hours with a disinfectant, and light but prolonged brushing of the teeth with a soapy solution or arsenical paste. A light lacto-vegetarian diet with much fruit juice should be given, and a purgative, if necessary. In medicamentous intoxications treatment should immediately be stopped. Should this be inadvisable, as in syphilis, daily injections of 1 cg. of mercuric cyanide may be given; these have a favourable action on the buccal lesions, which usually disappear after the third injection. All dental or other oral interventions should be deferred until the acute phase of the stomatitis has subsided.

468 Drug Therapy in Cardiac Affections

A. MUR (*Crónica Médica*, August 15th, 1934, p. 675), reviewing very critically several recent European and American publications respecting various heart affections, asserts that digitalis is still the outstanding remedy for cardiac insufficiency in its early stages, but in advanced cases other drugs must be employed. Auricular fibrillation is the fundamental indication for digitalis, and after it come the tachycardial arrhythmias and similar conditions. Whatever may be the type of cardiac derangement, and whatever its cause or the conditions which accompany it—renal, hepatic, sclerotic, or hypertensive—digitalis must be fearlessly employed when incompetence is present. It is waste of time to administer it when the heart is sound, as it will then neither produce one pulsation more, nor will it raise or diminish the arterial tension by a tenth of a degree or increase the urinary output by one cubic centimetre. His long and extensive experience of general anaesthetics convinces this author that latent insufficiency frequently manifests itself during or after anaesthesia, and compels him to advise as a routine measure pre-operative hypodermic injection of sparteine and strychnine.

469 Strychnine Therapy in Barbituric Acid Poisoning

O. G. HANSEN (*Nord. Med. Tidsskrift*, September 1st, 1934, p. 1118) reviews the literature of the treatment of barbituric acid poisoning with large doses of strychnine since Haggard and Greenberg in 1902 (*Journ. Amer. Med. Assoc.*, April 2nd, 1932, p. 1133) established the experimental basis of this treatment by their tests on dogs. At the author's hospital in Oslo two patients have thus been treated, the first being a woman of 55, who was admitted to hospital moribund, but who was kept alive for four and a half days, during which she received 63.5 cg. of strychnine by intravenous injection. Her death was hastened by bronchopneumonia and old-standing heart disease. The other patient was a man of 63, who was admitted to hospital comatose after having taken about 8 grams of veronal.

He recovered after having been given 17 cg. of strychnine by intravenous injection in several doses, 16 cg. being given in the course of the first twenty-four hours. From his observation of these cases and his study of the literature, the author concludes that the subjects of barbituric acid poisoning are remarkably tolerant of large doses of strychnine, but that the antagonism of the one drug to the other is not absolute, and that when strychnine is given in large enough doses to provoke toxic manifestations it is not always capable of neutralizing the effects of barbituric acid poisoning. It cannot yet be claimed with certainty that strychnine is so useful that it can take the place of other drugs, notably coramine, in the treatment of barbituric acid poisoning. The initial dose of strychnine by intravenous injection should be 1 cg., and the subsequent dosage should depend on the behaviour of the reflexes, notably the jaw reflex. The injections should be repeated even oftener than once an hour, as recommended by Ide, because of the transient nature of the effects of intravenous injections. Strychnine should not be given if there is any doubt as to the symptoms being exclusively or mainly due to barbituric acid poisoning.

Disease in Childhood

470 Acid Metabolism in Rheumatic Children

W. W. PAYNE (*Arch. Dis. in Child.*, August, 1934, p. 259) has attempted to determine whether an "acid diathesis" is present in rheumatism by examining the urine for evidence of an acid output in excess of what might be expected. His material consisted of a group of about 200 children attending a rheumatic clinic, and two control groups from the attendants of an asthma clinic and from a school. The choice of asthma as a second disease group was partly due to the assumption that an element of alkalosis entered into the asthmatic syndrome. This proved unfortunate in that it was later found that the children were receiving the equivalent of 145 c.cm. of decinormal hydrochloric acid a day, but evidence was obtainable that the dietetic and environmental conditions did not invalidate the results. The urines of the three groups were compared statistically in respect of the free, total, and organic acid, the phosphate contents, and also the pH. The results obtained indicated that a rheumatic child in a quiescent interval excreted more acid in its urine than did a normal or asthmatic child. Part of this excess of acid was due to organic acids. This excess was insufficient to disturb the equilibrium of the blood, and the author thinks it not surprising, therefore, that no significant differences have been found by those who have investigated the acidity and the ammonia-acid ratio of blood in rheumatism. He believes that there is some truth in the "acid diathesis" theory of this disease.

471 Venoclysis in Paediatrics

S. KARELITZ (*New York State Journ. Med.*, July 15th, 1934, p. 631) discusses the various indications for employing the continuous intravenous method of fluid administration in paediatrics. In the treatment of alimentary toxicosis, for example, before feeding can be resumed the shock-like state must be overcome, the circulation improved, the urinary secretion increased (to eliminate the retained toxins and excess of acid substances and tissue salt), and fluid replenished. To accomplish this, the continuous intravenous drip of 5 per cent. glucose in normal saline or Ringer's solution was found effective, 100 to 250 c.cm. being injected rapidly at first in twenty to thirty minutes, after which the flow was reduced to the rate of 100 to 200 c.cm., averaging 130 c.cm. per kilo of body weight in each twenty-four hours. This was supplemented with a blood transfusion, usually given within a few hours after the venoclysis had been started. The venoclysis was continued until improvement of the condition and the child regained ability to take two-thirds to three-quarters of its fluid requirement per ounce

without any ill effect on the gastro-intestinal condition. This procedure, together with a period of milk starvation for at least thirty-six hours, and in some cases for as long as five days, as well as realimentation by frequent small feedings according to a simple milk formula, increased daily for four or five days and thereafter as indicated, was tried successfully in over 100 cases of alimentary toxicosis. Other morbid conditions cited as yielding to this form of therapy include ketosis and coma associated with cyclic vomiting and diabetic coma, acute haemorrhagic nephritis with anuria and hypertension, chronic pyuria complicated by collapse, erysipelas, almost moribund pyloric stenosis with alkalosis, primary streptococcal peritonitis, and cases of severe burn. Complications mentioned are: local infection and thrombosis, embolism, anaphylactoid reaction, and oedema. Local occlusion of veins ensued after ten to ninety-six hours in about 25 per cent. of the cases, necessitating cutting down on to a second vein if the first could not be cleared. Local thrombophlebitis was observed in four cases, all of which cleared up after the application of wet dressings for one or two days. Anaphylactoid reactions disappeared when care was taken as regards the use of freshly prepared fluids in carefully cleansed vessels and tubing, when chemically pure salts were used, and when the fluid was injected slowly. Karelitz considers venoclysis the most effective method of reducing blood concentration or serum protein, of supporting blood pressure, and relieving vasomotor collapse.

472 Aetiology of Nocturnal Enuresis

C. J. C. EARL (*Brit. Journ. Child. Dis.*, July-September, 1934, p. 205) points out that the normal adult prostate offers a certain degree of resistance to the urinary stream, rendering it less forcible than in the child. In some enuretic children there appears to be a diminished tone in the external sphincter. Bony abnormalities of the lumbosacral region are more common than is generally supposed, but no relation to enuresis has been established. A relative weakness of the sphincter vesicae compared with the detrusor in children has been mentioned, but is better expressed as either a central nervous imbalance between the lumbar and cortical centres, which exists in all children until they are trained, or else as an autonomic imbalance of the hypervagotonic type. Irritating urines do not cause incontinence but frequency, and at times retention. Certain enuretics seem to have a nocturnal polyuria, although in the ordinary polyurias enuresis is not a symptom. Nocturnal *petit mal* is rare, but almost impossible to diagnose; it would be more likely causal in the infrequent enuretics. Psychological causes include faulty training in a neuropathic type, the psychological and social maladjustments tending to fix the symptoms. The author doubts the theory of urethral erotism, but agrees that the child regresses somewhat in sleep, the extent being in some measure comparable with existing conflicts and maladjustments. When the child's bladder fills at night and afferent stimuli reach the brain, what will happen next depends on three factors: (1) the perfection of training, the "conditioning" of his cortical inhibitory centre to visceral stimuli; (2) the degree of neurosis or conflict present in so far as this increases regression; and (3) the neuronic stability of the nervous system in general. The normal child inhibits the lumbosacral centre or wakes. The neuropathic child has certainly the last two, and probably the first of these three, factors against him, and so he wets the bed. A psychoneurosis, and particularly hysteria, appears to the author the most usual cause of nocturnal enuresis. In some enuretics the bladder is not sensitive to its own contractions, while in some there is a hypotonic sphincter. The acceptance of this theory of hysteria supports the importance of training, for the tendency for conversion hysteria to present itself in a functionally inferior part of the body is well known. Psychological therapy therefore appears to be the essential part of treatment, and the more unpleasant pseudo-surgical methods or drastic dietary restrictions must be condemned.

Obstetrics and Gynaecology

473

Ante-natal Care

Describing ante-natal care in the Netherlands, SALOMONSON (*Journ. Obstet. and Gynaecol. British Empire*, August, 1934, p. 533) stresses the importance of educating the potential parents. Between 500 and 600 women—that is, 3.3 per 1,000—die every year in connexion with pregnancy. Infant mortality for Amsterdam alone is 3.28 per cent.; for the whole country 4.5. Forty-four per cent. of the mortality occurs in the first week; 60 per cent. of the live births are under supervision, with a rising "perseverance percentage" for the first year. Puerperal sepsis is the cause of 30 per cent. of the maternal deaths, the figure remaining stationary for the last ten years, as have the stillbirths, 2.5 per cent.; both inexplicable findings. The Government organization is strongly supported by private societies. Reviewing conditions which affect "extended ante-natal care," the national diet is rich in vitamins and vegetables; there are no congested urban populations; communications are good, and hospital accommodation sufficient. Tables show an increasing tendency for mothers to go to hospital, and to have doctors instead of midwives, as formerly. There are three classes of midwives: (1) The expert accoucheuse, admitted for training by competitive examination; she may undertake any normal confinement, but knows when aberrations require a doctor. (2) A second class attends the mother and baby after delivery, the midwife supervising only, thus avoiding sepsis. (3) The humbler third class assists the second, and is trained to help in housework also. Doctors and midwives are registered for all areas in proportion to the population. As complications always reach a doctor the student's training begins in his fourth year, and lasts for three years. He is in contact with the patients who come under observation at the obstetrical ambulatory service from the fourth month of pregnancy onwards. Infant welfare clinics have spread very far—350 in 250 municipalities. Combination of these with ante-natal clinics is desirable.

474

Non-surgical Aids in Normal Labour

J. VORON and H. PIGEAUD (*Gynéc. et Obstet.*, August, 1934, p. 113) write with approval of the "accouchement médical" described by Kreis, in which the course of labour is shortened and alleviated by deliberate early rupture of the membranes and by repeated injections of "spasmolyse." In their own practice several years' successful experience, with no untoward incidents for mother or foetus, has led them to recommend "accouchement dirigé," of which the significant difference from the technique of Kreis consists in the additional use, in selected cases, of pituitary extract in minimal doses. Concerning rupture of the membranes, these authors remark that the part played by the bag of waters in effecting dilatation of the cervix is now known to be insignificant, if not deterrent. Artificial rupture of the membranes during the first stage accelerates delivery. They accordingly recommend that in delivery of an average size foetus presenting normally through a normal pelvis the membranes should be ruptured when the dilatation reaches 4 cm. diameter, provided that the uterine contractions are still regular. The membranes are at the same time lacerated, and the inferior pole of the ovum is partially separated from the lower uterine segment. Subcutaneous injections of "spasalgine" are given in a large proportion of cases—a first injection towards the end of the first stage, if uterine contractions become unduly painful or frequent but vaginal examination does not show with certainty the lower segment spasm, which is probably the causal factor, repeated injections if there is palpable spasm. In some cases chloral and quinine are given as well. Pituitary extract is given subcutaneously in small doses—two international units—which are confidently regarded as incapable of producing exaggerated uterine contractions, much less a tetanic contraction. The use of this drug is recommended (1) for relative inertia in the second stage,

as an alternative to forceps application, and (2) during the first stage, when, before attainment of full dilatation, pains become feeble and relatively infrequent. Evidence is given, in hystero-graphical tracings, of the beneficial effect of spasmolyse, pituitary extract, and rupture of the membranes on the expulsive activity of the uterus.

475

Haemorrhagic Disease in the Newborn

I. N. KUGELMASS and J. E. TRIYSCH (*Amer. Journ. Obstet. and Gynecol.*, August, 1934, p. 259) have treated haemorrhagic disease in the newborn, and by ante-natal treatment prevented it in a subsequent pregnancy. Foetal blood is in equilibrium with maternal, so that ante-natal tests can be made. Lack of prothrombin, less markedly of fibrinogen, is found; or an increase of antithrombin. In a case in which a mother lost four successive infants from haemorrhagic disease, ante-natal treatment during the fifth pregnancy resulted in a healthy infant. Treatment was refused during the sixth pregnancy, accepted during the seventh. The sixth baby died of uncontrollable haemorrhage; the seventh was healthy. The clotting function of the blood was shown to improve on a high protein diet. Presumably, therefore, the agents are synthesized in the liver. A high protein diet, specially including viscera and gelatin, is prescribed. Epistaxis and similar haemorrhagic symptoms were effectively treated on these lines also.

Pathology

476

Blood Pathology in Endocarditis Lenta

A. WYDRIN (*Wien. Arch. f. innere Med.*, August 10th, 1934, p. 231) reports a series of fifty cases of endocarditis lenta (chronic bacterial endocarditis). One in four showed a streptococcus in blood culture, *S. viridans* being twice as frequent as *S. haemolyticus*; no connexion could be traced between severity of cases and the presence or absence, or the denomination, of a streptococcus in the blood. The Wassermann test was positive in four cases, all of which showed, in addition to verrucose endocarditis, evidence of syphilis in the great vessels; the view that non-syphilitic subjects with ulcerative endocarditis may show a positive Wassermann reaction is to be regarded with distrust. About one-half had well-marked hypochromic anaemia, and occasionally a hyperchromic form with increased colour index was found. Leucocytosis was present in 40 per cent., leucopenia (a very unfavourable sign) in 32 per cent. Of sixteen patients with lymphopenia all died, but eosinophilia seemed to have no prognostic importance.

477

Immunization against Contagious Abortion

W. S. LORNE (*Veterinary Record*, August 18th, 1934, p. 927) reports the results of experiments extending over four years, which indicate that the use of a killed vaccine is very effective in clearing herds of contagious abortion. He points out that, while this disease may be economically eradicated from some herds by the elimination and segregation of reactors to the blood test, these methods are not likely to be practicable in most herds owing to the extent and arrangement of the farm buildings handicapping segregation. The employment of live vaccine is objectionable in that it does nothing of itself to eliminate infection, and it removes still further any tendency to try to eliminate the disease by blood testing and segregation. Lorne is convinced that dead vaccine immunization may well prove to be the ideal method. Associated with strict attention to hygiene precautions, it affords very early and satisfactory relief from this disease, rendering segregation steps unnecessary. There seemed to be no restrictions as regards the use of this vaccine, and the inoculations can be given at any time before or during pregnancy. There may be a decided decrease in the milk yield for a day or two after inoculation.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

478 Acute Pulmonary Congestion and Cardiac Asthma in Mitral Stenosis

S. MCGINN and P. D. WHITE (*Amer. Heart Journ.*, August, 1934, p. 697) report (1) ten cases of uncomplicated mitral stenosis, and (2) ten cases of mitral stenosis complicated by aortic valve disease or high blood pressure, in all of which attacks of acute pulmonary congestion with dyspnoea or definite wheezing were observed. The average age of the two groups was 31.3 and 50 years respectively. Eight of the ten patients in Group 2 died, within an average of two years after their first attack, and four of the first group in an average of three and a half years. In seventeen of the twenty cases exertion was the factor precipitating the attacks, in contrast to the results in a large series of cardiac asthma cases without mitral stenosis in which exertion appeared to excite attacks in only 8 per cent. In five individuals with mitral stenosis only attacks were precipitated by paroxysmal tachycardia. Six of the total twenty patients had auricular fibrillation. The attack of pulmonary congestion was fatal in two cases of uncomplicated mitral stenosis; post-mortem examination in three cases of this group showed no hypertrophy of the left ventricle. The author's view of the mechanism of the attacks is that when the heart rate is increased by effort, excitement, or paroxysmal tachycardia, the hypertrophied right ventricle of these hearts with mitral stenosis (but without heart failure) expels more blood than can pass through the mitral valve in a given time, resulting in pulmonary congestion, oedema of the lung, haemoptysis, and even death.

479 Latent Diabetes and Psoriasis

According to W. MILBRADT (*Derm. Woch.*, August 11th, 1934, p. 1045) alterations of carbohydrate metabolism, as shown by the double sugar-ingestion test of Staub and Traugott, are present in one case in three of psoriasis; but it is doubtful whether the skin disease is aggravated by the metabolic dyscrasia or provokes a latent diabetic tendency. It is advisable that patients suffering from psoriasis and found to present abnormalities of carbohydrate metabolism should receive fairly constant supervision. A case is described in which a male aged 21, suffering from psoriasis, was subjected to biological tests which were taken to justify the diagnosis of latent diabetes, although the blood-sugar level was not more than "high normal": three years later, during a recurrence of the psoriasis, the diagnosis of moderately severe diabetes was established by a history of recent thirst and by a lasting glycosuria, a high blood sugar, and a sugar-tolerance test which was only atypical by reason of a pronounced hypoglycaemic sequel, ascribed to hepatic disturbance. The last seemed to be secondary to hyperthyroidism, of which the patient had definite signs in a low degree.

480 Radiological Diagnosis of "Lobite" Tuberculosis

E. M. VAN BUSKIRK (*Radiology*, August, 1934, p. 189) considers that the term "lobite" tuberculosis is now well established to signify pulmonary tuberculosis with a definite lobar limitation, even though the lesion is undoubtedly an extensive patchy alveolitis or bronchopneumonia. He reports four personal cases; in three the disease was limited to the right upper lobe, and in the fourth to the right inferior lobe. Three varieties have been defined: in one the whole lung appears as a dense homogeneous shadow; in the second the film is similar, but a series of clean spots give the lung the appearance of scattered bread-crumbs or a honeycomb; and in the third there is a homogeneous shadow, with a cavity which is often very large, and is usually situated medially below the clavicle. This sharp delimitation of the tuberculous process can only be diagnosed by radiography, and the

author thinks that this line of investigation should be utilized more generally in routine health examinations. The incidence of lobitis is between 1 and 7 per cent. of all cases of pulmonary tuberculosis. Infants and children are rarely attacked, the patients being generally between the ages of 20 and 40, and more often women than men. The author thinks it probable that this form of inflammation does not spread to other lobes. It may appear as a recrudescence of earlier tuberculosis, or be a new exogenous infection. The symptoms usually resemble those of the ordinary incipient disease. The sputum is, as a rule, absent, or small in amount; tubercle bacilli are always found in it when it is abundant. In three out of four cases the disease starts insidiously. Adhesions are generally present, especially at the lateral edge of the fissure and at the apex. They alter the shape and situation of the fissure and the lobe when fibrous contraction occurs, or when pneumothorax is induced. Owing to the infrequency of this condition, coupled with its rather benign nature, few definite cases have come to necropsy. In one, reported in the literature, the lobe was of woody hardness, a dense fissure binding it firmly to the underlying lobe. Internally, there were knotty lesions, surrounded by a fibrous network, and more recent lesions and extensive patches of tuberculous bronchopneumonia containing tubercle bacilli. There was much interstitial sclerosis, with thickening of the blood vessels and bronchi. In the fibrous network, macrophages filled with carbon produced the typical appearance of anthracosis.

481 Radiology of Whooping-cough

F. TRILAZIC (*La Pediatria*, August, 1934, p. 921), from his observations in a paediatric clinic at Milan, came to the conclusion that the following radiological appearances may be found in the different stages of whooping-cough. At the onset of the paroxysmal stage the numerous small annular formations first described by Pincherle in 1925 are seen in the subclavian regions of both lungs, and elongated figures with more or less thickened margins. The latter represent dilatations of the small and medium-sized bronchi, while the annular formations represent tangential sections of the bronchi and possibly small areas of surrounding emphysema. At a later stage the basal triangle described by Göttsche in 1928 due to endobronchitis, endobronchiolitis, and peribronchitis is seen. The radiological picture thus faithfully reproduces the anatomical changes of whooping-cough.

Surgery

482 Fusion of the Kidneys

L. ZEISS and H. BOEMINGHAUS (*Zeit. f. Urol.*, 1934, Heft 9, p. 577) give pyelograms and clinical details of thirty cases of bilateral fusion of the kidneys (horseshoe kidney) and six of unilateral fusion, in which one ureter crosses the middle line (the so-called crossed dystopia) and the kidneys lie on the same side, one below the other, with the crossed one as a rule fused at its upper end with its fellow. From necropsy findings of Pagel the respective proportions of bilateral and unilateral renal fusion are 1 in 700 and 1 in 10,000. Owing to lack of the normal rotation of the kidney around its long axis the ureters open into the pelvis either in front or at the outer side, and the calyces open from it outwards but in various radial directions. These findings in a pyelogram, together with the demonstration of a medial and caudal displacement of the kidney, are those which enable a diagnosis to be made. It is important also that, owing to the alteration of the pelvic axes, these when prolonged meet not in the cranial but in the caudal direction. There is no characteristic symptomatology of renal fusion, and as a rule childhood and adolescence are free from suspicious signs: frequently the patient is a quasi-

neurasthenic, with vague symptoms of abdominal pain, meteorism, and spasms. If the finding of a palpable tumour, with a history of symptoms which are non-typical, leads to pyelographic examination, the diagnosis will be made with certainty. The frequency of secondary morbid conditions in fused kidneys is difficult to assess, but at necropsy two in five horseshoe kidneys show dilatation of the pelvis, often combined with infection and calculus formation. The treatment must be specially adapted to each particular case, but in all except six of Zeiss and Boeminghaus's cases it was conservative. If operation is necessary an extraperitoneal approach is desirable.

483 According to O. FRANCKE and G. CHIPAIL (*Journ. d'Urol.*, August, 1934, p. 102) the diagnosis of horseshoe kidney, thanks to a thin patient, a well-developed isthmus portion, and an easily palpable bilateral ptosis, can be made by ordinary physical examination; but usually radiographic methods are necessary, of which ascending is more important than descending pyelography. When—exceptionally in some 7 per cent. of cases, according to Leguen and Papin—the anatomical situation of the horseshoe kidney is normal, pre-operative diagnosis is impossible. Where there is abnormal position the radiological signs which are of value after pyelography are: (1) ptosis of the kidneys with medial displacement; (2) in consequence of the rotation of the kidney so that the internal border comes forward, a sagittal direction of the pelvis with radial, not unilateral, egress of the calyces; (3) sometimes a more complete rotation of the kidney, so that the hilum points outwards; and (4) the co-existence of some of these factors with congenital hydro-nephrosis.

484 Cleft Palate Surgery

R. IVY and L. CURTIS (*Ann. of Surg.*, September, 1934, p. 502) emphasize the low percentage of satisfactory results of operations for cleft palate. A good anatomical result should include not only complete closure of the cleft from side to side, but also a long, flexible, freely movable soft palate, capable of closing off the nasopharynx. If the distance between the posterior surface of the soft palate and the posterior wall of the pharynx is too great to permit contact when the soft palate is elevated, good speech cannot be expected, even though no fissure exists in the palate itself. It has been found that the operation advocated by Veau gives better anatomical results than the von Langenbeck operation in cases in which there is sufficient tissue present to make a velopharyngeal closure after operation. For those cases in which insufficiency of tissue will prevent velopharyngeal closure after the Veau operation, the Dorrance "push-back" operation gives excellent results. The varieties of cleft palate are divided into four principal forms: cleft limited to the soft palate, median cleft of the hard and soft palate, complete unilateral cleft, and bilateral cleft. When a cleft of the soft palate is present operation should be deferred until the child is from 2½ to 4 years of age. The Veau technique is used in these cases. The same applies to cases of median cleft of hard and soft palate. In cases of complete unilateral cleft it is important to correct the malposition of the premaxilla and establish continuity of the alveolar process while the bony structures are still pliable. The first operation should be carried out between 3 weeks and 3 months of age. This consists in the first-stage Veau operation on the hard palate and alveolar cleft, and closure of the lip by the Blair-Mirault technique. The cleft in the posterior part of the hard palate and soft palate is not closed until the child is over 2½ years old. When complete bilateral cleft is present this is converted into a unilateral cleft between 3 weeks and 3 months of age by doing the Veau operation on one side and closing the opposite side four weeks later. Detailed points are given of forty-three cases treated by the Veau operation and ten by the Dorrance "push-back" operation. There were no deaths and results in most cases showed considerable improvement.

Therapeutics

485 Treatment of Lymphogranuloma Inguinale

J. GRAY and J. Y. C. YIEN (*Chinese Med. Journ.*, July, 1934, p. 607) record a series of twenty-five cases of this disease in China, of which only four were female patients; the clinical course of sixteen under treatment was observed. Diagnosis was based on the Frei test, as well as on the clinical picture. The disease is characterized in the male by inguinal adenitis and the formation of fistulae; in the female by its sequelae—namely, rectal stricture and vulval elephantiasis. Potassium antimony tartrate was given in cases uncomplicated by syphilis in twice weekly intravenous injections of 5 c.cm., 7.5 c.cm., and 10 c.cm. of a freshly prepared sterile 1 per cent. solution. It gave good results in the early stages as a rule, but is not effective in the later ones. When syphilis is a complication, antisyphilitic treatment is promising. Besides these general medical measures the non-perforated glands were fomented and aspirated and the fistulae were dressed. Palliative measures, such as fulguration or dilatation of the anus or rectum by bougies, are valuable, but surgery is not indicated as a rule for the groin condition.

486 Treatment of Epidemic Encephalitis

R. A. KINSELLA and G. O. BROWN (*Journ. Amer. Med. Assoc.*, August 18th, 1934, p. 462) record their observations on 215 cases treated during the St. Louis epidemic in the summer of 1933. Besides symptomatic relief, patients received mercurochrome intravenously, transfusions of blood, and even intravenous injections of spinal fluid. The items of treatment that were commonly indicated were: (1) spinal puncture for diagnostic purposes and for the relief of headache; (2) administration of fluids, usually subcutaneously; (3) administration of liquid food by nasal tube if necessary; (4) absolute rest and, if necessary, sedation by morphine. The patient was best treated in a darkened room, free from noise and too frequent attention from nurses and doctors. In a series of 129 cases treated exclusively by this method the death rate was only 12 per cent.

487 Pathogenesis and Treatment of Hay Fever

E. URBACH (*Wien. klin. Woch.*, August 31st, 1934, p. 1073) advocates the confirmation of a diagnosis of hay fever by means of special tests, and condemns the older cutaneous and intracutaneous tests with pollen extracts as being too faulty. They may be positive when pollen, rubbed into the nose, does not cause an attack of hay fever, and may remain positive after desensitization; they may also be negative when hay fever is present. The author recommends a tampon saturated with a 20 per cent. solution of pollen extract and applied for five minutes to the mucous membrane of the nasal septum. By way of control the mucous membrane should first be touched with a tampon saturated with some bland substance to determine whether a non-specific sensitivity is present. If the test is negative a minute quantity of dried pollen should be applied to the mucous membrane. A positive result is one in which a typical attack of hay fever with tickling, sneezing, and rhinorrhoea is produced. Treatment should be by specific desensitization, and Urbach considers that this should be oral. In mild cases 2 grams of barley peptone are given on the fasting stomach daily; in severe cases grass pollen peptones are administered in 2-gram doses twice daily; in very severe cases mixed pollen peptones in 0.1 gram doses twice daily. At present there is difficulty in obtaining enough pollen, but experiments are in progress to evolve pollen-antibodies. This method of treatment has the advantage of allowing of desensitization and treatment solely during an attack of hay fever—pre-seasonal and all-the-year-round injections are condemned. There is, moreover, complete safety and painlessness, while the patient is independent of the doctor, except for the initial examination for the causal allergic factor.

Laryngology and Otology

488 Surgical Intervention in Middle-ear Suppuration

H. NEWHART (*Minnesota Med.*, August, 1934, p. 439) summarizes the indications for operation in suppurative otitis media, and concludes that it is far safer to operate too early than to wait too long. Immediate surgical intervention is required: when after adequate conservative treatment there is persistent pain and tenderness over the tip of the mastoid, and a purulent discharge has existed for one week; when there is swelling and fluctuation over the mastoid region, especially its tip, or over the zygomatic root, or when there is a hard infiltration towards the neck constituting a Bezold abscess, or whenever there is oedema of the posterior superior auricular canal wall; and when, even though all other symptoms are absent, there is a persistent discharge lasting over six weeks. Operation is urgently demanded with the onset of a rapid and severe loss of hearing, nystagmus, vertigo, nausea, and vomiting—indicating a threatened or actual labyrinthine involvement, with the possibility of extension through the internal auditory meatus, and a consequent diffuse meningitis or cerebellar abscess. The appearance of a facial paralysis may signify destruction in the direction of the vestibule, and an impending endocranial complication. It therefore calls for prompt surgery, as also does the appearance during otitis media of paralysis of the abducens nerve, accompanied with homolateral headache and pain in the eyeball, which frequently indicates involvement of the petrous cells. Symptoms pointing to the beginning of an endocranial complication demand an exploratory operation, and delay for the formation of a capsule round the infected focus should not be unduly prolonged. Newhart points out the urgency of securing a dry ear in chronic suppurative otitis media, since continuance of the discharge indicates that the deeper parts of the bone are diseased, the affected regions being often surrounded by sclerosed areas. Even an x-ray examination may not reveal the full seriousness of the condition. Under conditions of lowered resistance an alarming flare-up of the infection may occur. The author believes that an appreciable number of deaths under the age of 30 are due to ear diseases; and that these deaths are more often preventable than is generally realized.

489 Otitis in Sucklings

According to M. LITSCHKUS (*Münch. med. Woch.*, September 28th, 1934, p. 1492) there is a common connexion between non-alimentary intestinal intoxications in sucklings and suppuration in and around the middle ear, the suppuration being in the majority of cases the primary condition. Otitis in infancy is frequent, and is often undiagnosed. To see the drum is always possible, given sufficient patience and skill in the observer. Careful cleansing of the external auditory canal is usually a necessary preliminary: it must be remembered that 0.7 to 1 cm. from the external meatus the canal bends forward and thence runs inwards and downwards, and that the auricle should not be pulled upwards and backwards, but slightly backwards and more strongly downwards. Litschkus remarks that although conflicting views are held as to the priority of the morbid ear conditions in infants in whom these coexist with alimentary intoxications, the rapid and almost magic effect on the latter of treatment of the former—for example, by paracentesis—is universally admitted: he records further illustrative cases.

490 Nasal Sinus Disease in Children

W. MITHOEFFER (*Laryngoscope*, October, 1934, p. 789) believes that the start of the chronic nasal sinus disease of adult life can in many cases be traced to overlooked disease in childhood. The initial infection is the chronic nasopharyngitis of infancy and later, and from this port of entry the disease may travel upward into the nose and accessory cavities, as well as into the ear, the trachea, and bronchi. The author considers that each child suffering from recurrent attacks of nasopharyngitis followed by sinus diseases should be considered as having a con-

stitutional defect, and should be treated persistently. In many instances it will not be enough to remove the irritant and desensitize the patient: it will be necessary often to establish free nasal respiration by removing the hypertrophied overhanging edge of an inferior turbinate, infract the turbinate to the lateral wall, and correct a deviated septum. The author has had good results from this procedure, which is only undertaken when other methods have failed to bring about free nasal respiration. Removal of infected adenoid masses is similarly important, and during any such operation the accessory sinuses should always be examined, since failure to respond to it or to tonsillectomy is often due to undetected accessory sinusitis. Thyroid deficiency is often to be found in such children, especially when the nasal condition is the sequel of one of the exanthemata. Specific treatment is quickly beneficial, and chronic intestinal stasis may clear up simultaneously. To these may be added a high vitamin diet, instruction in nasal hygiene, and a course of hydrotherapy which will accelerate elimination, improve the nervous tone and general metabolism, and train the cutaneous resistance to heat and cold, thereby improving the circulation of the blood.

491 Supraglottic Tumours

Basing his conclusions on a series of 539 cases of malignant tumour of the larynx examined at the Mayo Clinic, F. A. FIGI (*Arch. of Otolaryngol.*, September, 1934, p. 361) reviews the therapeutics of this condition, and emphasizes certain unusual methods of approach. He agrees that the various types of pharyngotomy, with or without preliminary tracheotomy, remain the most satisfactory means of exposing these growths in most cases. Laryngofissure; splitting the lower lip, mandible, and tongue in the median line; indirect laryngoscopy; laryngeal suspension; and other forms of direct laryngoscopy are useful in selected cases. Following its exposure, the tumour may be dealt with by excision, cauterization, electrocoagulation, or irradiation. In some of the clinic cases laryngeal suspension with the Lynch apparatus was applied and, under direct observation, the neoplasm of the epiglottis or of the remainder of the supraglottic portion of the larynx was widely destroyed by electrocoagulation. The time required varies with the size of the tumour, its vascularity, and the dryness of the field. Figi believes that growths which are limited to the epiglottis can often be treated quite as satisfactorily and with less risk by diathermy and laryngeal suspension. Only inactive, fungating, or pedunculated lesions of limited extent should be subjected to this, however. Irradiation is a valuable adjunct to the surgical treatment of supraglottic tumours, but should rarely be used alone in such cases. Sarcomas often respond well. At the clinic indirect laryngoscopy is used almost entirely among adults for the removal of localized benign laryngeal tumours. Figi finds that with patients who co-operate, and with well-cocainized larynges, it is possible to undertake rather extensive procedures thus quite as satisfactorily as with a laryngeal suspension. The author considers the Hasslinger directoscope less satisfactory for the removal of benign and well-localized inactive malignant tumours of the upper part of the larynx, although it usually affords a fairly satisfactory view of pathological changes in this situation.

492 The Reticulo-endothelial System in Oto-rhino-laryngology

A. INFERRERA and A. DE BLASI (*Arch. Ital. di Otol., Rinol. e Laringol.*, November, 1934, p. 829) examined the reticulo-endothelial system by Adler and Reimann's Congo-red method in ten patients aged from 9 to 22 years, the subjects of enlarged tonsils and adenoids but not suffering from any other affection. In all but one case, in which it was fairly high (85) owing to the presence of acute mastoiditis, the Congo-red index was within the normal limits of 50 to 70. In view of the smaller number of cases the writers do not feel justified in drawing definite conclusions, which they postpone until they have collected a larger number of cases.

Obstetrics and Gynaecology

Pathology

493 Minor Complaints of Pregnancy

C. J. MARSHALL (*New York State Journ. Med.*, August 15th, 1934, p. 737) records a series of 165 consecutive private patients, 116 primiparae and 49 multiparae, in whom the minor symptoms of pregnancy and their treatment were studied. Abdominal pain was noted in 83 per cent., in the lower part of the abdomen as a rule. During the first three months it seemed to be attributable to the corpus luteum of pregnancy, and gave rise to suspicions of appendicitis when occurring on the right side. There was sometimes some epigastric distress, possibly due to cardiospasm or slight liver necrosis. During the later months of pregnancy there was pain over the lower lateral surfaces of the uterus and in the inguinal region, probably attributable to the stretching of the round ligaments as the uterus enlarged. Lying upon the painful side relieved it. Unrelieved constipation and gas distension of the colon caused pain in the hepatic and splenic flexures. Muscle cramps of the lower extremities occurred in 68 per cent., usually during the night and early morning. Marshall does not consider them due to an attempt to rectify the body balance, and found benefit result from walking and brisk massage of the leg, associated sometimes with calcium and parathyroid therapy, although calcium gluconate and viosterol were of little use. Backache (60 per cent.) was due to several causes, including strain of the muscles and vertebral ligaments, fallen arches, and referred pain from the enlarging uterus when it proved to be unrelieved by rest. Sacro-iliac relaxation was usually unilateral. Nausea (in primiparae 81 per cent., and in multiparae 65 per cent.) was one of the most distressing complaints. Various therapeutic measures were tried, but the author prefers rest in bed, acid foods, and occasional doses of sodium amylal. Corpus luteum, given subcutaneously, seemed to be useless. Heartburn (45 per cent.) was most common in the last five months of pregnancy. Milk seemed to relieve it, as did the avoidance of fried foods, sweets, highly spiced meats, raw fruits and vegetables, and coffee. An antacid powder containing bismuth subcarbonate, light magnesium oxide, and calcium carbonate, taken one hour after meals, was helpful. Constipation (73 per cent.) was treated by laxatives such as phenolphthalein or cascara, supplemented by an occasional enema. Oedema (74 per cent.) was relieved by one or two drachms of magnesium sulphate daily, and occasionally a salt-poor diet seemed to be of use. Insomnia (15 per cent.) was usually of nervous origin, and was dealt with accordingly. Profuse vaginal discharge (13 per cent.) was treated with a morning and evening douche of sterile 1 per cent. sodium bicarbonate solution, the vagina being cleansed with green soap and painted with 10 per cent. aqueous mercurochrome.

494 Local Anaesthesia with Percaine in Induction of Abortion

G. KRÄCHER (*Wien. klin. Woch.*, August 17th, 1934, p. 1018) describes 102 cases in which percaine in 0.5 per cent. solution (adrenaline being added) was injected in amounts of about 25 c.cm. each into the right and left paracervical nerve plexuses, for securing local anaesthesia in patients who required interruption of pregnancy on account of pulmonary tuberculosis, but for the same reason were unsuitable for inhalation narcosis. In sixty-six cases the anaesthesia was satisfactory in all respects; in twenty-two slight pain was reported and there was some restlessness; in the ten failures ether had to be given. Complications during, or more usually after, the operation were noted in sixteen cases—pallor, tachycardia, headache, and/or mental disturbance; whether attributable to quinine intoxication or to shock, the patients responded to subcutaneous injections of ephedrine. General anaesthesia, it is conceded, is preferable in very nervous subjects.

495 Immunization Power of the Plague Bacillus

H. SCHÜTZE (*Brit. Journ. Exper. Path.*, August, 1934, p. 290) has studied the resistance of the envelope antigen of the plague bacillus to heat and changes in pH. He has previously shown that this particular antigen is fully developed only when the organisms are grown at 31° to 37° C., and that it is responsible for the stimulation of protective antibodies when inoculated into rats. Plague vaccine, made from cultures grown on agar at 37° C. for four days, was sterilized at various temperatures, and doses of similar size were given intravenously to rabbits. Six animals were used for each type of vaccine. After three inoculations the rabbits were bled and the sera tested against a series of envelope antigen dilutions for their precipitin content. The results showed that vaccine heated to 56° C. for half an hour retained its envelope antigen unimpaired, while a temperature of 80° C. completely destroyed its power of exciting precipitin formation. It is to be noted, however, that the 80° C. antigen was still capable of reacting *in vitro* with a precipitating serum; the effect of heat had been to degrade it from a complete antigen to a haptene. In a second series of experiments the growth from a three-day agar culture was washed off with saline and found to have a reaction of pH 8. Part of this suspension was heated at 56° C. for half an hour, while another part was adjusted by the addition of acetic acid to pH 7.3 before heating. Equal doses of each vaccine were then inoculated into batches of six rabbits. It was found that the neutralized suspension called forth a considerably higher precipitin formation than the original suspension of pH 8. The practical conclusions, according to the author, are that for plague vaccine to be of maximum efficiency it should be neutralized before heating and should be killed at a temperature not exceeding 56° C.

496 Experimental Infection with Molluscum Contagiosum

M. OTA and P.-T. HUANG (*Derm. Woch.*, August 11th, 1934, p. 1054, and August 18th, 1934, p. 1077) have not been able to confirm other observers' reports of the transmissibility of molluscum contagiosum from one human to another; they have succeeded, however, in conveying the virus by injecting an emulsion of a nodule into the parenchyma of the rabbit's testicle. A variable latency is seen, swelling and granuloma formation occurring in some series of experiments in the first animals injected, in other series only after several transmissions from rabbit to rabbit. After filtration through porcelain the results were negative. The histological findings were congestion and cellular infiltration of the tunica vasculosa and interstitium, as well as the formation of nodular granulomata with central necrosis. Similar findings have been made with injection of varicella and variola virus. Lipschutz bodies could be found by staining smears from the infected testes, but Ota and Huang speak with reserve of their significance.

497 Infectious Mononucleosis

C. A. STUART, A. M. BURGESS, H. A. LAWSON, and H. E. WELMAN (*Arch. Int. Med.*, August, 1934, p. 199) record their observations on the cytological and serological aspects of twenty-eight sporadic cases of infectious mononucleosis. The morphological characteristics of the predominant blood cell at the height of the disease suggested that it was an immature lymphocyte, and this view was supported by the supravital staining methods employed. Amitosis of lymphocytes in the circulating blood similar to that noted in lymphatic leukaemia was found. Although the writers' observations confirm the contention of Paul and Bunnell that the sheep-cell agglutination test is a valuable aid in the diagnosis of infectious mononucleosis, they point out that this test, if unsupported by clinical and cytological evidence, may result in a false diagnosis.
